Continuing education, vocational training and employment must be pursued as the child grows older.

### Skin problems

Sensory impairment or loss, impairment of vasomotor regulation of skin blood flow associated with paralysis, double incontinence, possible anaemia and urinary tract infections all render the skin of patients with spinal cord injuries vulnerable to breakdown and infections. **Skin breakdown is preventable.**

In the acute stage, regular turning of the child together with adequate management of the bladder and bowels and vigilance in maintaining cleanliness will prevent skin breakdown.

In the rehabilitation stage, training of the parents and the child in self-care, hygiene and the provision of adequate seating can all assist.

### Pressure sores

Pressure sores, or 'bed sores', form over bony parts of the body when a person lies or sits on that part of the body for too long without moving. Where the skin is pressed against the bed or chair, the blood vessels are squeezed shut so that the blood cannot transport air to the skin and underlying tissue. If too much time passes without the person moving or rolling over, the skin and underlying tissue in that spot may become injured or die. First, a red or dark patch appears. Then, if the pressure continues, an open sore can form. The sore may start on the skin and work inwards, or it may start at a deep level, near the bone, and gradually work its way to the surface.

### Risk factors for pressure sores

When a healthy person lies or sits in one position for a long time, it begins to feel uncomfortable, or even painful, so they move or roll over, and the formation of pressure sores is prevented. The people who are most likely to develop pressure sores are those who are unconscious or who have no **sensation** in parts of their body, and who therefore do not feel the warnings of pain or discomfort when their body is being damaged. This includes people with spinal cord injury.

### Commonest sites of pressure sores

Pressure sores can form over any bony area. The sites where they are most likely to develop are shown in Figure 4.2.D.1.

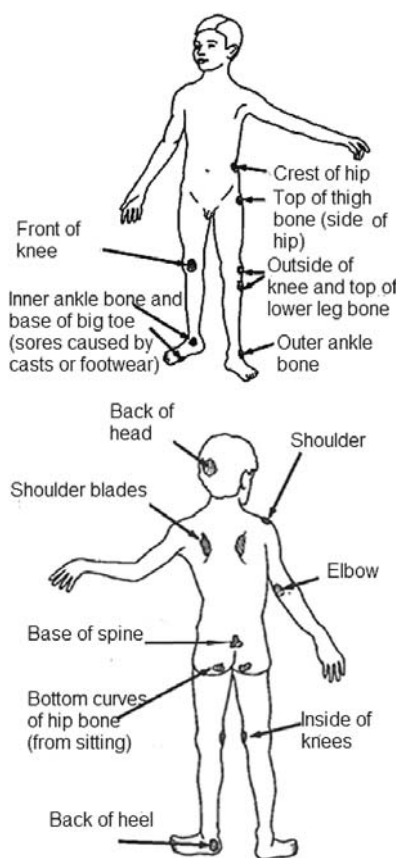

### Risks and complications associated with pressure sores

If pressure sores are not very carefully managed, they can become large and deep. Because they contain dead skin and tissue, they can easily become infected. If a sore reaches the bone, which often happens, the bone can also become infected. Bone infections can be very difficult to cure, may last for years, and may keep recurring even after the original pressure sore has healed.

Infections in deep pressure sores often spread to the blood and then affect the whole body, causing fever and general illness, including bacteraemia and septicaemia.

### Incidence of pressure sores

In patients who have lost sensation in parts of their body, **pressure sores are very common.** Most people with spinal cord injuries in developed countries, and nearly all people with such injuries in resource-limited countries, develop pressure sores. **Often the sores start to develop in hospital shortly after the injury, due to inadequate nursing care. Therefore it is important that the families of patients with spinal cord injuries, and those patients**

**FIGURE 4.2.D.1** Sites where pressure sores are most likely to develop, with the most high-risk areas (in the hip region) labelled in bold type.

themselves, learn as early as possible about the prevention and early treatment of pressure sores, and put this knowledge into practice.

### Prevention of pressure sores

It is important that both the child and their family are taught about the risk of pressure sores developing, and how to prevent them. The following actions are important:

- Avoid staying in the same position for very long. When lying down, turn from side to side or from front to back at least every 2 hours (or up to 4 hours if padding and cushioning are adequate). When sitting, lift the body up and change position every 10 to 15 minutes.
- Use thick soft padding, pillows or other forms of cushion arranged so as to protect bony areas of the body.
- Use soft clean dry bed sheets, and try to avoid them wrinkling. Change the bedding or clothing every day and also each time it becomes wet or soiled. A child who stays wet will develop pressure sores, especially if the wetness is caused by urine.
- Bathe the child daily. Dry the skin well by patting it, not rubbing it. It is probably best not to use body creams or oils, or talc, except on the hands and feet to prevent cracking, as these products soften the skin and make it weaker. **Never use heat-producing oils, lotions or alcohol.**
- Examine the whole body carefully every day, checking in particular those areas where pressure sores are most likely to develop. If any redness or darkness is present,

take extra care to prevent all pressure over this area until the skin returns to normal.

- Good nutrition is important for preventing pressure sores. Make sure that the child gets enough to eat (but do not let them become overweight). Give them plenty of fruits, vegetables, and protein-containing foods (beans, lentils, eggs, meat, fish and milk products). If the child looks pale, check for signs of anaemia (see Section 5.11.A), and make sure that they are given iron-rich foods (meat, eggs and dark green leafy vegetables) or take iron tablets (ferrous sulphate), as well as foods rich in vitamin C (oranges, lemons, tomatoes, etc.).
- As far as possible, the child should learn to examine their own body for pressure sores every day, and eventually learn to take responsibility for all the necessary preventive measures themselves.

### Other precautions

- To avoid pressure sores or other injuries developing on feet that have lost sensation, use well-fitted, well-padded sandals or shoes.
- Changing positions is important. When a child has recently had a spinal cord injury, they must be turned regularly, taking great care not to bend their back. Using a sheet under the body can help with turning.
- As the child gets stronger, hang loops and provide other aids, if necessary, so that they can learn to turn themselves.

At first it is important that the person turns, or is turned, at least **every 2 hours day and night**. Later, if there are no signs of pressure sores, the time between turns can gradually be lengthened to 4 hours. To avoid the child (or the person turning them) sleeping through the night without turning, an alarm clock can be very helpful.

**When the child begins to sit or to use a wheelchair, there is a new serious danger of pressure sores developing. The child must now get into the habit of taking the pressure off their bottom at least every 30 minutes.**

If their arms are strong enough, the child can lift up their whole body and hold it up for a minute or two. This allows the blood to circulate in the bottom.

If the chair has no arm rests, or if they can be removed, the child can lie sideways over a pillow on a high bed. They can rest for 15 to 30 minutes like this.

To prevent pressure sores, it is essential that the person who has lost sensation lies and sits on a soft surface that reduces pressure on bony areas. It is best for them to lie on a flat surface with a thick spongy mattress. A **thick foam rubber mattress** often works well. However, some foam is so spongy that it sinks completely under a person's weight, so that the bony area is not protected from the hard board underneath. A firm sponge with very small air bubbles (microcell rubber) works well, but is expensive.

A 'waterbed' (a bag-like mattress filled with water) or air mattress also works well.

In some countries, an excellent mattress material is made from rubber-coated coconut fibre. Urine can be washed out of the material by pouring water through it. Because this material is costly, a rehabilitation programme in Bangladesh has adopted the practice of cutting a square out of a cheap mattress and replacing it with a square of the coconut fibre sponge.

Careful placement of pillows, pads or soft folded

blankets can also help to prevent pressure sores. Such measures are especially important in the first weeks or months after a spinal cord injury, when the person should lie flat and be moved as little as possible. Pillows should be placed to avoid pressure on bony areas, and to keep the person in a position that is healthy and that helps to prevent contractures.

### Chair and wheelchair cushions

For the child who has lost sensation in their bottom, the type of seat cushion used is very important, especially if the paralysis makes it difficult for them to lift up or change positions. All patients with spinal cord injury should use a good cushion. Sitting directly on a canvas seat or a poorly padded wooden seat will cause pressure sores.

Good cushions can be made of 'microcel' rubber, which is fairly firm. It works best if it is cut and shaped to reduce pressure on bony areas.

A useful low-cost way to make a fitted cushion is to build a base out of many layers of thick cardboard glued together, and then cover it with a 2 or 3 cm thick layer of sponge rubber.

Wet the cardboard and sit on it wet for 2 hours, so that it moulds to the shape of the bottom. Then let it dry, and varnish it.

Before making a specially fitted cushion, you can make a 'mould' of the patient's bottom by having them sit in a shallow container of soft clay, mud or plaster. Note the bony hollows and form the seat to fit them.

Air cushions made from bicycle tyre inner tubes are excellent for the prevention of pressure sores, and for bathing on a hard surface. Use one, two or more tubes, depending on the size of the tube and the size of the child. Bind loops of the tubes together with thin straps of inner tube. Then pump in enough air to ensure that the whole of the child's bottom is held up by air. (This idea was suggested by wheelchair rider-builders at Tahanang Walang Hagdanan (House With No Stairs), Quezon City, Philippines.)

### Treatment of established pressure sores

Be alert for the first signs of a pressure sore by examining the whole body every day. Teach the child to do this using a mirror.

If early signs of a pressure sore (redness, darkness, swelling or open skin) are observed, change body positions and use padding to protect that area from pressure.

For larger areas (such as the bones near the base of the spine), you can try using a small (motor scooter) inner tube to keep the weight off the sore area. Put a towel over the tube to soak up sweat, as sweaty skin against the rubber can also cause sores.

**Warning: For small areas such as the heels, never use a ring or 'doughnut' of cloth to keep the weight off the sore, as this can cut off the blood supply to the skin inside the ring and make the sore worse.**

#### If a pressure sore has already formed:

- Keep the pressure off the sore area completely and continuously.
- Keep the area completely clean. Wash it gently with clean or boiled water twice a day. Do **not** use alcohol, iodine or other strong antiseptics.
- Make sure that the child has a healthy diet. If a large amount of liquid is lost from the sore, a lot of protein and iron will be lost with it. These must be replaced to

allow quicker healing. The child should also take iron tablets if signs of anaemia are present, and they should eat foods rich in protein (beans, lentils, eggs, meat, fish and milk products).

- Do not rub or massage areas where pressure sores might be forming, as this could tear weakened tissue and make the sore inside larger.

#### If the sore is deep and contains dead tissue within it:

- Clean the sore three times a day.
- Each time you clean the sore, try to scrape and pick out more of the dead rotten tissue. Often you will find that the sore is much larger inside than you first thought. It may go deep under the edges of the skin. Little by little remove the dead tissue until you come to healthy red flesh (or bone).
- Each time you have cleaned out the dead tissue, wash the sore out well with soapy water. Use liquid surgical soap if possible. Then rinse with clean (boiled and cooled) water. A syringe without a needle can help with irrigation.

If the sore is infected (signs of this include pus, foul smell, a swollen hot red area around the sore, or the presence of fevers and chills):

- Clean out the sore three times a day as described above.
- If possible, take the person to a clinical laboratory where a sample from the sore can be removed and cultured to find out what organisms are causing the infection and what is the most appropriate medication to treat it.
- If this is not possible, try treating the patient with penicillin, cloxacillin or flucloxacillin.

**If the sore does not get better, or if liquid or pus keeps draining from a deep hole, the bone may be infected, so tell the parents to take their child to the hospital.**

### Honey and sugar

Once a pressure sore is free of dead tissue, filling it two to three times a day with honey or sugar helps to prevent infection and speeds up healing. This treatment, which was used by the ancient Egyptians and was recently rediscovered by modern doctors, works remarkably well. It is now being used in some hospitals in the UK and the USA.

To make it easier to fill the sore, mix honey with ordinary sugar until it forms a thick paste. This can easily be pressed deep into the sore. Then cover the sore with a thick gauze bandage.

**It is important to clean out and refill the sore at least twice a day. If the honey or sugar becomes too diluted with liquid from the sore, it will feed the bacteria rather than kill them.**

The amount of honey that is needed on the wound depends on the amount of fluid that is being produced by the pressure sore. If there is a lot of fluid it will dilute the honey and make it less effective. The frequency of dressing changes required will depend on how rapidly the honey is being diluted. If there is no exudate, dressings need to be changed twice weekly to maintain the antibacterial properties of the honey as it enters the pressure sore. If the sore is producing a lot of fluid, the dressing will need to be changed twice a day.

To achieve the best results the honey should be applied to a dressing (cotton plus cellulose) which can absorb this

prior to application. If applied directly to the wound, the honey tends to run off and be less effective. Honey will not soak easily into absorbent dressings. Soaking is helped by warming the honey to body temperature and/or adding 1 part of water to 20 parts of honey to make the honey more fluid. If the pressure sore is producing a lot of fluid, the absorbent dressing can be secured in place using cling film taped over it to help to keep the honey on the wound.

Alginate dressings impregnated with honey are a good alternative to cotton/cellulose dressings, as the alginate is converted into a honey-containing soft gel. Any holes in the wound need to be filled with honey in addition to using a honey-impregnated dressing. As infection may be present in the tissues underlying the edges of the pressure sore,

honey dressings need to extend beyond the inflamed area surrounding the sore.

## 4.2.E Facilities for children with special needs and learning difficulties

### Introduction

**The most valuable asset is healthcare staff who can spend time with these children and their families, and preferably who are also able to visit them at home.**

**For children presenting at the hospital with established disabilities, the challenge is to ensure that they make the best use of their abilities and do not develop further disabilities.**

TABLE 4.2.E.1 Equipment for assessment

Equipment for physical examination	Equipment for skills assessment
Tape measure	20 brightly coloured wooden cubes, 2.5 cm in diameter
Auroscope	Threading beads of various sizes, and string
Ophthalmoscope	20 culturally appropriate pictures of common domestic objects, some of which have similar sounding names in the local language
Tendon hammer	Soft ball, approximately 10 cm in diameter
128-Hz tuning fork	Denver Developmental Screening Test
Simple audiometer	

### Aids for disabled children

This section outlines the types of aids that should be available for disabled children in all hospitals. There are many conditions which can cause disability, and **the aim of the aids listed is to minimise disability and maximise independent function**. It should be noted that some positions which may appear desirable (e.g. the upright walking posture in a child with excessive extensor tone) may adversely affect the child's ultimate mobility. The advice of a trained paediatric physiotherapist is invaluable.

David Werner's book, *Disabled Village Children*, is an excellent source of ideas and advice.

FIGURE 4.2.E.1 Lying aids.

### General principles

- 'Look first at my strengths and not at my weaknesses': the preservation of best function is primarily achieved by education of the child and their carers, but aids and appliances can be very useful.
- Always consider the developmental stage of the child.
- An understanding of the home environment of the child is essential (e.g. in some regions a donkey may be a more useful mobility aid than a wheelchair once the child leaves hospital).
- The prevention of secondary disabilities (e.g. contractures or pressure sores) is a major priority in the care of disabled children.
- Always consider the purpose of the aid that you think will help, and ask yourself the following questions:
  - How will this aid help this child to function in their daily life?
  - Will the use of this aid reduce this child's abilities to do other things?
  - Will the use of this aid improve the way the child feels about him- or herself?
  - Who will review this aid to ensure that it is still helping the child and is still the right size for the growing child?
  - Who will maintain this aid to ensure that it still works?

### **Developmental aids**

These are primarily used with children with delayed development, but may also be useful for children who have suffered a neurological insult, whether or not they are showing signs of recovery. Most children function better if they can experience a variety of positions and can be part of activities with others.

#### ***Lying aids***

Many children who are ill or who are recovering from illness spend most of their time lying on their back or on their side. Lying on their front helps to develop trunk and arm strength and stretches muscles in the hips, knees and shoulders. **A pillow under the chest** helps to release the arms and hands for play.

A **wedge** is a more substantial version of the same idea, and can be made from material such as stiff foam plastic. Some children who need to have their legs separated because of adductor spasm will need a leg separator or pillow, also made of similar material.

#### ***Sitting aids***

The type of sitting aids used will depend on the particular difficulties and developmental stage of the child. Most children with cerebral palsy benefit from being seated in a position in which their ankles, feet and hips are at 90 degrees and their legs are kept apart (abducted). There are many varieties of seats available. For a young child, a **corner seat** is often helpful. Special seating can also be fun (e.g. the 'steam engine').

Children with spasticity also often benefit from a slight tilt backwards. The position and amount of head support needed depend on the amount of head control and extensor tone.

#### ***Standing aids***

These may be useful for children who are showing improvement in their motor skills and can be expected to learn to stand independently, but are also useful for children who may never stand independently, because the standing position aids the circulation and also bone growth and strength, particularly of the hip joints. Some children find standing frames difficult to get used to at first, and may need encouragement to use them.

#### ***Walking aids***

There are a wide variety of these aids available. Perhaps the most useful is a walking frame that goes behind the child and which can have a variety of attachments depending on the child's balance and arm strength. Some **parallel bars** are also useful and will need to be set at different heights depending on the size of the child.

A selection of **underarm crutches**, **elbow crutches** and **tripod sticks** will be useful. These can often be made locally, and will need to be of various sizes.

**Note that underarm crutches can cause nerve damage if the child hangs off the crutches when attempting to walk.**

#### ***Wheelchair technology***

This is beyond the scope of this book. The general principles listed at the beginning of this section apply. Remember that a wheelchair is not the only solution for an otherwise immobile child. If the child has no sensation in their buttocks as a result of spinal cord damage, they will be at

risk of developing pressure sores if they remain seated in the same position for long periods of time. They can learn ways of taking the pressure of their buttocks. If pressure sores have developed, getting around the hospital may be better using a **gurney**.

#### ***Eating and drinking aids***

Utensils with thick handles and cups with handles on both sides may be easier to use for children who find gripping difficult. It may be helpful to put a non-slip material underneath a bowl or plate to stop it sliding while the child is eating (a damp cloth works very well). Eating and drinking aids must be easy to wash. Assessments by occupational and speech and language therapists (if available) are invaluable for children with complex feeding difficulties.

#### ***Toileting aids***

For details, see Section 4.2.D.

#### ***Communication aids***

Children who are unable to communicate verbally because of deafness and/or inability to use their oro-motor muscles will often be able to use a **communication board** or book with pictures of objects, people and actions. If the child is unable to point using a finger, hand, toe or foot, they may well be able to 'eye point'. An attentive carer will be aware that the child is eye pointing, and the use of a communication aid may 'unlock' the child who had previously been assumed to be unable to communicate beyond indicating pleasure or distress. More technological solutions are available using computers with specialised software which enables children to 'speak', but the basic principle of being able to select a pictorial representation of an object or an idea is the same.

#### ***Aids to prevent common secondary problems developing in hospital*** ***Preventing foot drop***

One of the commonest preventable complications in children with weak legs is the development of foot drop. This should not happen in your hospital. Regular exercises to move the ankles through their full range of movement should be done at least twice a day. The use of tight or heavy bed covers should be avoided, as they may hold weak feet in a bad position. It is best for the feet to rest with the ankles at 90 degrees. This is easily ensured by positioning a roll of blanket or similar material so that the feet are braced in this position.

#### ***Preventing knee and hip contractures***

Regular exercises that take the joints through as full a range of movement as possible are the mainstay of prevention. If possible, the child should spend some time each day lying on their front with their hips and knees extended.

#### ***Preventing scoliosis***

This is achieved by symmetrical positioning of the child so that attention must be paid to both lying and sitting positions. With excessive and asymmetrical muscle tone it is often difficult to prevent scoliosis, and once it has developed, it often gets worse, particularly at times of rapid growth.

**Preventing pressure sores**

Pressure sores develop anywhere in the body where skin is kept under pressure for too long. This commonly happens in areas where sensation has been lost, and will develop more quickly if the circulation is poor. There is no substitute for good nutrition and regular moving and turning of the child. The skin should regularly be gently cleaned and dried, and moisturising lotion used. Prevent bony areas from pressing

on each other and on the mattress by using pillows or foam wedges, for example, between the knees or under the heels (see Section 4.2.D).

system or organ  
dysfunction**

## 5.1 Upper airway disorders

### 5.1.A Acute upper airway infections: croup and epiglottitis

#### BOX 5.1A.1 Minimum standards

- Dexamethasone/prednisolone.
- Nebulised 1 in 1000 adrenaline.
- Choking management skills.
- Intubation.
- Cricothyrotomy or tracheostomy.
- Antibiotics: cefuroxime, chloramphenicol, ceftriaxone, ceftazidime.
- *Haemophilus influenzae* immunisation.
- Measles immunisation.

#### Introduction

Obstruction of the upper airway (larynx and trachea) is potentially life-threatening. The cardinal feature is stridor (a harsh noise during inspiration), which is due to narrowing of the air passage in the oropharynx, subglottis or trachea. If the obstruction is below the larynx, stridor may also occur during expiration. **Like the wheeze in asthma, the loudness of the stridor does not indicate the severity of the obstruction.** There may also be hoarseness and a barking or seal-like cough. The severity of the obstruction is best assessed by the degree of sternal and subcostal recession, and the respiratory and heart rate. Increasing agitation or drowsiness, or central cyanosis, indicates severe hypoxaemia and hypercapnia and the need for urgent intervention.

The major causes of severe stridor are viral croup (caused by measles or other viruses), foreign body, retropharyngeal abscess, diphtheria, and trauma to the larynx.

#### Differential diagnosis of upper airway obstruction

- 1 Collapse of airway due to muscle tone loss or build-up of secretions due to poor cough reflex:
  - Depressed conscious level from any cause.
  - Drug or alcohol intoxication or overdose.
  - Bulbar palsy.
  - Myopathy.
- 2 Airway inflammation and oedema:
  - Infective:
    - Upper respiratory tract infection in an infant.
    - Viral croup.
    - Bacterial tracheitis.
    - Epiglottitis.
    - Severe tonsillitis.
  - Non-infective:
    - Recurrent croup.
    - Anaphylaxis.
- 3 Space-occupying lesion or structural abnormality:
  - Intranasal, pharyngeal or in upper trachea:
    - Adenoidal hypertrophy.

- Foreign body.
- Retropharyngeal abscess.
- Tumour.
- Extrinsic haematoma (e.g. post thyroidectomy).
- Congenital pharyngeal, laryngeal or upper tracheal abnormalities:
  - Choanal atresia.
  - Laryngomalacia.
  - Subglottic stenosis.
  - Laryngeal web or haemangioma.

For diagnosis of a space-occupying lesion or structural abnormality, a specialist ENT examination under anaesthetic may be needed (if available).

#### Croup

Croup is a condition characterised by inspiratory stridor, hoarse voice, barking cough and a variable degree of respiratory distress.

- This definition embraces several distinct disorders.
- **Acute viral laryngotracheobronchitis (viral croup).** This is the commonest type of laryngotracheal infection (representing over 95% of cases). Peak incidence is in the second year of life, and most hospital admissions are between 6 months and 5 years of age. The stridor is usually preceded by fever (< 38.5°C) with coryza, and symptoms tend to be worse at night. If narrowing is minor, the stridor will be present only when the child hyperventilates or is upset. As the narrowing progresses, the stridor becomes both inspiratory and expiratory, and is present even when the child is at rest. Children under 3 years in particular may develop features of increasing obstruction and hypoxaemia with marked sternal and subcostal recession, tachycardia and agitation. If the infection extends distally to the bronchi, wheeze may also be audible.
  - **Recurrent or spasmodic croup.** Some children have repeated episodes of croup without preceding fever and coryza. The symptoms are of sudden onset at night, and often persist for only a few hours. The condition is associated with atopic disease (e.g. asthma, eczema, hay fever). The episodes can be severe, but are more commonly self-limiting.
  - **Bacterial tracheitis or pseudomembranous croup.** This dangerous condition is one of the important complications of measles but may occur without that antecedent. Infection of the tracheal mucosa with *Streptococcus pneumoniae*, *Staphylococcus aureus* or *Haemophilus influenzae* B results in copious purulent secretions and mucosal necrosis. The child appears

toxic with a high fever, with marked signs of respiratory obstruction. In the UK, over 80% of these children need intubation and ventilatory support to maintain an adequate airway. The croupy cough and the absence of drooling help to distinguish this condition from epiglottitis. Clinical and radiological signs of segmental

collapse and consolidation related to bronchial occlusion are usual. The cough is often persistent and ineffective in clearing the secretions, the illness has a prolonged course, and the restoration of normal mucosa usually takes several weeks. The condition is much less common than the two preceding ones.

TABLE 5.1.A.1 Severity of croup

Sign	Mild	Moderate	Severe
Upper airway noise	Hoarse voice, barking cough, mild stridor intermittently on inspiration only	As before, with stridor constant and also some on expiration	Stridor usually decreases as exhaustion occurs
Effort of breathing	Mild increase, some intercostal recession	Further increase in effort, nasal flare, tracheal tug, accessory muscle usage	Major increase in effort gives way to exhaustion and poor but gasping effort
Efficacy of breathing	Not distressed by effort. No cyanosis, SaO <sub>2</sub> may be normal	Distressed by effort. Cyanosis not usually visible but SaO <sub>2</sub> is low	Cyanosis visible if haemoglobin is in normal range, SaO <sub>2</sub> is very low
Conscious level	Alert, usually still playing	Anxious and distressed. Not playing, little interaction, drowsy	Conscious level severely reduced, causing respirations to slow, reflex gasps and apnoeas
Cardiovascular	Mild increase in heart rate	Rapid heart rate	Severe tachycardia progresses to bradycardia and hypoxic cardiac arrest

### Emergency treatment of croup

- These children (and their parents) may be very frightened. **Do not alarm them further by putting instruments in the child's throat, by giving painful injections or by trying to place an IV cannula.** Crying increases their oxygen demand and may increase laryngeal obstruction **and even cause total airway obstruction.** Keep the child on their parent's lap and explain the condition and the treatment. Tell the mother to alert the nurses or doctors if the child breathes more quickly or has marked sternal recession. **These are danger signs for hypoxaemia.**
- Ensure adequate oral fluid intake.

Many children who are admitted to hospital have hypoxaemia. Humidified oxygen should be given through nasal cannulae or a face mask held just in front of the child's face by the parent. **Do not use nasopharyngeal catheters to give oxygen, as these can precipitate dangerous paroxysms of coughing and total airway obstruction.**

Milder cases of croup should not routinely be given oxygen, as this can frighten the child.

- Croup can be a very painful condition. Even if the child does not have a high temperature, prescribe regular paracetamol, but do not force the child to take this.
- There is very good evidence that steroids help. Children with mild, moderate or severe croup all benefit from steroids. Give 0.6mg/kg dexamethasone once or twice a day. This should be given orally, **as it works just as well as if given parenterally. If the child vomits, repeat it or give the same dose intramuscularly.** An expensive but effective treatment is nebulised budesonide 2 mg in 2 mL; it may be repeated 30–60 minutes later.
- Nebulised adrenaline (5 mL of 1 in 1000 adrenaline nebulised, preferably with oxygen) will bring rapid and effective relief for severe croup. The relief lasts only for about 1 hour, but it can be repeated (although the effect diminishes), and this treatment gives the steroids time to start working. **Arrange for the child to be seen quickly**

**by an anaesthetist.** Monitor the oxygen saturation with a pulse oximeter.

- A few children need intubation. This should be done under general anaesthetic. **If there is doubt about the diagnosis, or difficulty in intubation is anticipated, an ENT surgeon capable of performing a tracheostomy should be present.** In intubated children, 1 mg/kg prednisolone every 12 hours reduces the duration of intubation.
- Severely ill or toxic children and those with measles croup should receive an antibiotic effective against *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Staphylococcus aureus*. If available, cefuroxime 150 mg/kg/day in four doses IV or ceftriaxone 80 mg/kg IV or IM once daily. An alternative is chloramphenicol 25 mg/kg IV 6-hourly.

### Inhaled foreign body (see Section 5.2.C)

**Suspect the diagnosis if there has been a sudden onset of cough and stridor in a well child.** Ask the parents and child whether there has been any access to peanuts or other food, toys or other small objects that could have been put in the mouth.

### Management

If the foreign body is causing symptoms of stridor, coughing and respiratory distress, emergency management of choking is required (see Section 1.12 on Basic Life Support, which describes acute choking management).

In addition, call an ENT surgeon for laryngoscopy (if available). A laryngeal foreign body may present very acutely with cyanosis or loss of consciousness. Therefore urgent direct laryngoscopy may be necessary.

In the absence of an ENT surgeon, tracheostomy or cricothyrotomy may be necessary (see Section 8.2 for cricothyrotomy procedure).

## Acute epiglottitis

This is a severe infection caused by *Haemophilus influenzae*. Peak incidence is at 2–3 years of age. It is less common than croup, but important, as **the diagnosis needs to be made fast because rapid progression of stridor in the ill toxic child may be fatal within hours if not promptly treated**. Cough is not a prominent feature, and the stridor has a soft quality, often with an expiratory component. The child tends to drool and assume an upright posture.

Unlike croup, epiglottitis is always severe and progression is rapid. It is always a medical emergency. Fortunately, since the introduction of *Haemophilus influenzae* type B (HiB) vaccine the disease has become much less common in those countries where the vaccine is used.

Do not:	Do:
Examine the throat	Reassure the child and their parents, and calm the child
Lie the child down	Attach a pulse oximeter
X-ray the neck	Give oxygen if SpO <sub>2</sub> is < 94% using a face mask held close to <b>but not on</b> the child's face by the parent with the child sitting on their lap
Perform invasive procedures	Call an anaesthetist and an ENT surgeon
Use a nasopharyngeal tube to give oxygen	Arrange examination under anaesthesia
	Arrange for high-dependency care to be available

### Management

- Elective intubation under general anaesthetic is the treatment of choice. Often a much smaller diameter than the usual endotracheal tube for the child's age will be needed because the airway is so swollen internally. The endotracheal tube still needs to be the right length for the child's age. This is why children's endotracheal tubes should not be pre-cut to size. The diagnosis is confirmed by laryngoscopy under general anaesthetic just prior to intubation ('cherry-red epiglottitis'). **An ENT surgeon must be present if possible.**
- While the child is anaesthetised, the following procedures should be performed: blood cultures, throat swab and IV line.
- Recommended antibiotic therapy is chloramphenicol

TABLE 5.1.A.1 Contrasting features of croup and epiglottitis

Feature	Croup	Epiglottitis
Onset	Over days	Over hours
Preceding coryza	Yes	No
Cough	Severe, barking	Absent or slight
Able to drink	Yes	No
Drooling saliva	No	Yes
Appearance	Unwell	Toxic, very ill
Fever	38.5°C	38.5
Stridor	Harsh, rasping	Soft
Voice muffled	Hoarse	Reluctant to speak
Need for intubation	1%	80%

50mg/kg IV immediately, then 25mg/kg IV 6-hourly. If available, cefuroxime or cefotaxime 50mg/kg IV 6-hourly or ceftriaxone 80mg/kg once daily IV or IM should be effective.

- Following intubation the child will be able to breathe humidified air spontaneously, ideally with nasal continuous positive airway pressure (CPAP) (see Section 1.25 and 8.3). Sedation (discuss with anaesthetist) may be required in order to prevent self-extubation, but the child will then usually require assisted ventilation. Most children will be ready for extubation after 48 hours.

An alternative is to fix the child's arms to their thorax using a bandage to stop them pulling out the endotracheal tube but the stress to the child caused by this may have a deleterious effect on recovery. If possible, have a relative sit with the child to reassure them.

## Angioneurotic oedema

See Section 5.1.B on anaphylaxis.

There are usually areas of painless swelling obvious in other areas of skin and mucous membranes. The eyes, lips and tongue are particularly likely to be affected. Stridor is caused by laryngeal oedema.

### Management

- Give adrenaline, 10 micrograms/kg IM.
- Give adrenaline, 5mL of 1 in 1000 nebulised with 100% oxygen.
- Give 100% oxygen.
- Give hydrocortisone, 4mg/kg IV over 15 minutes or IM and repeat 8 hourly as required.
- Give chlorphenamine, 250 micrograms/kg IV or orally (maximum dose 2.5mg) or
  - 6 months to 6 years 2.5mg and repeat up to 4 times in 24 hours
  - 6–12 years 5mg and repeat up to 4 times in 24 hours
  - 12–18 years 10mg and repeat up to 4 times in 24 hours.
- Give Ringer-lactate or Hartmann's solution or 4.5% albumin (if available), 10–20mL/kg, if the child is shocked.
- Intubation or even tracheostomy may be required (contact the ENT team).

## Airway/inhalational burns (see Section 7.3.1.b)

Such burns are caused by inhalation of hot gases or toxic vapours. They may be associated with extensive skin burns. **Be aware that airway obstruction may develop even if it is not obvious on first assessment.**

### Management

- **Admit the child to a high-dependency unit (if available).**
- Give hydrocortisone, 4mg/kg IV 6-hourly.
- Give Ringer-lactate or Hartmann's solution or 4.5% albumin boluses (10–20mL/kg) for shock as required.
- Intubation or tracheostomy may be necessary if indicated by assessment.

## Diphtheria (see Section 6.1.C for further details on management)

Diphtheria is characterised by gradual onset of stridor in a child (usually 2 to 3 years old) with neck oedema

and ulcerating lesions of the tonsillar bed forming a grey membrane. Bleeding may occur at the site and down the nose. The diagnosis may be confirmed by throat swab and **urgent Gram stain**. There will usually be no evidence of DTP vaccination.

### 5.1.B The child with anaphylaxis

#### BOX 5.1.B.1 Minimum standards

- ABC of resuscitation.
- Adrenaline.
- Oxygen.
- Salbutamol by nebuliser or spacer.
- Hydrocortisone.
- Antihistamine.

Consider the diagnosis of anaphylaxis if any of the following symptoms are present when there is a history of previous severe reaction, rapidly progressive or increasingly severe symptoms, a history of asthma, eczema or rhinitis (atopy).

**This situation is potentially life-threatening** and may result in a change in conscious level, collapse, or respiratory or cardiac arrest.

#### Introduction

Anaphylaxis is an immunologically mediated reaction to ingested, inhaled or topical substances, which may progress to life-threatening shock and/or respiratory distress.

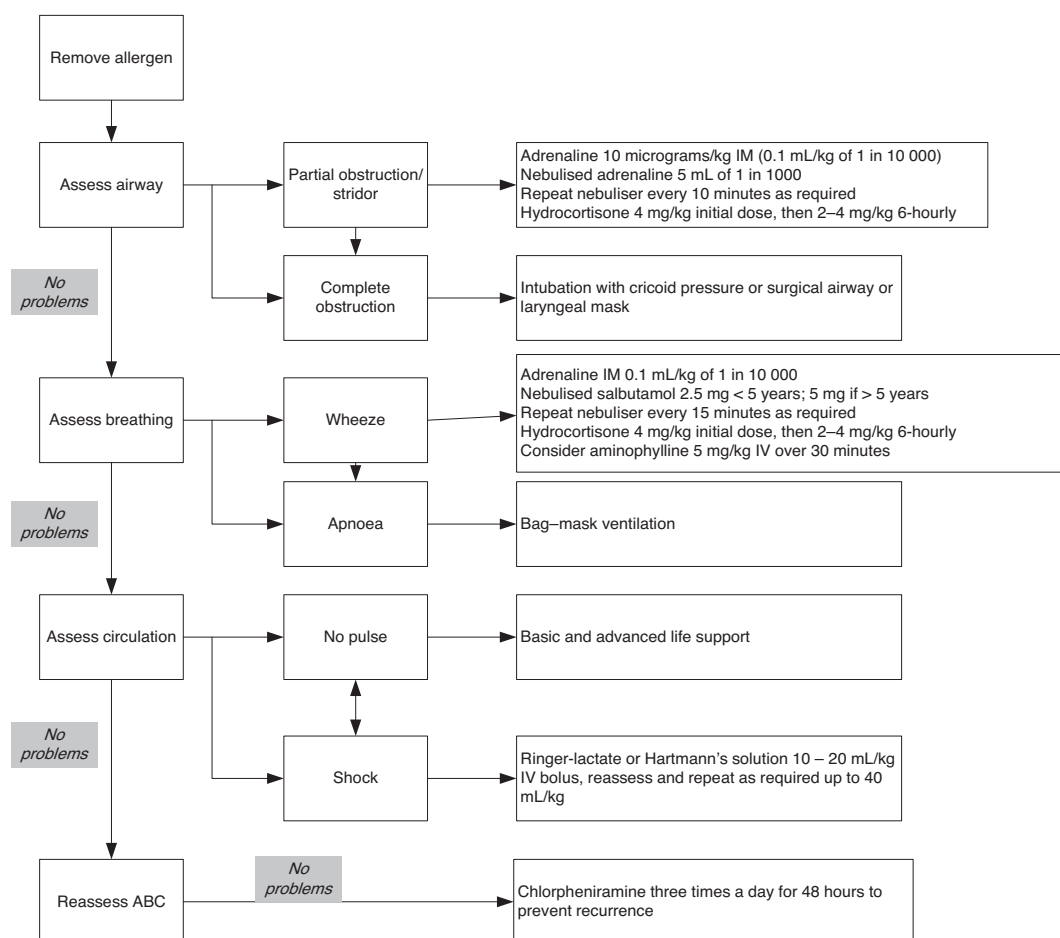

Common causes include allergies to penicillin, anaesthetic agents, blood transfusion, **radiographic contrast media**, and certain foods, especially nuts.

#### Management

See **Figure 5.1.B.1**.

Remove the source of allergen if possible (e.g. take down the blood giving set if blood transfusion is the cause).

The key to anaphylaxis treatment is intramuscular adrenaline.

**FIGURE 5.1.B.1** Pathway of care for anaphylaxis in a child. Note: Adrenaline should be repeated every 5 minutes. If repeated doses are ineffectual, use an IV infusion of adrenaline (see below)

**Airway: assessment and resuscitation**

- If there is no problem with the airway, assess **B**reathing.
- If stridor is present there is obstruction (usually at the larynx):
  - Give 10 micrograms/kg adrenaline IM, then 5 mL adrenaline 1 in 1000 nebulised.
  - Give 100% oxygen.
  - Consider intubation, and call for anaesthetic and ENT assistance.
- If there is stridor with complete obstruction, intubate or create a surgical airway (see Section 8.2).

**Breathing: assessment and resuscitation**

- If there is no problem with breathing, assess the **C**irculation.
- If there is no breathing, give five rescue breaths using a bag-valve-mask with 100% oxygen and assess the circulation.
- If the child is wheezing, give 10 micrograms/kg adrenaline IM and salbutamol (either by nebuliser 2.5 mg if under 5 years of age or 5 mg if over 5 years, (nebulised with 100% oxygen) or 1000 micrograms (5 puffs) of a metered dose inhaler via a spacer and repeated as required).

**Circulation: assessment and resuscitation**

- If there is no problem with the circulation, observe the child.
- If there is no pulse, start basic life support, assess the rhythm and treat.
- If the child is shocked, give 10 micrograms/kg adrenaline IM and 20 mL/kg IV bolus of Ringer-lactate or Hartmann's solution. It may be necessary to give adrenaline IV if shock is present (see below for dosage).

**Reassess ABC and continue to give 100% oxygen**

- If there is airway deterioration, repeat IM adrenaline 10 micrograms/kg with or without intubation.
- If the child is still wheezy, repeat IM adrenaline 10 micrograms/kg and hydrocortisone 4 mg/kg IV by slow injection. Consider giving aminophylline 5 mg/kg by slow IV injection over 20–30 minutes followed by a 1 mg/kg/hour IV infusion or salbutamol 4–6 micrograms/kg IV slow injection followed by an IV infusion of 0.5–2.0 micrograms/kg/minute.
- If the child is still shocked, repeat IM adrenaline 10 micrograms/kg and give a further bolus of 10 mL/kg Ringer-lactate or Hartmann's solution. If there is a poor response then give a further 10 mL/kg and consider

**TABLE 5.1.B.1 Features of anaphylaxis**

Severity	Symptoms	Signs
Mild	Burning sensation in mouth Itching lips, mouth and throat Feeling of warmth Nausea and abdominal pain	Urticarial rash Angio-oedema Conjunctivitis Red throat
Moderate	Coughing and wheezing Loose stools Sweating Irritability	Bronchospasm Tachycardia Pallor
Severe	Difficulty with breathing Faintness or collapse Stridor Vomiting Uncontrolled defecation	Severe bronchospasm Laryngeal oedema Shock Respiratory arrest Cardiac arrest

giving an adrenaline infusion (see below). Intubation and ventilation may be needed if there is a poor response as now a total of 40 mL/kg of crystalloids have been given by bolus.

- If there is no problem, observe the child.
- If there are no symptoms other than rash or itching:
  - Give oral antihistamine (chlorphenamine, 250 micrograms/kg).
  - Give oral steroids (0.5–1 mg/kg oral prednisolone).

**Adrenaline**

Adrenaline is given intramuscularly unless there is intractable shock or cardiac arrest, in which case it should be given IV or by the intra-osseous route.

If repeated IM injections of adrenaline are not effective or last only a short time, start giving adrenaline IV. For treatment of children in severe shock:

- Place 1 mg (1 mL of 1 in 1000 adrenaline) in 50 mL of Ringer-lactate solution.
- Then give 2–5 mL (40–100 micrograms) in a child (depending on size) and 1 mL (20 micrograms) in an infant under 1 year of age. Give **IV slowly** using a peripheral vein or ideally a central vein, if possible with ECG monitoring.
- Repeat as required.
- An infusion of adrenaline at 0.05–2.0 micrograms/kg/minute may be needed (preferably via a central vein and using a syringe pump).

**5.1.C The child with tonsillitis, otitis media, mastoiditis or retropharyngeal abscess****BOX 5.1.C.1 Minimum standards**

- Antibiotics: penicillin/amoxicillin/erythromycin.
- Quinolone antibiotic ear drops.
- Adrenaline nose drops.
- Wicking.

**Tonsillitis**

Tonsillitis is a common childhood disorder. The bacteria most commonly involved are beta-haemolytic streptococci, *Streptococcus pneumoniae* and *Haemophilus influenzae*, and around 50% of attacks are viral.

Classic symptoms include pyrexia and sore throat.

Swallowing solid food is difficult, and fluid intake must be encouraged. Painful cervical lymphadenopathy is the rule, and referred earache from the IXth cranial nerve is common. Febrile convulsions may occur in younger children, who may also present with acute abdominal pain without any throat symptoms, due to mesenteric lymphadenitis.

### Examination

- Tender lymphadenopathy beneath and/or behind the mandible.
- Red enlarged tonsils with or without purulent exudate.

### Differential diagnosis

Diphtheria and infectious mononucleosis (see Section 6.1.C for diphtheria and later in this section for infectious mononucleosis).

### Treatment

- Give paracetamol (20 mg/kg 4- to 6-hourly) for pain relief. Bear in mind that attacks are often viral, and often antibiotics are not needed.
- Penicillin is still an effective antibiotic, and in **serious cases** in hospital give penicillin 12.5 mg/kg four times daily orally. If the child is allergic to penicillin, erythromycin may be used.
- Rarely there is acute partial airway obstruction due to massive tonsillar enlargement. In this case use IV benzylpenicillin 25 mg/kg 6-hourly and IV hydrocortisone 4–8 mg/kg initially, and then a further dose 4 hours later if needed at 4 mg/kg.

### Recurrent tonsillitis

- If the number of attacks increases with age rather than decreasing, tonsillectomy is appropriate if it is safe to perform in the healthcare facilities available.
- As a rule of thumb, six attacks per year for 2 years over the age of 5 years could indicate a case for tonsillectomy.
- It is often said that peritonsillar abscess (quinsy) is an indication, but one attack of quinsy is not enough to warrant the operation.

### Indications for tonsillectomy

In the past, tonsillectomy was performed all too often. Sleep-related upper airway obstruction (see Section 5.1.D) is a good reason for undertaking tonsillectomy, and about 10% of tonsil operations are currently done for this reason.

### Peritonsillar abscess (quinsy)

This is a complication of tonsillitis, and it presents with a unilateral swelling of the soft palate, deflecting the uvula to the opposite side, with associated trismus. Surgical drainage is often necessary as well as IV penicillin as described above.

### Acute suppurative otitis media (ASOM)

Acute suppurative otitis media is a mucosal infection of the middle ear and mastoid air cells, arising via the Eustachian tube. *Streptococcus pneumoniae* and *Haemophilus influenzae* are the bacteria most commonly involved, and about 50% of cases are caused by viruses.

The symptoms are hearing loss, earache and fever. Pain is due to the bulging tympanic membrane from accumulated pus. Rupture leads to otorrhoea with rapid symptom improvement. Localising signs may be absent

in infants, who may present with fever and systemic illness. On examination the tympanic membrane is red and bulging.

### Treatment

- **Many cases of otitis media are incorrectly diagnosed:** any child who is crying or has a fever will tend to have pink eardrums. Earache often presents at night. This is usually due to Eustachian tube obstruction occurring when the child is sleeping, from accumulated mucus in the postnasal space resulting in a negative pressure in the ear, which wakes the child up with discomfort. Paracetamol, plus sitting up and drinking, will open the Eustachian tube and thus relieve the symptoms. Antibiotics are unnecessary.
- In true otitis media with bulging eardrums, treat the child as an outpatient and **always give an antibiotic as described below. It is not safe to withhold antibiotic treatment.** Give oral amoxicillin 40 mg/kg twice a day for 7–10 days. If amoxicillin is not available give co-trimoxazole (trimethoprim 4 mg/kg/sulfamethoxazole 20 mg/kg twice a day) for 7–10 days.
- Paracetamol relieves pain and reduces fever.
- Ephedrine nose drops (0.5%) given 8-hourly for a maximum of 5 days may help to open the Eustachian tube and speed resolution.
- If the eardrum is perforated, the ear must be kept dry until the resulting perforation has healed. This is achieved by teaching the parent to undertake wicking as follows. Roll a clean soft absorbent cotton cloth or strong tissue paper into a wick. **Never use a cotton-tipped applicator, or flimsy paper that will fall apart in the ear, or a stick of any kind.** Place the wick in the ear and remove it after a few seconds, when it is wet. Repeat until the ear is dry. Wicking should be undertaken at least three times daily, usually for 1 to 2 weeks, until pus is no longer present. **The parent must not leave anything in the ear after wicking, must not put oil or any other fluid in the ear, and should prevent the child from going swimming or putting their head under water until the ear has been dry for at least 2 weeks.**
- Check that the child has recovered at follow-up 1 week later. If ear pain or discharge persists, treat the child for 5 more days with the same antibiotic and continue wicking the ear. Follow up in 5 days.

### Chronic otitis media

If pus has been draining from the ear for 2 weeks or longer and there is perforation of the ear drum, the child has a chronic otitis media infection.

### Treatment

- Treat as an outpatient.
- Keep the ear dry by wicking (see above).
- Instil topical antibiotic ear drops (always without steroids, which must not be used in children) three times daily for 2 weeks. Drops containing quinolones (norfloxacin, ofloxacin, ciprofloxacin) are more effective than other antibiotic drops; 0.3% ciprofloxacin drops (5 drops twice daily) have been most researched.
- Oral antibiotics are not indicated unless there is an acute otitis media.
- Topical antiseptics and steroids should not be used.

**Follow-up after 1 week**

If the ear discharge persists despite ear wicking and ciprofloxacin drops, consider IV antibiotic treatment with antibiotics that are effective against *Pseudomonas* (such as gentamicin, azlocillin and ceftazidime), in addition to wicking. Do not give oral antibiotics for a chronically draining ear.

If chronic suppurative otitis media (CSOM) continues despite the above treatment, do not forget the possibility of TB.

**Secretory otitis media**

This may lead to recurrent attacks of acute suppurative otitis media (ASOM) because the exudate acts as a culture medium for repeated infections. **Occasionally, myringotomy with grommet insertion is necessary.** The alternative treatment is long-term low-dose oral antibiotics (trimethoprim 2 mg/kg once daily (maximum dose 100 mg) at night for 3 months). Eustachian tube function may also be improved by adenoidectomy.

**Acute mastoiditis**

This is a complication of ASOM. The mucosa of the mastoid system is always inflamed in ASOM. Mastoiditis occurs when the mucosal inflammation spreads to the adjacent bone, causing osteitis, and eventually the outer cortex of the mastoid is breached, leading to a subperiosteal abscess behind the ear. The symptoms are similar to those of ASOM, but the signs include a forward displaced pinna with a tender fluctuant swelling in the post-auricular sulcus.

**Complications**

Not only is the outer cortex of the mastoid involved, but also the bone adjacent to both the middle and the posterior cranial fossa can be affected, occasionally leading to **extradural abscess, meningitis and brain abscess.**

**Facial nerve paralysis** may occur from the pressure of pus on an exposed facial nerve.

**Treatment**

- Give IV benzylpenicillin 50 mg/kg IV 6-hourly plus chloramphenicol 50 mg/kg 8-hourly IV OR plus flucloxacillin 50 mg IV 6 hourly both for 5 days and then orally (penicillin 25 mg/kg four times daily and chloramphenicol 50 mg/kg 8-hourly) for another 5 days. Alternatively, give ceftriaxone 100 mg/kg IV/IM for 10 days. If there is no improvement within 24–48 hours or the child's condition deteriorates, surgical drainage is necessary.
- The key is to provide drainage for the mastoid system. **If it is not possible to do a full-scale mastoidectomy (due to lack of equipment or expertise),** a dramatic improvement, in conjunction with intravenous antibiotics, may be obtained by incising the abscess (avoiding the mastoid tip in the small child where the facial nerve may be exposed) and opening into mastoid air cells.
- If signs of meningitis or a brain abscess (indicated by a reduced level of consciousness, a fit or localised neurological signs) are seen or suspected, give high-dose IV antibiotics as for meningitis (see Section 5.16.B) and refer the child immediately to an appropriate specialist.

**Glandular fever/infectious mononucleosis**

This is caused by the Epstein–Barr virus and may be similar in presentation to diphtheria.

**Diagnosis**

There are atypical lymphocytes on blood, monospot and Paul-Bunnell tests (usually but not always positive).

**Management**

- **Do not give ampicillin, amoxicillin or Augmentin** for throat infections until glandular fever has been excluded (there is a risk of severe skin reaction). Antibiotics are unhelpful in glandular fever. Treatment is symptomatic.
- Give IV maintenance fluids if swallowing problems are causing dehydration.
- Give IV hydrocortisone 4 mg/kg 6-hourly if signs of airway obstruction occur.
- Intubation/tracheostomy is rarely indicated.

**Retropharyngeal abscess**

Most common in infants and young children, retropharyngeal abscess (RPA) is an abscess located behind the posterior pharyngeal wall (the retropharyngeal space).

RPA is usually caused by a bacterial infection originating in the nasopharynx, tonsils, sinuses, adenoids or middle ear, and can also result from a penetrating injury or a foreign body. It may result from suppuration of retropharyngeal lymph nodes from infected tonsil, adenoid, tooth or penetrating foreign body. The most common causative organisms are beta-haemolytic streptococci, *Staphylococcus aureus*, *Haemophilus parainfluenzae* and anaerobic organisms.

RPA is a relatively uncommon illness, and therefore may not receive prompt diagnosis in children presenting with stiff neck (limited neck mobility or torticollis), some form of palpable neck pain (which may be in 'front of the neck' or around the larynx), malaise, difficulty swallowing, high fever, stridor, trismus, dribbling of saliva, croupy cough or enlarged cervical lymph nodes. Early diagnosis is essential. Infection in the retropharyngeal space can pass down behind the oesophagus into the mediastinum, producing an extremely dangerous mediastinitis.

Peroral surgical drainage of the abscess by incision under anaesthetic (or without anaesthetic in an emergency) is often required. An ENT specialist (if available) must be called urgently.

Surgery may be required urgently to relieve obstruction, but not all patients with retropharyngeal abscesses require surgery. One study found that of 162 paediatric patients with retropharyngeal abscess, 126 required surgery initially, and of the 36 patients who were initially treated conservatively with high-dose antibiotics, 17 required surgery. Surgery is best undertaken using general anaesthesia undertaken by an experienced anaesthetist, as there is risk of rupture of the abscess during intubation. In patients who present with severe airway obstruction, tracheostomy may be required before surgical drainage.

High-dose IV antibiotics, such as ampicillin plus flucloxacillin plus metronidazole, cefuroxime or ceftriaxone plus metronidazole, or clindamycin plus metronidazole, are required in order to control the infection, and can be used to reduce the size of the abscess prior to surgery.

Chronic retropharyngeal abscess is usually secondary to tuberculosis of the cervical spine or spread from an infected lymph node, and the patient needs to be started on anti-TB treatment as soon as possible.

A CT scan (if available) is the definitive diagnostic test.

A lateral X-ray of the neck will usually show swelling of the retropharyngeal space, with the following:

- increased prevertebral soft tissue shadow
- air and fluid level in the pre-vertebral area
- concavity or straightening of the cervical vertebral column
- the air column is pushed forward.

If the retropharyngeal space is more than half of the size of the C2 vertebra, it may indicate retropharyngeal abscess.

A chest X-ray will also be valuable to exclude pneumonia and to show the size of the mediastinum.

### Mediastinal tumours (see Section 5.14)

These often present with the slow onset of stridor in a child with other symptoms and signs (e.g. pallor, lethargy) may be precipitated or aggravated by mediastinal radiotherapy used for treatment of malignant causes.

### Management

- X-ray the chest and mediastinal inlet.
- Intubation may be required as a temporary measure.
- Treat the primary cause.

## 5.1.D The child with sleep-related upper airway obstruction

### BOX 5.1.D.1 Minimum standards

- Appropriate surgery (especially tonsillectomy and adenoidectomy).
- Steroids: topical nasal and, for acute use, oral.

### Introduction

The incidence of sleep-related upper airway obstruction depends on the method of diagnosis (it affects 1–3% of preschool children). It is associated with both enlargement of the tonsils/adenoids and reduced tone or diameter in the upper airway.

Groups at risk are children with any of the following:

- Pierre-Robin sequence
- craniofacial syndromes
- Down's syndrome
- cerebral palsy
- neuromuscular disease
- sickle-cell disease
- Prader-Willi syndrome.

### Presenting features

- Snoring: this occurs in more than 10% of healthy 4- to 5-year-olds, and in most cases is benign.
- Sleep disturbance and restlessness.
- Apnoeic episodes followed by inspiratory gasps.
- Sleeping with the head extended.
- Subcostal and sternal recession during sleep.
- Mouth breathing and halitosis.
- Daytime hyperactivity, poor concentration and irritability (young children).
- Daytime sleepiness (older children).
- Pulmonary hypertension.
- Heart failure.

These features may be associated with developmental delay, impaired cognitive function and behavioural disorders. The disorder is insidious – the child may appear completely normal when awake, and the problem is most or only apparent during rapid eye movement (REM) sleep.

### Investigations

A sleep observation or study is most useful. This can be done either by direct observation of the child during sleep with the chest and face exposed, or by video recording at home during sleep by the parents, looking for the following:

- chest wall recession
- snoring
- sleep position
- nocturnal restlessness.

It is also useful to monitor oxygen saturation (SpO<sub>2</sub>) during sleep. An abnormal result would be a lowest level of less than 87% or more than three dips below 90% during the night.

Also consider the following investigations:

- barium swallow: to assess bulbar function and exclude tracheal compression
- upper airway endoscopy: to assess the structure and dynamics of the upper airway
- lateral X-ray of the post-nasal space: to assess the size of the adenoids.

### Measurement of oxygen saturation (SpO<sub>2</sub>)

Methodological issues that affect this measurement include the following:

- the instruments used (e.g. functional vs. fractional haemoglobin)
- exclusion of motion artefact
- averaging
- altitude
- inclusion of apnoeic pauses.

### Normal data

In children outside infancy, a normal oximetry recording should have the following:

- 1 a median SpO<sub>2</sub> level of  $\geq$  95%
- 2 no more than four desaturations of  $\geq$  4% per hour
- 3 no abnormal clusters of desaturation defined as  $\geq$  5 in a 30-minute period.

Widely used criteria for abnormality in nocturnal oximetry recordings are falls of more than 4% below baseline and

desaturations below 90%. The measure that correlates best with poor academic performance is the lowest level of SpO<sub>2</sub> (nadir) during the night (normal value is > 87.5%).

### Adverse effects of hypoxaemia

These include the following:

- poor weight gain
- developmental delay
- poor cognitive function
- pulmonary hypertension
- cyanotic apnoeic episodes.

### Treatment

- Time: the airway enlarges with growth.
- Obstruction is worse with infections and may need a rescue course of steroids (e.g. prednisolone 0.5 mg/kg once daily for up to 7–10 days).
- Topical steroids/decongestants.

- Tonsillo-adenoidectomy.
- Nasal CPAP.
- Nasopharyngeal tube (in infants).
- Tracheostomy.

### Nasal CPAP (see Section 1.25)

This is an effective non-invasive treatment, but it is associated with the following potential problems:

- compliance
- side effects:
  - skin sores
  - nose bleeds
  - conjunctivitis
  - aerophagy.

### Reference

British Lung Foundation. *OSA in Children*. A leaflet for the parents of children with obstructive sleep apnoea. [www.blf.org.uk/Conditions/Detail/OSA-in-children#overview](http://www.blf.org.uk/Conditions/Detail/OSA-in-children#overview).

## 5.2 Lower airway disorders

### 5.2.A Bronchiolitis

#### BOX 5.2.A.1 Minimum standards

- Oxygen.
- Oxygen saturation monitor.
- Bag-valve-mask system.
- Cannulae for thoracostomy.
- Antibiotics.
- Nasal CPAP.

### Introduction

Wheezing is a whistling noise heard during expiration. The child who has cough or difficulty breathing **and** wheezing will fit into one of the following categories:

- bronchiolitis (mainly less than 1 year old)
- asthma (over 1 year old)
- pneumonia with wheezing (any age).

In pneumonia with wheezing in children over 1 year of age and in asthma, a bronchodilator provides important symptomatic relief. An aerosol and large-volume spacer (which may be improvised) is the best way of administering a bronchodilator (see below). Bronchodilators are not routinely effective in bronchiolitis, but may be tried in some cases.

A lower respiratory viral infection, typically most severe in young infants, occurs in annual epidemics, and is characterised by airways obstruction and wheezing. Respiratory syncytial virus is the most important cause. Secondary

bacterial infection may occur and is common in some settings. Episodes of wheeze may occur for months after an attack of bronchiolitis, but will eventually stop. Some babies who have had bronchiolitis go on to have asthma, but both bronchiolitis and asthma are common conditions, and a causal relationship has not been established.

### Clinical features of bronchiolitis

- Infants are coryzal, have a troublesome cough and may feed poorly or even be unable to suck and feed. There may be vomiting.
- The nose is often obstructed by secretions.
- On examining the chest, there may be hyperinflation, chest wall indrawing, nasal flaring, grunting, wheeze and fine crackles at the lung bases.
- Young infants may present with apnoeic/hypoxaemic episodes which may be recurrent and life-threatening.
- There may be hypoxaemia, with SaO<sub>2</sub> less than 94%, with or without cyanosis.
- Some infants will have such severe respiratory distress that there is gasping; this is pre-terminal.

### Treatment

Only supportive treatment (e.g. oxygen, gentle suction of the nose, and fluids) is of benefit. Antibiotics and bronchodilators have no role. However, in the most severe cases and unless you are **certain** that pneumonia is not present,

it is safer to give antibiotics and a trial of a bronchodilator (stop the bronchodilator if it is not helping).

Non-invasive respiratory support to help to overcome small airway obstruction (nasal CPAP and continuous negative extrathoracic pressure (CNEP)) may be valuable (see Section 1.25 and Section 8.3). CNEP may be more effective because of the nasal blockage that accompanies bronchiolitis.

- Give oxygen by nasal cannulae to keep  $\text{SaO}_2$  in the range 94–98%. Check that the nasal cannulae are in the correct place, and check frequently that they are not blocked by secretions.
- Nasal clearance. Gentle nasal suction should be used to clear secretions in patients in whom nasal blockage is thought to be causing respiratory distress. This may be aided by saline nasal drops or spray.
- Ensure that daily maintenance fluids are achieved. If this is not possible by mouth, use nasogastric feeding. This should be considered in any patient who is unable to maintain oral intake or hydration (use the mother's expressed breast milk if possible and if tolerated).
- If the patient is vomiting despite nasogastric feeding, or severe respiratory distress is present, give fluids IV.
- If there are signs of pneumonia, give antibiotics (see Section 5.3.A).
- If fever ( $\geq 39^\circ\text{C}$  or  $\geq 102.2^\circ\text{F}$ ) is causing distress, give paracetamol. High fever is the exception rather than the rule in bronchiolitis, and should make you suspect bacterial infection.

#### Failure to improve

If the condition worsens suddenly, consider pneumothorax, although this is uncommon. Tension pneumothorax associated with major respiratory distress and shift of the

heart requires immediate relief by needle thoracocentesis (i.e. placing a needle to allow the air that is under pressure to escape) (see Section 8.3). If needle thoracocentesis is helpful, insert a chest tube with an underwater seal until the air leak closes spontaneously and the lung expands (see Section 8.3). **The signs of pneumothorax in severe bronchiolitis may be difficult to detect clinically. However, needle thoracocentesis in the absence of a pneumothorax may cause one, so if you are unsure, take a chest X-ray.** Even on a chest X-ray, the diagnosis may be very difficult due to the areas of hyperlucency in bronchiolitis caused by air trapping.

**If respiratory failure develops, nasal continuous positive airways pressure (CPAP) or continuous negative extrathoracic pressure (CNEP) may be of benefit (see Section 8.3).**

**If apnoeic episodes develop (this is most likely in premature infants), give bag-valve-mask resuscitation, then nasal CPAP or CNEP. Sometimes intubation and ventilation may be needed in a high-dependency ward (if available); if so, contact an anaesthetist urgently.**

#### Infection control

Bronchiolitis is infectious and easily transmitted to other infants and young children in hospital. Babies in the neonatal unit are particularly at risk. The following strategies may reduce the risk of cross-infection (see Section 1.2):

- hand washing between patients
- the wearing of gloves and aprons
- ideally isolate the affected patient, but close observations are needed
- restrict visiting by anyone with symptoms of upper respiratory tract infection.

## 5.2.B Asthma

### BOX 5.2.B.1 Minimum standards

- Inhaled bronchodilators (with spacers).
- Inhaled steroids.
- Prednisolone/hydrocortisone.
- Nebulised bronchodilators.
- Oxygen.
- Salbutamol, magnesium sulphate, adrenaline and aminophylline.
- Pulse oximetry.

#### Introduction

Asthma is a condition characterised by episodic or recurrent symptoms of cough, prolonged expiration with wheeze, chest tightness and shortness of breath without fever (although some episodes are precipitated by an upper respiratory tract infection which may have an accompanying fever). It is due to variable and reversible airway obstruction associated with chronic airway inflammation. Asthma has become more prevalent over the last 20 years, along with the other atopic conditions such as allergic rhinitis and eczema. This is particularly so in well-resourced countries, where it is reported to occur in up to 10–15% of children.

Young children (under 5 years of age) often have 'asthma-like' symptoms (cough, wheeze and shortness of breath) in response to respiratory infections, but with no demonstrable problem between infections. This tendency often stops in the early school years. In these children, treatment of episodic symptoms with acute asthma therapies ('relievers') may still provide relief of symptoms, but 'preventers' (i.e. inhaled steroids) will not usually be of benefit unless the child has continuous symptoms or is likely to be atopic (e.g. due to a personal or family history of asthma, eczema or allergic rhinitis). In the youngest children (less than 2 years old) with severe episodes or symptoms continuing between infections (interval symptoms), it is necessary to consider other diagnoses, such as bronchiectasis, tuberculosis, foreign body and cystic fibrosis.

#### Diagnosis of asthma between episodes

The diagnosis is clinical, and is based on a **history** of the following:

- recurrent cough (mostly dry, becoming productive with exacerbations), wheeze, shortness of breath or chest tightness
- symptoms worse at night, and on exertion

- symptoms worsened by respiratory infections, inhaled irritants (e.g. cigarette smoke), cold air, animal fur, excitement or upset
- a personal or close family history of eczema, rhinitis or asthma.

**Examination** may identify any of the following:

- no abnormalities
- slow growth
- overinflation of the chest, Harrison's sulci
- wheeze, particularly on forced expiration
- rhinitis or eczema.

### Investigations

Investigations are not usually needed, but may help to support the diagnosis or exclude other conditions:

- 1 Chest X-ray. This is normal or shows overinflation (flat diaphragms and hyperlucency, particularly when severe or acute), or increased perihilar linear markings.
- 2 Peak flow (in children aged 7–8 years or over). This may show the following:
  - more than 15% variability from morning to night (keep a peak flow diary)
  - a fall after 5–10 minutes of hard exercise
  - a rise after a dose of inhaled bronchodilators (e.g. salbutamol)
  - **spirometry will show FEV1:FVC of less than 85% and concavity in the flow-volume loop, which is at least partially reversed by a dose of inhaled bronchodilators.**

Skin prick tests, or IgE RASTs, do not aid the diagnosis, and only infrequently help in the management.

Symptoms that resolve with bronchodilators with or without steroids support the diagnosis, but bear in mind that conditions other than asthma may also show reversibility.

### Ongoing management

- Avoid allergic/irritant factors (e.g. smoke, chemical fumes, house dust mites, animal fur). Discourage cigarette smoking and acquiring new pets at home.
- Do not prevent the child from exercising, but pre-dose them 5–10 minutes beforehand with a dose of inhaled beta-2 agonist bronchodilators (e.g. salbutamol).

### Use of 'reliever' medication

- Occasional symptoms (e.g. on 2 to 4 days per week) may be managed with only the use of a bronchodilator (a 'reliever'), and do not usually need a 'preventer' (see below).
- Use inhaled drugs where possible, except in acute severe or life-threatening attacks, when the IV route may be used.

**FIGURE 5.2.B.1** 'Spacer' made from a large plastic bottle in use with an inhaler.

- Use an aerosol spray (metered-dose inhaler) with a spacer (first choice):
  - A commercial medium- to large-volume spacer (e.g. Volumatic, AeroChamber), or a large (2-litre) plastic bottle with the aerosol sealed into one end, and the open end held closely over the nose and mouth (see Figure 5.2.B.1).
  - Use 200–1000 micrograms of salbutamol (2–10 sprays); more may be needed in younger children, or if the patient is acutely breathless (and repeated).
  - Each spray or puff should be inhaled individually in turn with 4 to 5 breaths, rather than filling the spacer device with multiple sprays.
  - For children under 5 years of age, attach a face mask (e.g. inverted adult mask) to the mouthpiece of a spacer.

Clean the spacer with soapy water and leave it to dry naturally to reduce static electrical charges on the inside. Alternatively, use a nebuliser to deliver salbutamol (this is less portable).

**Children with asthma should always have immediate access to their usual reliever inhaler device. Children over 7–8 years of age may keep their device with them.**

### Use of 'preventer' medication

More frequent symptoms, regular nocturnal symptoms or daily use of a bronchodilator should be treated with regular medication aimed at controlling airway inflammation (a 'preventer'), such as inhaled steroids. Use inhaled (preferably through a spacer) beclomethasone propionate or budesonide, 200–400 micrograms twice daily.

- Rinse the mouth (if feasible) after each dose of inhaled steroid.
- Aim for rapid control of symptoms, and then tail down the dose over a period of months.
- Gaining control may be helped by a short course (7–10 days) of systemic steroid (e.g. prednisolone 500 micrograms/kg once daily after food or milk, maximum daily dose 40 mg).
- Continue with bronchodilator use for symptom relief (but avoid regular use).

For frequent or severe symptoms, consider:

- whether the diagnosis is correct
- aggravating factors (e.g. rhinitis, stress, gastro-oesophageal reflux)
- whether the medication is being taken, and whether it is being taken correctly
- increasing the inhaled steroid dose (beclomethasone to 400–800 micrograms twice daily) **or**
- **adding leukotriene antagonists (e.g. montelukast), which are useful in preschool children, or a long-acting inhaled drug (e.g. salmeterol) or**
- oral methylxanthines (e.g. theophylline 5 mg/kg three to four times a day)
- **as a last resort**, use of alternate-day oral prednisolone (start at 500 micrograms/kg on alternate days and reduce rapidly to 100 micrograms/kg on alternate days, to the nearest 1 mg or 5 mg tablets). Stop as soon as possible.

Children on inhaled or oral steroids should have regular

checks of their growth and be watched for steroid side effects (e.g. oral thrush)

The control of asthma should be regularly reviewed (e.g. 3-monthly) and medication stepped up or down depending on the symptoms and on peak flow measurements **or spirometry** in those over 7 years of age. Families should be given written instructions and helped to change the treatment themselves, with support.

### Management of an episode of acute asthma

Initial treatment of a mild to moderate acute attack of asthma is as follows:

- Reassure the child and their parents, and avoid upset as this may exacerbate respiratory distress.
- Give a regular inhaled beta-2 agonist bronchodilator, such as salbutamol aerosol 200–1000 micrograms (2 to 10 sprays each of 100 micrograms, with each spray given after every four to five breaths) via a spacer every 30 minutes to 2-hourly until the child is better.
- If the child does not respond to the spacer, give 2.5 mg salbutamol for children under 5 years and 5 mg salbutamol for those over 5 years via a nebuliser 2- to 4-hourly (use oxygen to drive the nebuliser if possible).
- Give systemic steroids: oral prednisolone 1 mg/kg (maximum dose of 40 mg) for 3–5 days, depending on the duration of symptoms; administer with food or milk to avoid gastric irritation.
- Treat or remove any exacerbating factors (see the 'Diagnosis' section above).
- Give antibiotics only if there are signs of pneumonia, especially a persistent fever.

### Very severe or life-threatening asthma

Features of severe or life-threatening asthma include the following:

- being too breathless to feed, drink or talk
- marked recession/use of accessory muscles
- respiratory rate of more than 50 breaths/minute
- pulse rate of more than 140 beats/minute
- poor chest movement or silent chest
- exhaustion, agitation or reduced conscious level (due to hypoxia or hypercapnia)
- hypoxaemia (SaO<sub>2</sub> less than 90% in air or cyanosis) (this is a very late sign).

Treat immediately (use the 'ABC' approach):

- Give **100% oxygen** via a face mask with reservoir bag held by the parent or nurse close to the child's face at 10–15 litres/minute to keep SaO<sub>2</sub> in the range 94–98%.
- Give salbutamol inhaled from a nebuliser, 2.5 mg nebulules for children under 5 years and 5 mg for those over 5 years, and repeated as required (drive the nebuliser with oxygen at 6–8 litres/minute rather than compressed air). Sometimes nebulisers may be needed continuously (described as 'back to back', i.e. as each nebule finishes, repeat with another).
- If a nebuliser is not available, use inhaled salbutamol via a spacer (but now without a valve that needs opening with each breath; see Figure 5.2.B.1, in which the home-made 'spacer' has no valve) as described above in acute asthma. That is, give salbutamol aerosol 1000 micrograms (10 sprays each of 100 micrograms,

with each spray given after every four to five breaths) via the spacer every 5–10 minutes initially and then, once there is some improvement, 10 sprays over four to five breaths each, every 10–30 minutes until the child is better. Children under 4 years of age are likely to require a face mask connected to the mouthpiece of a spacer for successful drug delivery. Inhalers should be sprayed into the spacer in individual sprays and inhaled immediately by tidal breathing.

- If nebulised or inhaled beta-agonist bronchodilators are not available or are not effective and the child is deteriorating, give an intramuscular injection of adrenaline: 10 micrograms/kg (0.01 mL/kg of 1 in 1000 solution, up to a maximum of 300 micrograms), measured accurately with a 1-mL syringe (**ensure that the needle is not in a vein before injecting**). If there is no improvement after 15 minutes, repeat the dose once.
- **In addition to the bronchodilator treatment, give systemic steroids either as IV/IM hydrocortisone 4 mg/kg 4- to 6-hourly (preferable) or as oral prednisolone (see above) until recovery.** Start the steroids as soon as possible. A soluble preparation dissolved in a spoonful of water is preferable in those unable to swallow tablets. Use a dose of 20 mg for children aged 2–5 years. Repeat the dose of prednisolone in children who vomit, and give IV (or IM if a venous cannula cannot be inserted) hydrocortisone (4 mg/kg repeated 4-hourly) in those who are unable to retain orally ingested medication. Treatment for 3–5 days is usually sufficient, but the length of the course should be tailored to the number of days necessary to bring about recovery. Weaning is unnecessary unless the course of steroids exceeds 14 days.

**If two to three doses of inhaled bronchodilator and systemic steroids do not result in improvement, or if life-threatening features are present, use:**

- IV beta-2-agonist salbutamol (loading dose 5 micrograms/kg over 10–15 minutes in children under 2 years of age and 15 micrograms/kg over 2 years of age). If resources allow (i.e. only where high-dependency or intensive care is available), this can be followed by 1–2 micrograms/kg/minute (maximum of 5 micrograms/kg/minute) adjusted according to response and heart rate, and with monitoring of serum potassium levels as this electrolyte falls when salbutamol is given IV (see below)
- **or** IV magnesium sulphate 40 milligrams/kg (maximum of 2 grams) over 20 minutes
- **or** both of the above
- an alternative to the above treatments is to give aminophylline (loading dose 5 mg/kg over 20 minutes, followed by 1 mg/kg/hour by IV infusion in children aged 1–12 years and 500 micrograms/kg/hour in patients aged over 12 years or under 1 year). Do not give the loading dose if the child has already received any form of aminophylline or caffeine in the previous 24 hours. Side effects include nausea, vomiting, tachycardia or tachyarrhythmia and seizures, and consequently this treatment is less preferred.

Severe and life-threatening hypokalaemia may occur with IV salbutamol, potentiated by steroids. If possible, monitor the ECG continuously and check potassium levels 12-hourly. ECG signs of hypokalaemia are ST depression, T-wave

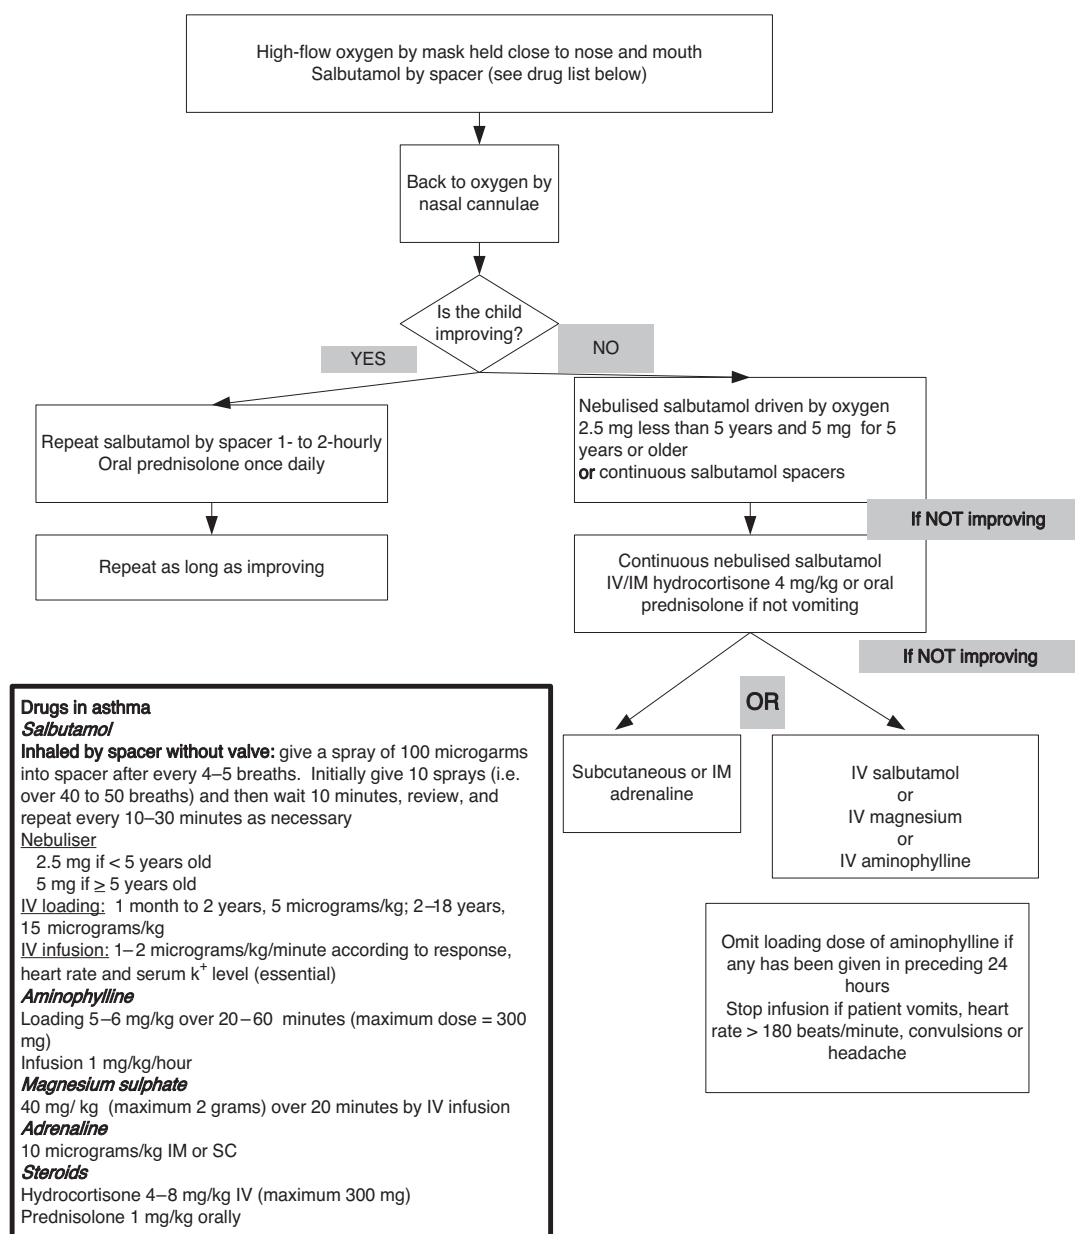

FIGURE 5.2.B.2 Pathway of care for very severe or life-threatening asthma.

reduction and prominent U waves. Ensure that maintenance potassium intake is given in the infusion fluid.

If there is a poor response to the above treatment, or the child's condition worsens suddenly, obtain a chest X-ray to look for evidence of pneumothorax. In the presence of hyperinflation from asthma, detection of a pneumothorax on the chest X-ray may be difficult.

Monitor the above clinical features regularly, and also monitor oxygen saturation, by pulse oximeter if available. Keep  $SAO_2$  in the range 94–98% by administering oxygen, either by face mask or by nasal cannulae. Use oxygen to drive nebulisers.

If the above measures do not result in improvement, or the child is tiring and gasping, this may progress to a respiratory arrest. Positive airway pressure would be the usual next step. Some respiratory support can be given by the use of a bag-valve-mask system to increase tidal breaths, but beware of aspiration (insert a nasogastric tube).

**Transcutaneous  $pCO_2$  monitoring is valuable in severe asthma.**

In cases that do not respond to the above measures, obtain a chest X-ray and consider mechanical ventilation (slow rate, long expiration). A blood gas measurement showing respiratory acidosis can be valuable at this time, but remember that invasive procedures can worsen respiratory distress.

If intubation and ventilation become essential, ketamine induction followed by inhalational anaesthetic gases (e.g. halothane) may assist bronchodilatation.

**Indications for intubation and ventilation (if available) in severe asthma include the following:**

- increasing exhaustion
- progressive deterioration in clinical condition
- oxygenation decreasing and/or oxygen requirement increasing

- pCO<sub>2</sub> increasing (if measurable from arterial/capillary gas)
- sudden deterioration – and always consider the possibility of a pneumothorax.

### Follow-up care

Once the child has improved sufficiently to be discharged

home, prescribe inhaled salbutamol through a metered-dose inhaler with a suitable commercially available or home-made spacer (see Figure 5.2.B.1), and instruct the parents in how to use this.

Following any acute episode, review asthma control and management, including correct use of medications and the need for a step up in 'preventive' treatment.

## 5.2.C The child with an inhaled foreign body

### BOX 5.2.C.1 Minimum standards

- Chest X-ray.
- Antibiotics.
- Physiotherapy.
- Bronchoscopy.

### Introduction

Any small object that can get through the trachea or large bronchi, such as a seed, a peanut or an eraser from the top of a pencil, can lodge in the lower airway. If the object is too small to cause life-threatening choking it will enter the lower respiratory tract and cause subacute respiratory symptoms after an initial coughing bout.

### Diagnosis

There may be a clear history from the parent or child of an episode of coughing or choking, followed by difficulty in breathing.

- On examination of the child's chest, look to see whether there is less chest expansion on one side when breathing in.
- Feel the trachea. It may be pushed away from the midline by air trapping on the side affected by the foreign body.
- This may also be seen on a chest X-ray (if available) (see Figure 5.2.C.1), ideally an expiratory and inspiratory film.

An inhaled foreign body in a young child can go down the right or left side. In older children and adults, a foreign body on the right side is more common. There may be a harsh wheezing noise heard on the side of the chest where the foreign body has lodged.

### Treatment

Air may be trapped in the lungs beyond the point where the foreign body has lodged, or this part of the lung may become infected. Give the child antibiotics. Chloramphenicol, 25 mg/

**FIGURE 5.2.C.1** Chest X-ray of a child with a foreign body occluding the right middle and right lower lobe bronchi. The right upper lobe of the lung shows air trapping due to a 'ball-valve' effect. The foreign body is not visible because it is not radio opaque.

kg every eight hours, is a good first choice, but add flucloxacillin or cloxacillin 25 mg/kg six hourly if there is a suspicion of or proven infection with *Staphylococcus aureus*. If there is evidence of severe pneumonia use the antibiotic combination in Section 5.3.A for severe pneumonia. Removal of a foreign body is a specialised procedure that must be carried out using a bronchoscope. Treat the infection until the child can be transferred to a hospital where this procedure can be performed. Some gentle physiotherapy may help, but take care not to dislodge the foreign body, as this will cause infection and obstruction in another part of the lung.

If the foreign body is not removed there will be subsequent bronchiectasis and recurrent chest infections (see Section 5.3.B).

For the management of choking, see Section 1.12.

## 5.3 Lung disorders

### 5.3.A Pneumonia

#### BOX 5.3.A.1 Minimum standards

- Oxygen.
- Pulse oximeter.
- Antibiotics.
- Immunisations: pneumococcal.
- Chest X-ray.
- TB and HIV testing.

#### Acute respiratory infection

There are two categories of acute respiratory infection (ARI).

- **Acute upper respiratory infection (AURI):** above the vocal cords and epiglottis. These infections include colds, tonsillitis and otitis media. They are not life-threatening, but may lead to disability (e.g. otitis media is a leading cause of deafness in resource-limited countries) and complications (e.g. rheumatic fever following streptococcal pharyngitis).
- **Acute lower respiratory infection (ALRI):** below and including the vocal cords and epiglottis. These infections include croup (and other infectious causes of upper airway obstruction), pneumonia and bronchiolitis. Acute upper airway obstruction is described in Section 5.1.

#### Importance of acute respiratory infection

Pneumonia is responsible for around two million deaths annually in children under 5 years of age. In resource-limited countries, most of these infections are bacterial, and the most common causative bacteria are *Streptococcus pneumoniae* and *Haemophilus influenzae*. **In severely malnourished children, *Klebsiella pneumoniae* and *Staphylococcus aureus* are the most common causative organisms.**

#### Immunisation

Pneumococcal conjugate vaccine has been introduced to the primary immunisation schedule in many well-resourced countries, and reduces the incidence of X-ray-proven pneumonia in infants by around one-third. The HiB vaccine (against encapsulated *Haemophilus influenzae* type B) will not protect against unencapsulated *H. influenzae*, which causes some cases of pneumonia in resource-limited countries. Nevertheless, the HiB vaccine is very effective against other very serious infections caused by *H. influenzae* (e.g. meningitis, epiglottitis), and should be given to all infants in every country. Unfortunately, around 34 million children do not receive routine immunisations, and most of these are **living** in resource-limited countries.

#### Management of the child with acute upper respiratory infection

##### Coryza or pharyngitis

These are common self-limiting viral infections that require only supportive care. Antibiotics should not be given. Wheeze or stridor may occur in some children, especially infants. Most episodes end within 14 days. Cough lasting 30 days or more may be caused by tuberculosis, asthma or pertussis.

##### Presentation

These infections present with cough, running nose, fever and sore throat, but **not** with fast breathing, chest indrawing, stridor or danger signs for pneumonia (see below). Wheezing may occur in young children (see Section 5.2.A).

##### Treatment

- Treat the child as an outpatient.
- Soothe the throat and relieve the cough with a safe remedy, such as a warm sweet drink.
- Relieve high fever ( $\geq 39^{\circ}\text{C}$  or  $\geq 102.2^{\circ}\text{F}$ ) with paracetamol if it is causing distress.
- Give normal fluid requirements plus extra breast milk or fluids if there is a fever. Small frequent drinks are more likely to be taken and less likely to be vomited.
- Clear secretions from the nose before feeds using a cloth which has been soaked in water and twisted to form a pointed wick.
- Do not give any of the following:
  - antibiotics (they are not effective for viral illnesses and do not prevent pneumonia)
  - remedies containing atropine, codeine or codeine derivatives, or alcohol (which may be harmful)
  - medicated nose drops.

Advise the mother to feed the child normally, to watch for fast or difficult breathing, and to return if either develops or if the child is unable to drink or breastfeed.

Inform the mother that the child has mucus in the upper airways that 'drops' in the lungs, so the child coughs in order to remove it, and this means that the cough in itself is not dangerous.

#### Management of the child with acute lower respiratory infection (ALRI)

Children at greatest risk of dying from an ALRI have the following risk factors:

- age under 1 year
- malnutrition

- pneumonia as a complication of infection with measles, pertussis, malaria or HIV.

### Diagnosis of ALRI

In many hospitals in resource-limited countries, special tests (e.g. blood culture, microbiology of respiratory secretions, X-rays) may be limited or unavailable. However, because the prevalence of bacterial pneumonia is high, the diagnosis must usually be made clinically. This will not be 100% accurate, so a few children may receive antibiotics unnecessarily (i.e. clinical diagnosis has less than 100% **specificity**). However, it is more important not to miss children who do need antibiotics (i.e. clinical diagnosis should have a good **sensitivity**). Clinical diagnosis may be as accurate as an X-ray and more helpful in deciding whether treatments such as oxygen are indicated. The clinical features will also help to decide how severe the child's infection is and what treatment is appropriate.

The following clinical features should be recorded:

- The presence of **cyanosis**, which is best seen in the lips or tongue. It may be missed if the lighting is poor or if the child is anaemic (e.g. due to co-infection with malaria), and it can be difficult to detect in black children. Cyanosis is a late sign of respiratory problems, and if possible oxygenation should be assessed with a pulse oximeter. Normal saturation at sea level ( $\text{SaO}_2$ ) is greater than 94%.
- Inability of the child to drink.
- The presence of chest wall indrawing (an inward motion of the lower chest wall when the child breathes in).
- The presence of grunting (expiratory braking).
- The presence of hyperinflation (asthma or bronchiolitis).
- Elevated respiratory rate. Respiratory rate is measured over 1 minute, using a suitable timing device. The respiratory rate in children varies with age. Table 5.3.A.1 lists the abnormal values for respiratory rate for various age groups.

**TABLE 5.3.A.1 WHO definition of abnormally fast breathing**

Age	Abnormally fast breathing
< 2 months	$\geq 60$ breaths/minute
2–12 months	$\geq 50$ breaths/minute
12 months to 5 years	$\geq 40$ breaths/minute

Remember that conditions such as severe anaemia, dehydration and high fever are accompanied by a raised respiratory rate.

A high fever in a child with breathing difficulties may be due to pneumonia, bacterial tracheitis or even epiglottitis. If the airway is clear, the most likely diagnosis is pneumonia. Although high fever and respiratory signs are the usual way for pneumonia to present, pneumonia should always be considered in the list of causes of abdominal pain and neck stiffness.

Clinical examination (or chest X-ray) cannot reliably differentiate between a viral pneumonia and a bacterial one, so all cases are treated with antibiotics.

Features of pneumonia include the following:

- fever, cough, breathlessness and lethargy
- pleuritic chest pain, abdominal pain and neck stiffness (these indicate pleural involvement)

**FIGURE 5.3.A.1** Right middle lobe pneumonia. Note the loss of the right heart border.

**FIGURE 5.3.A.2** Left lower lobe pneumonia. Note that the silhouette of the diaphragm cannot be seen on the left. The right middle lobe is also affected.

**FIGURE 5.3.A.3** Right upper lobe pneumonia. Note that the horizontal fissure is pulled up.

- signs of consolidation:
  - dull percussion
  - reduced breath sounds
  - bronchial breathing may be absent in an infant
- chest X-ray may show pleural effusion or empyema as well as consolidation.

Auscultation should always be undertaken, **but only after first checking for cyanosis, observing the breathing pattern and the other signs as described above**. Important clinical signs include evidence of the following:

- consolidation or effusion/empyema
- wheeze

- bronchiolitis (hyperinflation with crackles at the lung bases)
- alveolitis (e.g. in HIV-induced *Pneumocystis pneumonia*) with end-inspiratory crackles.
- pericardial involvement (rare)
- pneumothorax (rare).

A chest X-ray may be helpful if there is any doubt about the diagnosis or if the child is seriously ill.

Figures 5.3.A.1, 5.3.A.2 and 5.3.A.3 show the appearance of lobar pneumonia affecting different lobes.

Additional features of ARLI usually include a fever and a cough. Pleuritic chest pain (which may radiate to the abdomen) may also be present in older children if the diagnosis is pneumonia.

Table 5.3.A.2 gives guidelines for the assessment and treatment of acute respiratory infection. Children with the following features should be managed differently, as described elsewhere in this book:

- stridor (see Section 5.1.A)
- wheeze (see Sections 5.2.A and 5.2.B)
- severe malnutrition (see Section 5.10.B)
- signs suggesting meningitis (see Section 5.16.B).

### Diagnosis of severe pneumonia

This is diagnosed by the presence of cough or difficult breathing plus at least one of the following:

- central cyanosis

- inability to breastfeed or drink, or vomiting after every drink
- convulsions, lethargy or unconsciousness
- severe respiratory distress.

In addition, some or all of the other signs of pneumonia may be present, such as the following:

- fast breathing:
  - age < 2 months:  $\geq 60$  breaths/minute
  - age 2–11 months:  $\geq 50$  breaths/minute
  - age 1–5 years:  $\geq 40$  breaths/minute
- nasal flaring
- grunting (in young infants)
- lower chest wall indrawing
- chest auscultation signs of pneumonia:
  - decreased breath sounds
  - bronchial breath sounds
  - crackles
  - abnormal vocal resonance (decreased over a pleural effusion, and increased over lobar consolidation)
  - pleural rub.

Obtain a chest X-ray and SaO<sub>2</sub> (if available).

For children with no evidence of pneumonia but with signs suggesting a chest infection, look for ear and throat infections or infections in another system and treat accordingly.

**TABLE 5.3.A.2** The management of children with different severities of acute lower respiratory tract infection (ALRI) (modified from the WHO *Pocket Book of Hospital Care for Children*, second edition 2014)

Sign or symptom	Classification	Treatment
Central cyanosis and/or SaO <sub>2</sub> < 90% Severe respiratory distress (e.g. head nodding, gasping, chest wall indrawing, grunting) Fast breathing as below under 'pneumonia that is not severe' Decreased breath sounds and/or bronchial breathing Crackles in the lung fields Vocal resonance and percussion suggesting consolidation and/or effusion Pleural rub Inability to drink, vomiting, reduced consciousness	Severe pneumonia	Admit to hospital Give IV/IM appropriate antibiotics* Give oxygen Manage the airway Treat high fever if present If the child has HIV infection, refer to specific guidelines (and see Section 6.2.D)
<b>Plus</b> signs of pneumonia in the row below		
Fast breathing but no chest wall indrawing: $\geq 60$ breaths/minute in a child aged < 2 months $\geq 50$ breaths/minute in a child aged 2–11 months $\geq 40$ breaths/minute in a child aged 1–5 years Definite crackles on auscultation	Pneumonia that is not severe	Home care (but depends on home circumstances and overall clinical state of the child) Give an appropriate antibiotic* Advise the mother when to return if treatment fails on amoxicillin and more appropriate second-line treatment is needed Follow up in 2 days
No signs of pneumonia or severe pneumonia	No pneumonia Cough or coryza	Home care Advise the mother to return for follow-up in 5 days if not improving If coughing for more than 14 days, consider investigations for TB, asthma, inhaled foreign body, pertussis, HIV, bronchiectasis and lung abscess (see Figure 5.3.C.1).

\* See details of antibiotics, routes of administration and durations for different categories of pneumonia in section 'Antibiotics' below

### Oxygen

Children with severe or very severe pneumonia are likely to be hypoxaemic. However, cyanosis is a late sign of hypoxaemia.

**Oxygen must always be available in sufficient quantity to provide 24-hour treatment without depending on the availability of a reliable electricity supply.**

Give oxygen if the child shows any of the following:

- restlessness (if oxygen makes the child more comfortable)
- severe chest wall indrawing
- a breathing rate of more than 70 breaths/minute (in a child aged 2 months to 5 years)
- grunting (in an infant under 2 months of age)
- gasping
- if a pulse oximeter is available, SaO<sub>2</sub> of less than 94% (at sea level; lower values will be normal at high altitude, and normal values of SaO<sub>2</sub> should be known for healthy local children in your area if it is at high altitude). Aim to maintain SaO<sub>2</sub> in the range 94–98%.

**Give oxygen** until the signs of hypoxia (e.g. severe lower chest wall indrawing, high breathing rates and/or SaO<sub>2</sub> < 94% in air) are no longer present.

### Oxygen delivery

A good source of oxygen is an oxygen concentrator. This is a durable piece of equipment, but it requires a continuous supply of mains electricity to provide oxygen. It works on the 'molecular-sieve' principle, removing nitrogen from room air. The alternative is cylinder oxygen, but cylinders must be replenished regularly and need to be available at all times, which is expensive and may give rise to transport difficulties. **A combination of the two supplies of oxygen is essential.** An oxygen generator which can provide oxygen and fill cylinders when the electrical power is available (e.g. Diamedica equipment). The concentrator or cylinder should be connected to a low-flow meter. The use of a flow splitter will allow up to four children to receive oxygen from one source. The oxygen should be delivered to the child using nasal cannulae. **These should be only 2–3 mm long, to avoid nasal irritation.**

Figure 5.3.A.4 shows the delivery of oxygen through nasal cannulae.

**A mask should be used to give high-flow oxygen during resuscitation.**

**FIGURE 5.3.A.4** Nasal cannulae for delivering oxygen. The cannula has been taped to the child's cheeks, close to the nostrils. The tubing is run under the child's shirt to stop them pulling it, and leads to the low-flow meter and oxygen concentrator or cylinder. A flow splitter may be used.

Nurses should check frequently that the nasal cannulae are not blocked with mucus and are in the correct position, and that all connections are secure.

### Antibiotics

Children who are vomiting or who require IV fluids should have their antibiotics given intravenously (preferably), or intramuscularly **if vascular access is difficult to achieve or maintain**, for the first 48 hours. Some antibiotics, such as gentamicin, are always given IV or IM. Certain antibiotics are reserved for specific circumstances, such as high-dose co-trimoxazole for suspected *Pneumocystis jirovecii* pneumonia, and flucloxacillin or cloxacillin for pulmonary abscess or bacterial tracheitis where *Staphylococcus aureus* is likely to be responsible. These are described at the end of the section on antibiotics.

#### For severe pneumonia:

- Give ampicillin 50 mg/kg IM/IV or benzyl penicillin 50 000 units/kg that is 30 mg/kg IM or IV every 6 hours plus gentamicin 7.5 mg/kg IM or IV once a day for 5 days. Then, if the child responds well, complete treatment with oral amoxicillin (25 mg/kg three times a day, maximum 500 mg, or 1 gram in severe cases) plus IM or IV gentamicin 7.5 mg/kg once daily for a further 5 days.
- Alternatively, if the above are not available, give chloramphenicol (25 mg/kg IM or IV every 8 hours) until the child has improved. Then continue orally four times a day for a total course of 10 days.
- Or use ceftriaxone (80 mg/kg IM or IV once daily) or cefotaxime (50 mg/kg IV 6-hourly) for 10 days.
- If the child does not improve within 48 hours, switch to gentamicin (7.5 mg/kg IM or IV once a day) and cloxacillin (50 mg/kg IM or IV every 6 hours), as described below for possible staphylococcal pneumonia.

#### For pneumonia that is not severe:

- Treat the child as an outpatient.
- Give amoxicillin 40 mg/kg twice a day for 5 days.
- Give the first dose at the clinic, and teach the mother how to give the other doses at home.
- In infants aged 2–12 months who have some of the signs suggestive of non-severe pneumonia without a high fever but **with** wheeze, the most likely diagnosis is bronchiolitis. This is caused by a virus, and in the absence of signs suggesting the development of secondary bacterial infection (severe pneumonia), antibiotics are not necessary (see Section 5.2.A). The WHO recently published the following conclusion: **Antibiotics are not routinely recommended for children aged 2 months to 5 years with non-severe pneumonia (that is, fast breathing with no chest indrawing or danger signs) with a wheeze but no fever (temperature below 38°C), as the cause is most likely to be viral.**

### Symptomatic and supportive treatment for children with all degrees of pneumonia

Nurse the child in a thermoneutral environment (lightly clothed in a warm room at around 25°C).

Fever:

- Remember that fever may not be simply due to the child's pneumonia. Consider other diagnoses, such as malaria.
- If the child has fever ( $\geq 39^\circ\text{C}$  or  $\geq 102.2^\circ\text{F}$ ) that appears

to be causing distress, give paracetamol oral or rectally, 10–15 mg/kg 4- to 6-hourly.

- Remove by gentle suction under direct observation any thick secretions in the throat which the child cannot clear.
- Ensure daily maintenance fluids appropriate for the child's age, but avoid over-hydration.
- Encourage breastfeeding and oral fluid intake.
- If the child cannot drink, insert a nasogastric tube and give maintenance fluids in frequent small amounts. If the child is taking fluids adequately by mouth, do not use a nasogastric tube, as it increases the risk of aspiration pneumonia. Encourage eating as soon as food can be taken. When the child is recovering, nutritional rehabilitation may be necessary.

### Failure to start to improve within a few days

If the child has not improved after 2 days, or if their condition has worsened, re-examine them thoroughly, looking for signs of pleural effusion/empyema and other causes of fever. If possible, obtain a chest X-ray. This may show a pleural effusion or empyema (see Section 5.3.B) into which antibiotics cannot penetrate, or it may show the characteristic pneumatoceles (lung abscesses) of staphylococcal pneumonia.

Also consider *Mycoplasma pneumoniae* or *Bordetella pertussis* infections. **Pertussis should be recognisable because of the characteristic nocturnal emetic cough and the whoop in the child over 2 years of age.**

Prescribe **erythromycin** if either of these infections is suspected. It should be given orally as follows:

- 125 mg 6-hourly (children aged 1 month to 2 years)
- 250 mg 6-hourly (children aged 2–8 years)
- 500 mg 6-hourly (children over 8 years of age).

### Pneumonia that does not respond to standard antibiotics within 2 weeks

#### Tuberculosis

A child with persistent fever for more than 2 weeks and signs of pneumonia should be evaluated for tuberculosis. If another cause of the fever cannot be found, tuberculosis should be considered and treatment for tuberculosis, following national guidelines, may be initiated and response to anti-tuberculous treatment evaluated (see Section 6.1.N).

### Children who are HIV-positive or in whom HIV is suspected

Some aspects of antibiotic treatment are different in children who are HIV-positive or in whom HIV is suspected. Although the pneumonia in many of these children has the same aetiology as in children without HIV, pneumocystis pneumonia (PCP), often at the age of 4–6 months, is an important additional cause which must be treated when present (see Section 6.2.D). While confirming the diagnosis, give ampicillin plus gentamicin as described above for severe pneumonia.

### Staphylococcal pneumonia

Staphylococcal pneumonia is suspected if there is rapid clinical deterioration despite treatment, a pneumatocele or necrotising pneumonia with effusion on chest X-ray, numerous Gram-positive cocci in a smear of sputum, or heavy growth of *Staphylococcus aureus* in cultured sputum or empyema fluid.

- Treat with cloxacillin (50 mg/kg IM or IV every 6 hours) and gentamicin (7.5 mg/kg IM or IV once a day) for at least 7 days.
- When the child improves, continue cloxacillin/flucloxacillin orally four times a day for a total course of 3 weeks. Note that cloxacillin can be substituted by another anti-staphylococcal antibiotic, such as oxacillin, flucloxacillin or dicloxacillin.

### Severe dehydration

This may be a problem in pneumonia, arising from high fever and poor fluid intake (see also Section 5.12.A for the treatment of diarrhoea and Section 5.5.A for the management of shock).

Look for signs of dehydration or shock (tachycardia, weak pulse, poor peripheral circulation, and capillary refill time prolonged by more than 3 seconds).

- **If the child is shocked:** Site an intravenous line and give a bolus of crystalloid – for example, Hartmann's solution, Ringer-lactate or colloid 10–20 mL/kg (10 mL/kg in a neonate).
- **If the child is not shocked but is clinically dehydrated** (see Section 5.12.A): Give oral rehydration solution (ORS), 15–20 mL/kg/hour for 2 hours orally or via nasogastric tube. Encourage breastfeeding.

### Management of ALRI in special circumstances

#### Management of the child under 6 months of age

Young infants with severe ALRI/pneumonia may not cough, but rather they may present with apnoea, poor feeding or hypothermia. Remember that in infants under 2 months of age, the abnormal respiratory rate cut-off is higher (> 60 breaths/minute). For infants aged 2–12 months the cut-off is > 50 breaths/minute.

- Some chest wall indrawing is normal during REM (dream) sleep.
- **All infants with severe ALRI/pneumonia should be admitted to hospital for treatment.**
- Bronchiolitis is a frequent cause, and usually involves hypoxaemia due to ventilation to perfusion mismatch. Oxygen is usually required. Additional respiratory support (see Section 5.2.A) may also be necessary, especially if there is apnoea or severe respiratory distress leading to exhaustion.
- Grunting (a short expiratory noise at the start of expiration) is **common and usually an indication for oxygen.**
- **Avoid using chloramphenicol in infants under 2 months of age** (there is a risk of development of 'grey baby syndrome'). Use benzylpenicillin or ampicillin plus gentamicin instead.
- Respiratory infection in neonates may rapidly develop into septicaemia, shock and death, so it is essential to act quickly (see Section 3.4).

### 5.3.B Pleural effusion, empyema and bronchiectasis

#### BOX 5.3.B Minimum standards

- Oxygen.
- Pulse oximeter.
- Chest drain.
- Antibiotics.
- Physiotherapy.
- Chest X-ray/ultrasound.

#### Pleural effusion

A pleural effusion is a collection of fluid between the chest wall and the lung. A small effusion of clear fluid is common in children with pneumonia. Effusion should be suspected when one side of the chest sounds very dull to percussion and the breath sounds are very quiet. It can also be seen as usually unilateral shadowing on the X-ray. Usually this fluid will quickly disappear once the infection has been treated. However, if treatment is started late, or the child is unlucky, this clear fluid can become infected, too. This leads to pus accumulating in the chest cavity (an empyema).

On examination, the chest is dull to percussion and breath sounds are reduced or absent over the affected area. A pleural rub may be heard at an early stage before the effusion is fully developed. A chest X-ray shows fluid on one or both sides of the chest.

**An ultrasound examination may be helpful for identifying the size of the effusion and guiding drainage.**

When empyema is present, fever persists despite antibiotic therapy, and the pleural fluid is cloudy or frankly purulent.

#### Treatment

If a pleural effusion is suspected, X-ray the chest if possible. If this confirms your suspicions, perform a diagnostic tap as follows:

- 1 In the case of young children, the child should sit on the mother's lap, facing her. The mother then holds the child tightly in a bear hug. Older children can sit or lie

on a bed, but it is important to explain carefully to them what is being done and have an assistant to hold the child steady.

- 2 Percuss out the area of dullness, put on sterile gloves and clean the skin with alcohol.
- 3 Gently inject some local anaesthetic (1% lidocaine) under the skin, down to the rib, using an orange (25-gauge) or blue (23-gauge) needle.
- 4 Then take a fresh 20-gauge needle or butterfly needle connected to a syringe and press the needle through the chest wall just below the level where the percussion note becomes dull. **Remember to go just above the rib (to avoid the intercostal blood vessels)** and aspirate all the time. Ultrasound support is ideal if available.
- 5 When fluid appears, aspirate a diagnostic specimen and send this for microscopy, protein, glucose, cell count, Gram and Ziehl-Neelsen stain (low yield for acid-fast bacilli), and culture for bacteria and tuberculosis. Remember that a clear fluid aspirate can suggest another diagnosis, such as tuberculosis or lymphoma (especially if bloodstained).
- 6 Aspirate as much fluid as possible during the procedure to allow the child to breathe more comfortably. A three-way tap connected to the catheter can be helpful. **Ensure that air cannot enter the pleural space.** If clear fluid (straw coloured or brown) is aspirated, remove sufficient fluid to relieve distress and then remove the needle.

If more than a few millilitres of fluid containing pus (opaque) are aspirated, and this does not easily pass down the needle, a chest drain will be required. This must be a sterile procedure, and is performed as follows:

- 1 Select a drain, the largest that will comfortably pass through the intercostal space into the cavity by holding the tip of the tube in the forceps. Do not use the stylet, as this can damage the lung.
- 2 Position the child and locate the effusion in the same way as for the diagnostic tap.
- 3 Use sufficient local anaesthetic (1% lidocaine).
- 4 Make an incision in the skin and part the underlying muscle with artery forceps.

**FIGURE 5.3.B.1** Chest X-ray of right-sided empyema. Note that this 5-year-old boy had a 1-week history of fever and shortness of breath. There was dullness to percussion and reduced air entry at the right lung base.

**FIGURE 5.3.B.2** Chest X-ray in the same child after placement of a right-sided chest drain.

- 5 Avoid the neurovascular bundle on the inferior part of the rib by keeping the incision and passage of the drain on top of the rib.
- 6 When the pleura is reached, puncture it with the forceps and thread the chest drain through the pleural hole.
- 7 Ensure that all of the drainage holes of the catheter are inside the chest.
- 8 Fix the drain with a gauze dressing, tape and a suture.
- 9 Connect to an underwater seal. If the drain has been placed correctly, fluid will flow out and the fluid level will 'swing' with respiration.

Give ampicillin or cloxacillin/flucloxacillin 50 mg/kg IV or IM every 6 hours plus gentamicin 7.5 mg/kg IM/IV once daily. After at least 7 days IV/IM antibiotics, and providing the child is improving, continue flucloxacillin/cloxacillin orally 50 mg/kg 6 hourly for a total of 3 weeks from the onset of the antibiotics.

If the patient does not improve despite adequate chest drainage and antibiotics consider HIV and/or TB.

Figures 5.3.B.1 and 5.3.B.2 show the chest X-ray in a child with empyema, and the effect of placing a chest drain.

## Lung abscess

### Diagnosis

A lung abscess is a collection of pus in the lung. This can result from an untreated foreign body, aspiration of other material (e.g. vomit), infection with *Staphylococcus aureus*, or as a complication of bronchiectasis. When examining the child, the findings may be similar to those in the child with pneumonia, though they will often have been ill for longer. A chest X-ray (if available) will be helpful. Ultrasound scanning can show whether the abscess lies close to the posterior chest wall.

### Treatment

Antibiotics are the most important form of treatment, and a long course (4–6 weeks) must be given. Give ampicillin or flucloxacillin/cloxacillin 50 mg/kg IV/IM every 6 hours

plus gentamicin 7.5 mg/kg IM/IV once daily. Continue, as in empyema, for up to 3 weeks. If you are certain that the abscess lies close to the posterior chest wall, it can be aspirated in the same way as an empyema (see above).

**A chest drain must never be placed in a pulmonary abscess, as this can create a fistula.**

Surgical management may be required for a large abscess, especially if haemoptysis or a deterioration despite appropriate antibiotic therapy occur.

If the child has been ill for weeks, ensure good nutrition.

## Bronchiectasis

### Diagnosis

Bronchiectasis occurs when the bronchi become baggy and full of mucus and pus. Bronchiectasis may follow infection such as tuberculosis, pertussis and measles. It may be due to congenital problems such as cystic fibrosis (see Section 5.3.C) and rarer lung diseases in which there are abnormal cilia or abnormal ciliary activity, or an inhaled foreign body that has not been removed (see Section 5.2.C).

Sometimes a child who has had lobar pneumonia does not recover fully, and develops bronchiectasis in the affected lobe. There are other rare causes, such as some viral infections.

Children with bronchiectasis usually cough and produce sputum every day. Their symptoms may become much worse at times due to secondary infection. The child may have finger clubbing, a hyperinflated chest and coarse crackles in many parts of the lung. Look for thickened bronchi and areas of consolidation on the chest X-ray.

### Treatment

Bronchiectasis cannot be cured, although **occasionally symptoms can be improved by removing the lung lobe that is most severely affected.** The child and their parents must understand that daily treatment with chest physiotherapy and frequent courses of antibiotics will be needed. The use of physiotherapy is described in Section 8.3.

## 5.3.C Cystic fibrosis

### BOX 5.3.C.1 Minimum standards

- Diagnostic testing.
- Pancreatic enzyme supplements.
- Fat-soluble vitamins (A, D and E).
- Daily chest physiotherapy.
- Early use of antibiotics, including flucloxacillin, amoxicillin, chloramphenicol, ciprofloxacin, gentamicin and ceftazidime.

## Introduction

### Pathophysiology

In the cells lining the airways of patients with cystic fibrosis (CF), chloride ions cannot leave the cell to enter the bronchial lumen. The cell cytoplasm has a high salt content, and water moves from the airway lumen into the cell by osmosis. The mucus within the lumen then becomes dehydrated.

Sticky mucus interferes with the action of the respiratory cilia, and this leads to bacterial colonisation of the airway, with chronic inflammation and neutrophil damage. There are also viscid secretions in the biliary tract, pancreas and reproductive system, causing poor fat digestion and very low fertility in male patients.

Cystic fibrosis is an autosomal-recessive genetic disorder that affects the lung, digestive system, sweat glands, liver, pancreas and reproductive system. Most deaths from cystic fibrosis are caused by respiratory failure. In well-resourced countries, many patients now survive well into adulthood.

### Incidence

The incidence of cystic fibrosis in countries such as the UK and the USA is around 1 in 2500 live births, and around 1 in 25 of the population are carriers. Very little is known about

the frequency of the disorder in resource-limited countries. Diagnosis relies on the sweat test, which is difficult to perform where laboratory facilities are limited. The incidence of cystic fibrosis among black South Africans is thought to be between 1 in 700 and 1 in 14000, with between 1 in 14 and 1 in 60 of the general population being carriers. In some well-resourced countries there is routine screening of newborn infants from heelprick blood samples.

### The CF gene

The CF gene is on chromosome 7. The commonest mutation causing disease is DF508, and it occurs all over the world. (It is as common in cystic fibrosis patients in North Africa as it is in those in Northern Ireland.) Over 1000 other mutations have been found, many of which are rare. The gene product is a protein which sits on the apical membrane of epithelial cells and regulates the movement of chloride ions. As cystic fibrosis is a recessively inherited condition, two abnormal genes, one from each parent, are required for the disease to occur, and then this protein is defective and chloride transport is disrupted.

### Presentation Meconium ileus

In the newborn period, babies may present with a triad of:

- failure to pass meconium in the first 24 hours
- abdominal distension
- vomiting.

This picture may also occur in surgical conditions (e.g. Hirschsprung's disease, imperforate anus), and any sick newborn infant may develop non-specific abdominal distension. Around 15% of babies with cystic fibrosis present with meconium ileus (i.e. difficulty passing thick, sticky meconium, leading to small bowel obstruction).

### Presentation in older children

This includes the following:

- malabsorption (pale, greasy stools)
- failure to thrive
- rectal prolapse
- chronic and recurrent chest infections
- partially digested material with a high fat content may block the ascending colon (distal intestinal obstruction syndrome).

### Differential diagnosis

The differential diagnosis of chronic cough and failure to thrive includes the following:

- pulmonary tuberculosis
- bronchiectasis (especially following measles, which may also cause chronic diarrhoea)
- HIV infection.

Figure 5.3.C.1 shows a flow diagram for investigation of the child with chronic cough and failure to thrive, in areas where pulmonary tuberculosis and HIV infection are prevalent.

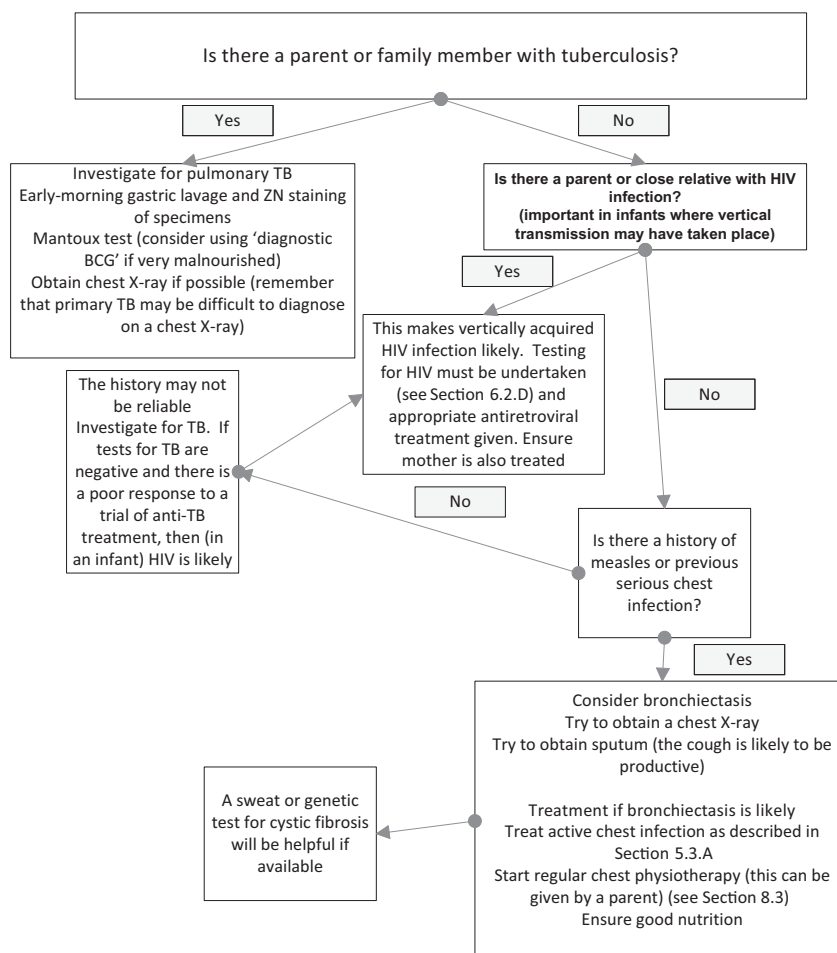

FIGURE 5.3.C.1 Differential diagnosis of the child with chronic cough and failure to thrive.

## Diagnosing cystic fibrosis

### The sweat test

This detects the high levels of chloride and sodium in sweat that occur in cystic fibrosis patients. The principle of the test is to allow pilocarpine to diffuse into the skin of the forearm using an electric current (pilocarpine iontophoresis), which stimulates sweating via cholinergic receptors in sweat glands. The sweat is collected on filter paper and the weight, chloride and sodium concentrations are calculated. At least 100 mg of sweat are needed. Values highly suggestive of cystic fibrosis are concentrations of chloride and sodium of greater than 60 mmol/litre, with a higher concentration of chloride than sodium. False-negative and false-positive results are usually a consequence of faulty test technique, which is why there is a need for a specialised laboratory and experienced technician, which should be available in at least one hospital in every country.

### Genetic tests

These can be performed on very small amounts of blood, collected as a dried blood spot on filter paper. It is possible to send dried blood spots to a genetics laboratory for analysis. A negative genetic test does not rule out cystic fibrosis (only common genes are tested).

## Management

Treatment of children with cystic fibrosis in resource-limited countries has been identified as a priority area by the WHO. For practical reasons, children with cystic fibrosis can be seen regularly in a clinic alongside children with bronchiectasis. It is important that the child's parents understand that cystic fibrosis cannot be cured. However, these children can lead active lives with minimal symptoms initially, provided that daily treatment is given and deteriorations are treated promptly.

### Pancreatic enzyme supplements

Most children with cystic fibrosis will require pancreatic enzyme supplements (e.g. Creon, Solvay Healthcare, or Pancrease, Janssen-Cilag). Young infants are given half a capsule per milk feed. Older children may need over 10 capsules per meal. The capsules contain protease, lipase and amylase. The lipase is the most important component for preventing malabsorption. Most brands contain 5000–10 000 units of lipase per capsule. The correct dose of pancreatic enzyme supplements is not necessarily related to age, but rather it is the amount required to control symptoms of steatorrhoea and achieve normal growth. The maximum dose (expressed as units of lipase) is 10 000 units/kg/day.

### Fat-soluble vitamins

The child should be given extra fat-soluble vitamins. Appropriate doses are vitamin E, 50 mg once daily in infants and young children (aged 0–5 years), 100 mg/day in older children (aged 5–12 years), and 200 mg/day in patients over 12 years of age. Vitamin E may be given as vitamin E suspension 100 mg/mL or as 50 mg tablets. Multivitamin drops, such as Abidec, which contains vitamin A 4000 units/6 mL and vitamin D<sub>2</sub> 400 units/6 mL, are also required.

Abidec should be given as follows:

- 0.3 mL/day for newborn infants

- 0.6 mL/day for infants aged 1–12 months
- 1.2 mL/day for children over 1 year of age.

Remember that an adequate calorie intake is vital. **Do not restrict fat in the diet.**

### Chest physiotherapy

Routine daily chest physiotherapy should be started as soon as the diagnosis is suspected. The most common method is percussion and postural drainage. In young infants this can be performed with the child across their parent's lap, whereas in preschool children a foam 'wedge' helps the child to achieve the correct position for postural drainage. The percussion element of the treatment involves firm 'clapping' movements with the flat of the hand against the child's chest. Older children and teenagers should be encouraged to take a more active part in their physiotherapy. A technique incorporating periods of diaphragmatic breathing followed by a forced expiration or 'huff', causing coughing, is suitable at this age.

(For physiotherapy techniques, see Section 8.3)

### Antibiotics

Children with cystic fibrosis have intermittent or chronic infection with *Staphylococcus aureus* in the first 2 to 3 years of life. *Haemophilus influenzae* is also seen in the early years and should be treated as a pathogen. In most children, chronic infection with *Pseudomonas aeruginosa* becomes established sooner or later. Later still, a variety of opportunistic organisms colonise the lungs. If the results of sputum or 'cough swab' cultures are available, these will allow you to choose an appropriate antibiotic. If not, the likely organisms in the age groups described above will be a rough guide. Ideally, the child's respiratory microorganisms should be monitored on a frequent and regular basis so that the appropriate antibiotic can be given promptly.

### Antibiotic prophylaxis

In well-resourced countries, a continuous prophylactic oral antibiotic is often given to children with cystic fibrosis, up until 2 years of age. An antibiotic active against *S. aureus*, usually flucloxacillin, is chosen. In resource-limited countries this may not be an option, either because the diagnosis is made late or because continuous antibiotics are too expensive. However, flucloxacillin (125 mg twice daily) should be prescribed if possible for children under 2 years of age. Once mucoid *Pseudomonas aeruginosa* has become established, respiratory deterioration occurs, so in well-resourced countries various antibiotic regimes are used to reduce the bacterial burden in the lungs and slow down lung damage. Oral ciprofloxacin, inhaled nebulised colistin or intravenous ceftazidime and tobramycin are variously used. Up-to-date details on antibiotic treatment for cystic fibrosis can be found on the website of the charity the Cystic Fibrosis Trust ([www.cysticfibrosis.org.uk](http://www.cysticfibrosis.org.uk)).

### Treatment of exacerbations

If the cough worsens or the child produces more sputum, a full course of antibiotics should be started and continued for at least 2 weeks. Longer courses of antibiotics are given than in most other conditions. The following antibiotics are suitable.

**Flucloxacillin****TABLE 5.3.C.1** Oral flucloxacillin doses

Age (years)	Dose	Number of doses/day
< 1 year	125 mg	4
1–6 years	250 mg	4
7–12 years	500 mg	4
> 12 years	500–1000 mg	4

**Amoxicillin or ampicillin****TABLE 5.3.C.2** Oral amoxicillin or ampicillin doses

Age (years)	Dose	Number of doses/day
< 1 year	125 mg	4
1–7 years	250 mg	4
> 7 years	500 mg	4

Flucloxacillin, combined with amoxicillin, has good activity against *S. aureus* and *H. influenzae*.

An alternative is chloramphenicol, which is active against *S. aureus* and *H. influenzae*. Its activity against *P. aeruginosa* is poor. Children with cystic fibrosis may receive many courses of antibiotics in their lifetime, and it is important to limit the number of courses of chloramphenicol that they receive, because of the risk of aplastic anaemia. However, because chloramphenicol is cheap and readily absorbed when given orally, it is justified to use it sparingly in cystic fibrosis. The oral dose of chloramphenicol is 12.5 mg/kg 6-hourly.

If *P. aeruginosa* has been identified in sputum, or infection is suspected, use one of the following antibiotics.

**Gentamicin**

**Dose:** 7.5 mg/kg, once daily for 2 weeks.

**Monitor gentamicin levels if possible. Peak is 5–10 micrograms/mL and trough is < 1 microgram/mL.**

Patients with cystic fibrosis often have more rapid renal clearance and have lower levels for a given dose than other

patients. If possible, combine gentamicin with another antipseudomonal antibiotic, such as ceftazidime.

**Ciprofloxacin****Dose:**

Age < 1 year: 7.5 mg/kg/dose.

Age 1–3 years: 62.5 mg.

Age 3–7 years: 125 mg.

Age 7–12 years: 250 mg.

All age groups should have two doses of ciprofloxacin daily, and a course will last 2 weeks.

**Ceftazidime**

**Dose:** 50 mg/kg, three times daily, given over 30 minutes for 2 weeks.

**Other manifestations and complications of cystic fibrosis**

In addition to those features mentioned above under clinical presentation, the following may occur:

- haemoptysis (not usually a major problem)
- pneumothorax (usually small because of chronic pleural thickening)
- bronchiectasis
- biliary cirrhosis, portal hypertension and oesophageal varices
- diabetes mellitus (requiring insulin)
- infertility (in men)
- women may become pregnant but will need careful management of their chest problems
- 'meconium ileus equivalent' (obstructed bowel occurring in older children)
- arthropathy.

With the best care or in those rare patients with mild disease, survival is possible into the fourth decade. Careful management will improve the quality of life greatly for children in resource-limited countries. Sadly, most patients with cystic fibrosis, in any part of the world, ultimately die of respiratory failure.

## 5.4 Cardiac disorders

### BOX 5.4.A.1 Minimum standards

- Electrocardiograph.
- Chest X-ray.
- Prostaglandin E.
- Oxygen.
- Beta-blockers.

### Introduction

Congenital heart disease occurs in 5–8 in 1000 live births.

Every country should have immediate access to a hospital that can surgically correct the easily curable acquired or congenital heart defects. The reality is very different with more than 90% of countries without access to such facilities.

Investigations or treatments, which are likely to be unavailable or irrelevant in the absence of a specialist cardiac centre are highlighted.

**TABLE 5.4.A.1 Percentage frequency of common congenital heart defects in the UK**

Ventricular septal defect (VSD)	32%
Persistent ductus arteriosus (PDA)	12%
Pulmonary stenosis	8%
Atrial septal defect (ASD)	6%
Coarctation of the aorta	6%
Tetralogy of Fallot	6%
Aortic stenosis	5%
Transposition of the great arteries	5%
Hypoplastic left heart syndrome	3%
Atrioventricular septal defect (AVSD)	2%

Cardiac defects may present as any of the following:

- cyanosis in the newborn period
- cyanosis in the older infant
- cardiovascular collapse in the newborn period
- cardiac failure in infancy
- an asymptomatic murmur.

This section explains how to recognise the presence of congenital heart disease in each of these clinical scenarios, and provides enough information to make a working diagnosis. Management decisions can then be made when modern imaging techniques are not immediately available.

### The cyanotic newborn

#### Is there a cardiac problem?

When a child is referred as a 'blue baby', first check to see whether there is genuine central cyanosis. Examine the lips and tongue for blue discoloration, and confirm the clinical impression by measuring the oxygen saturation (less than 94% is abnormal). If there is central cyanosis this may have a cardiac or respiratory cause.

**TABLE 5.4.A.2 Features that distinguish cardiac from respiratory cyanosis in the neonate**

Cardiac cyanosis	Respiratory cyanosis*
Mild tachypnoea but no respiratory distress	Respiratory distress
May have cardiac signs on examination	Chest X-ray: abnormal lung fields
Arterial blood gas: $pO_2 \downarrow$ , $pCO_2 \downarrow$ or normal	Arterial blood gas: $pO_2 \downarrow$ , $pCO_2 \uparrow$ or normal
Fails hyperoxia test	Passes hyperoxia test

\*A respiratory cause for cyanosis is more likely in infants born preterm.

The hyperoxia test is performed as follows:

- 1 Ensure that there is good IV access.
- 2 Monitor oxygen saturations continuously.
- 3 Give 100% oxygen for 10 minutes.
- 4 Take an arterial blood gas sample in the right arm (preductal).
  - If  $pO_2$  is lower than 20 kPa (150 mmHg), a cardiac cause of cyanosis is likely (the test is 'failed').
  - If  $pO_2$  is higher than 20 kPa, a respiratory cause of cyanosis is likely (the test is 'passed').
  - Although pulse oximetry cannot reliably be used in place of an arterial blood gas, a resting saturation of less than 80% and a saturation of less than 90% after 10 minutes in 100% oxygen suggests cyanotic heart disease requiring early intervention.
  - **Note: Oxygen administration could cause closure of the arterial duct, precipitating profound hypoxaemia in some types of cyanotic congenital heart disease.**
  - Prostaglandin E (which opens the duct) should therefore be available at the time of the test and should be given if oxygenation deteriorates.

Persistent pulmonary hypertension of the newborn (PPHN) may often mimic cyanotic heart disease using these clinical criteria. However, PPHN is usually distinguished by a history of fetal distress, resuscitation is often needed at birth, and there may be neurological signs. Improvements

in oxygenation may be possible after intubation and ventilation, and saturations in the right arm may be significantly higher than those in the feet, suggesting right-to-left shunting across the arterial duct.

### What type of cardiac defect is present?

Cyanotic cardiac defects can be divided into three broad categories, as described below.

Once cyanotic congenital heart disease is suspected, attempt to place the defect in one of the three categories. This may be done using Table 5.4.A.3, which describes the typical findings in each physiological category. These guidelines assist the clinician but are not infallible, and the nature of the defect is sometimes only clear after echocardiography.

### Cyanotic heart diseases

#### Low pulmonary blood flow

In defects where there is low pulmonary blood flow the physiology is the same regardless of the precise anatomy of the defect. Deoxygenated blood returning from the systemic veins cannot flow through the right side of the heart to the lungs. The pulmonary blood supply is therefore via the arterial duct. The deoxygenated blood from the right side of the heart shunts to the left side of the heart (via either an atrial or a ventricular septal defect), and the left ventricle receives both deoxygenated blood from the right heart and oxygenated blood from the pulmonary venous return. Blood entering the aorta is therefore not fully oxygenated, and the child appears cyanosed. If the duct closes, the infant becomes profoundly cyanosed and is unlikely to survive unless pulmonary blood flow is rapidly restored. This is **duct-dependent pulmonary circulation**, an example of which is shown in Figure 5.4.A.1.

**FIGURE 5.4.A.1** The circulation in pulmonary atresia with intact ventricular septum. PDA, patent ductus arteriosus; Ao, aorta; PA, pulmonary artery; LA, left atrium; LV, left ventricle; RV, right ventricle; RA, right atrium.

### Complete transposition of the great arteries (TGA)

Here the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle (see Figure 5.4.A.2). Systemic venous return enters the right side of the heart and is recirculated to the systemic arteries. Pulmonary venous return enters the left side of the heart and is recirculated to the lungs. Oxygenated blood and deoxygenated blood are therefore separated in two parallel circuits. Oxygenated blood enters the systemic circulation only when there is mixing between the two circuits. Mixing occurs at atrial level (across the foramen ovale) and at ductal level (while

**FIGURE 5.4.A.2.** Transposition of the great arteries. For explanation of abbreviations, see legend to Figure 5.4.A.1.

**FIGURE 5.4.A.3** The circulation in double-outlet left ventricle. For explanation of abbreviations, see legend to Figure 5.4.A.1.

the duct remains open). Systemic oxygen saturation reflects the amount of mixing (which in turn depends on the size of these communications). If the atrial communication is small, oxygenation may therefore be duct dependent.

### Common mixing lesions

In common mixing lesions, oxygenated pulmonary venous blood and deoxygenated systemic venous blood mix in one of the cardiac chambers. An example is shown in Figure 5.4.A.3. The systemic output is therefore only partly oxygenated. The relative amounts of pulmonary and systemic

blood in the mixture determine the oxygen saturation and the mode of presentation. If pulmonary blood flow is high, cyanosis is minimal, and the child usually presents at about 2 months of age in heart failure. If pulmonary blood flow is low (the complex lesion may coexist with pulmonary stenosis), cyanosis is severe and is often detected early.

Once the defect has been placed in one of these categories, immediate management decisions can be made. Although it is not imperative to reach a more specific diagnosis, an anatomical diagnosis can sometimes be made using clinical information and simple investigations.

**TABLE 5.4.A.3 Features that help to distinguish the three types of cyanotic congenital heart defect**

	Low pulmonary blood flow	Complete TGA	Common mixing lesion
pO <sub>2</sub> at rest	Often ≤ 35 mmHg	Often ≤ 35 mmHg	Often ≥ 45 mmHg
SaO <sub>2</sub> at rest	< 80%	< 80%	80–90%
pO <sub>2</sub> hyperoxia test	Often ≤ 50 mmHg	Often ≤ 50 mmHg	75–200 mmHg
SaO <sub>2</sub> hyperoxia	< 90%	< 90%	90–100%
Chest X-ray	Reduced pulmonary vascular markings	Normal or increased pulmonary vascular markings with or without narrow mediastinum	Normal or increased pulmonary vascular markings

**TABLE 5.4.A.4 Conditions with low pulmonary blood flow**

Critical pulmonary stenosis
Pulmonary atresia with intact ventricular septum
Tetralogy of Fallot (with severe right ventricular outflow tract obstruction)
Pulmonary atresia with ventricular septal defect
Absent right atrioventricular connection

### **Pulmonary atresia with intact ventricular septum and critical pulmonary stenosis**

These two conditions are similar pathologies with either complete or almost complete closure of the pulmonary valve. Both are often associated with hypoplasia of the right ventricle. There is either no murmur or a soft murmur at the lower left sternal border (tricuspid regurgitation). The chest X-ray usually shows a normal heart size. The precordial leads on the ECG usually show decreased right ventricular voltages (small R waves in leads V1 and V2) and dominant left ventricular voltages (prominent S waves in leads V1 and V2 and prominent R waves in leads V5 and V6).

### **Tetralogy of Fallot and pulmonary atresia with ventricular septal defect**

These two pathologies are also similar, but in Fallot's tetralogy the right ventricular outflow tract is patent, albeit narrow, generating a high-pitched ejection systolic murmur at the upper left sternal border. In both defects, the cardiac silhouette on the chest X-ray has a concavity on the left heart border where there is usually a convexity produced by the right ventricular outflow tract and pulmonary artery. The ECG shows dominant right ventricular voltages (normal neonatal RS progression).

### **Absent right atrioventricular connection (also known as tricuspid atresia)**

There is often a long harsh systolic murmur (this may arise from a restrictive ventricular septal defect or pulmonary stenosis). The precordial leads on the ECG show decreased

right ventricular voltages and dominant left ventricular voltages. The QRS axis is characteristically directed to the left and superiorly between 0 and –90 degrees.

### **Complete transposition of the great arteries**

There is usually no murmur. The ECG shows dominant right ventricular voltages (normal neonatal RS progression). Therefore, if a newborn is severely cyanosed and otherwise appears clinically normal, actively look for a narrow mediastinum on the chest X-ray to help to make the diagnosis.

### **Management of defects with low pulmonary blood flow or complete TGA**

- Do not give oxygen after the hyperoxia test, as it may precipitate ductal closure.
- Start IV prostaglandin E (PGE) to maintain ductal patency. There are two formulations, namely prostaglandin E1 (PGE1) and prostaglandin E2 (PGE2). Commence PGE1 at 25 nanograms/kg/minute or PGE2 at 5 nanograms/kg/minute.
- PGE infusion is made up by adding 30 micrograms/kg of prostaglandin to 50 mL of 5% dextrose (if the pump runs at 1 mL/hour this is equivalent to 10 nanograms/kg/minute).
- If saturations are initially very low and fail to improve 10 minutes after starting PGE, intubate and ventilate the baby in air and increase the PGE dose to 50 nanograms/kg/minute. The dose can be increased further to a maximum of 100 nanograms/kg/minute if there is still no response. Prostaglandin sometimes causes vasodilation, so fluid boluses may be required at high doses of PGE in order to maintain blood pressure.
- PGE often causes hypoventilation and apnoea (particularly at doses of PGE2 above 10 nanograms/kg/minute). If oxygen saturations initially improve with PGE and then start to fall, assess respiratory effort. If respiration is shallow or slow, intubate and ventilate in air.
- If oxygen saturations start to fall after PGE is started, and respiratory effort appears adequate, increase the

PGE dose stepwise until a response is seen. At doses over 10 nanograms/kg/minute watch very carefully for hypoventilation.

- Arrange for an urgent paediatric cardiology review and transfer the child to a cardiac centre.
- Defects with poor pulmonary blood flow usually require a systemic to pulmonary artery shunt (modified Blalock–Taussig shunt) to provide a stable pulmonary blood supply. Where special interventional expertise is available it may be possible to implant a coronary stent in the duct to maintain patency and avoid surgery.
- TGA often requires enlargement of the interatrial communication by balloon atrial septostomy, followed by an arterial switch operation if surgical expertise is available.
- For critical pulmonary valve stenosis or pulmonary atresia, early intervention to open the pulmonary valve is required. This can be done by the transcatheter route if interventional expertise is available.

#### Management of common mixing lesions

- Monitor the child on the neonatal unit.
- Arrange for an echocardiogram as soon as possible to define the anatomy.
- If oxygen saturations fall progressively to less than 70%, commence PGE and arrange for an urgent paediatric cardiology review.
- Once the anatomy is defined it may be possible to discharge the baby without further treatment (after paediatric cardiology advice has been obtained).

### The older infant with cyanosis

#### Is there a cardiac problem?

When an older infant presents with cyanosis, cardiac pathology is likely if:

- Respiratory distress is not severe.
- There is no carbon dioxide retention.
- Respiratory pathology is not evident on the chest X-ray.
- The cardiovascular examination is abnormal (see below).

#### What type of cardiac defect is present?

The cyanotic defects that commonly present after the neonatal period are tetralogy of Fallot and cyanotic defects with high pulmonary blood flow. They may escape detection at birth because cyanosis is initially only mild. In tetralogy of Fallot, there is right ventricular outflow tract obstruction and a large ventricular septal defect (VSD) (right ventricular hypertrophy and aortic override are the other components of the tetralogy). The right ventricular outflow tract obstruction limits blood flow to the pulmonary arteries, causing deoxygenated blood to shunt right to left across the VSD, resulting in cyanosis. With time, the right ventricular outflow tract obstruction usually becomes more severe, causing further reductions in pulmonary blood flow, more right to left shunting, and increasing cyanosis.

#### Cyanotic defects with high pulmonary blood flow

In cyanotic defects with high pulmonary blood flow (mostly common mixing defects), pulmonary flow increases as pulmonary vascular resistance decreases over the first few weeks of life, resulting in progressively worsening cardiac failure.

**TABLE 5.4.A.5 Cyanotic defects with high pulmonary blood flow**

Truncus arteriosus
Total anomalous pulmonary venous connection
Double-outlet left ventricle
Absent right atrioventricular connection with large ventricular septal defect (tricuspid atresia)
Pulmonary atresia with large or multiple aorto-pulmonary collateral arteries
TGA with large ventricular septal defect

#### Findings in defects with high pulmonary blood flow

- May present with cardiac failure at 2–6 weeks of age.
- Active praecordium.
- Murmur usually present (may be systolic, diastolic or continuous).
- Increased pulmonary vascular markings on chest X-ray.

#### Management of cyanotic defects with high pulmonary blood flow

Define the anatomy by echocardiography. Manage cardiac failure medically (see Section 5.4.B). Surgical correction or pulmonary artery banding will be necessary in most cases.

#### Findings in tetralogy of Fallot

- May present with increasing cyanosis.
- May present with an ejection systolic murmur at the upper left sternal border.
- Reduced pulmonary vascular markings on chest X-ray, and concavity on the left heart border where there is usually a convexity produced by the right ventricular outflow tract and pulmonary artery.
- Children are often asymptomatic, but there may be sudden periods of increased cyanosis known as hypercyanotic spells.

#### Characteristics of hypercyanotic spells

- Spells often occur on waking from sleep or after feeding.
- The infant becomes restless and agitated.
- There is increased cyanosis and pallor.
- Respiration is often rapid and shallow.
- In severe spells, crying is followed by limpness or loss of consciousness.
- Spells usually last 1–5 minutes, but may last longer when severe.
- The ejection systolic murmur shortens or becomes inaudible.

#### Management of tetralogy of Fallot

The anatomy should be confirmed by echocardiography, preferably within a few weeks of presentation, and surgical correction should be carried out between 6 and 12 months of age (although it can be carried out later).

**Hypercyanotic spells may be life-threatening. If a child starts to have such spells, discuss this with a paediatric cardiologist immediately, as it is an indication for urgent surgery.**

If hypercyanotic spells are more than a few minutes in duration, treat them urgently as follows:

- Knee–chest position.
- Give oxygen by face mask.
- Give an IV bolus of Ringer–lactate or Hartmann’s solution

10–20 mL/kg, as during spells children are often relatively hypovolaemic.

- Give IV or IM morphine, 100 microgram/kg (or IV ketamine 1 mg/kg).
- Give IV propranolol at an initial dose of 20 micrograms/kg with a maximum of 100 micrograms/kg (have isoprenaline ready in case of excessive β-blockade).
- Adrenaline may make spells worse.
- General anaesthesia and artificial ventilation are needed in intractable cases.
- If cyanosis persists, consider an emergency aorto-pulmonary shunt.

### Neonatal cardiovascular collapse

#### Is there a cardiac problem?

When a child presents in shock in the first month of life, the working diagnosis is often dehydration or sepsis. The following features help to distinguish cardiac causes of poor systemic output from non-cardiac causes:

- collapse in the first 2 weeks of life
- poor feeding, lethargy and tachypnoea prior to collapse
- hepatomegaly
- pulmonary oedema and cardiomegaly on chest X-ray
- lack of response to intravascular volume expansion.

#### What type of cardiac defect is present?

Left heart obstruction is the most likely cardiac cause of cardiovascular collapse with low systemic output in the first 2 weeks of life:

TABLE 5.4.A.6 Left heart obstruction

Critical aortic stenosis
Hypoplastic left heart syndrome (HLHS)
Coarctation of the aorta
Interrupted aortic arch

FIGURE 5.4.A.4 Hypoplastic left heart. For explanation of abbreviations, see legend to Figure 5.4.A.1.

### Hypoplastic left heart syndrome

In hypoplastic left heart syndrome all of the left heart structures are small (see Figure 5.4.A.4). There is insufficient forward flow through the left ventricle and the aortic valve to support the systemic circulation. Pulmonary venous return cannot pass through the left heart, so it crosses the atrial septum and enters the right atrium, mixing with systemic venous return. Mixed pulmonary and systemic venous blood enters the right ventricle and is pumped to the pulmonary arteries and also across the arterial duct to supply the systemic circulation. Ductal flow passes to the descending aorta and retrogradely around the aortic arch to supply the head and neck vessels and the coronary arteries. Ductal flow is not fully oxygenated, so there is a degree of central cyanosis. When the duct closes, the cardiac output falls precipitously, the infant becomes shocked, and cardiac failure develops. This is duct-dependent systemic circulation. The haemodynamics are the same in **critical aortic stenosis**.

### Coarctation of the aorta

Coarctation of the aorta consists of a narrowing in the descending aorta close to the aortic end of the arterial duct. Contractile tissue may extend from the duct into the aorta so that when the duct closes it draws in the adjacent section of aorta, causing obstruction. Flow to the head and neck vessels is maintained, but flow to the lower body distal to the coarctation site is dramatically reduced. The infant becomes shocked and acidotic. Cardiac failure develops secondary to high systemic afterload. This is also an example of the systemic circulation depending on ductal patency (although systemic blood flow may not directly depend on a right-to-left shunt through the duct). In **interrupted aortic arch**, perfusion to the lower part of the body depends on right-to-left ductal flow and presentation is similar to that with coarctation.

The following features help to distinguish between the lesions:

- If all of the pulses are weak or absent, consider HLHS or critical aortic stenosis.
- If the right arm pulses are palpable and the femoral pulses are weak or absent, consider coarctation or interrupted aortic arch (note, however, that all pulses may initially be impalpable if the cardiac output is poor).
- If four limb blood pressures demonstrate significantly lower blood pressures in the legs than in the right arm (a gradient of more than 20 mmHg), consider coarctation or interrupted aortic arch.
- Coarctation often presents towards the beginning of the second week of life.
- HLHS often presents in the first 2 days of life.
- In HLHS, the ECG shows reduced left ventricular voltages (small R waves in leads V5 and V6).

Other cardiac causes of cardiovascular collapse in the first few weeks of life are supraventricular tachycardia (SVT) (see Section 5.4.C) and cyanotic congenital heart disease with duct-dependent pulmonary blood flow (when the duct closes, the ensuing profound hypoxaemia causes acidosis and cardiovascular collapse). SVT should be evident on the ECG and cyanotic heart disease should be suspected when the oxygen saturation remains low after instituting the management described below for left heart obstruction.

### Emergency management of low systemic output secondary to left heart obstruction

- 1 Check the ECG (to exclude SVT as a cause of collapse).
- 2 Obtain peripheral IV access if not already established (if IV access is difficult, intra-osseous access should be obtained).
- 3 Give a fluid bolus of 10 mL/kg Ringer-lactate or Hartmann's solution if not already given.
- 4 Intubate and ventilate if there is significant respiratory distress (high PEEP, 8–10 cmH<sub>2</sub>O).
- 5 Once ventilated, commence prostaglandin E<sub>1</sub> or E<sub>2</sub> at 100 nanograms/kg/minute (give for 30 minutes, then reduce to 25 nanograms/kg/minute, reducing again to 10 nanograms/kg/minute when stabilised). If the initial clinical condition is not poor, commence PGE<sub>2</sub> at a lower dose of 10 nanograms/kg/minute, which should avoid PGE-related apnoea and the need for ventilation.
- 6 Admit the child to the paediatric ICU.
- 7 Check blood sugar levels, full blood count, urea and electrolytes, coagulation, calcium levels and magnesium levels, and correct abnormalities.
- 8 Take blood cultures and treat with IV antibiotics, as sepsis cannot be excluded.
- 9 Check arterial blood gas (using the right arm if possible).
- 10 Give IV furosemide 1 mg/kg if the chest X-ray shows pulmonary oedema.
- 11 Insert central venous access and an arterial line.
- 12 Reassess whether further intravascular volume is needed (give if the central venous pressure is low).
- 13 Give dopamine 5–10 micrograms/kg/minute if perfusion remains poor or the blood pressure remains low.
- 14 Give adrenaline 0.1–0.2 micrograms/kg/minute if perfusion remains poor or the blood pressure remains low (by central venous access only).
- 15 If acidosis is profound and not improving with other measures, give IV sodium bicarbonate 4.2%.
- 16 Ask for an urgent paediatric cardiology review and advice.

### Asymptomatic murmurs

When a child presents with an asymptomatic murmur, first examine them for cyanosis and measure the oxygen saturation. If there is desaturation, refer the child for an echocardiogram, as cyanotic congenital heart disease requires a detailed anatomical assessment. Tetralogy of Fallot is the most likely diagnosis. If cyanosis is excluded, the child may have an innocent cardiac murmur or one of the following defects.

TABLE 5.4.A.7 Initially asymptomatic heart lesions

Left-to-right shunts	Left or right heart obstruction
Small to moderate-sized VSD	Pulmonary stenosis
Small to moderate-sized PDA	Aortic stenosis
Atrial septal defect (ASD)	Coarctation of the aorta
Partial AVSD	

Innocent murmurs are characterised as follows:

- The Still's murmur is a vibratory short systolic murmur heard at the lower left sternal border or apex.
- The venous hum is a soft continuous murmur heard

best below the clavicles, and is abolished by pressure over the jugular vein or lying down with the neck flexed.

- The pulmonary flow murmur is a soft ejection systolic murmur at the upper left sternal border, and may be confused with an ASD or mild pulmonary stenosis.
- The neck bruit is an ejection systolic murmur that is maximal above the clavicle and may be confused with aortic stenosis.

The cardiac defects are characterised as follows:

- In **coarctation**, the right arm blood pressure is often elevated, the femoral pulses are weak or impalpable, and there is brachiofemoral delay.
- The **patent ductus arteriosus (PDA)** has a continuous murmur that is loudest in the left infraclavicular region.
- The **ventricular septal defect (VSD)** has a harsh pansystolic murmur that is loudest at the lower left sternal border radiating to the lower right sternal border.
- **Aortic stenosis, pulmonary stenosis, atrial septal defect (ASD) and partial atrioventricular septal defect (AVSD)** all have an ejection systolic murmur at the upper left sternal border.
  - In **aortic stenosis** the ejection systolic murmur is harsh and may be heard at the upper right and left sternal border. The murmur radiates to the carotid arteries and there is often a carotid thrill. There may be an ejection click at the apex if the stenosis is at valvar level.
  - In **pulmonary stenosis**, the ejection systolic murmur is harsh and radiates to the back. There may be an ejection click along the left sternal border if the stenosis is at valvar level.
  - In an **atrial septal defect (ASD)** there is a soft ejection systolic murmur at the upper left sternal border from increased flow across the pulmonary valve. There is sometimes a fixed widely split second heart sound, and there may be a mid-diastolic murmur at the lower left sternal border (from increased flow across the tricuspid valve) when the left-to-right shunt is large.
  - In **partial atrioventricular septal defect (AVSD)** there is an abnormal atrioventricular valve and a defect in the atrial septum. There may be a blowing pansystolic murmur at the lower left sternal border or apex from atrioventricular valve regurgitation. The ejection systolic murmur may mimic an ASD, but the defect is distinguished by a superior QRS axis on the ECG.

Unless the murmur is clearly innocent, perform an ECG and chest X-ray.

Right ventricular hypertrophy (RVH) is indicated by an R wave in lead V1 > 98th centile for age (≥ 20 mm is always abnormal), a neonatal RS progression beyond the neonatal period (dominant R waves in lead V1 and dominant S waves in lead V6) or an upright T wave in lead V1 before the teenage years.

Left ventricular hypertrophy (LVH) is indicated by T inversion in leads V5 and V6, loss of the Q wave in lead V6 or the amplitude of the R wave in lead V6 plus S wave in lead V1 > 98th centile for age (≥ 50 mm is always abnormal). RVH may indicate significant right heart obstruction or high pulmonary artery pressure (secondary to a large left-to-right shunt or pulmonary vascular disease). LVH may indicate significant left heart obstruction. Cardiomegaly and

increased pulmonary vascular markings on the chest X-ray may indicate a large left-to-right shunt.

Any child who is thought to have an anatomical defect on the basis of the clinical examination, or any child with an abnormal ECG or chest X-ray, should if possible be referred to a paediatric cardiologist for an echocardiogram and opinion. If there is evidence of a significant left-to-right shunt (see Section 5.4.B) in a VSD or PDA, the referral should be as soon as possible, as there is still a risk of pulmonary vascular disease even when the child does not present in heart failure.

### Rheumatic fever

For the diagnosis and treatment of rheumatic fever, see Section 5.13.

### Long-term consequences of rheumatic fever

After an attack of acute rheumatic fever there may be permanent valve damage. Rheumatic heart disease occurs when acute valve inflammation is followed by scarring and fibrosis, resulting in various degrees of shortening, thickening, rigidity, deformity, retraction and fusion of the valve cusps. The commonest valve lesions are mitral regurgitation, mitral stenosis and aortic regurgitation.

Rheumatic heart disease is most severe and progressive in (1) children who initially have severe carditis in (2) children who have recurrent attacks of acute rheumatic fever. The prognosis is more favourable if recurrences are prevented (residual cardiac disease may disappear or improve and valve damage only worsens in a few cases). It is therefore crucial to maintain continuous antibiotic prophylaxis to prevent further valve damage, particularly as children are prone to develop a recurrence after the initial attack (below).

### Mitral regurgitation

Mitral regurgitation is the commonest valve lesion in children with rheumatic heart disease. Patients are often asymptomatic during childhood as symptoms are caused by left ventricular failure which may take as long as two decades to develop. However, cases may present before adolescence and mitral regurgitation may be rapidly progressive in regions where the incidence of rheumatic fever is high and recurrent rheumatic fever is common. Mitral regurgitation may be diagnosed by the presence of a blowing apical pansystolic murmur radiating to the left axilla. There may also be a third heart sound and a short low frequency mid-diastolic murmur from increased transmitral flow.

Features of severe mitral regurgitation:

- Easy fatigue (caused by low cardiac output)
- Shortness of breath on exertion (caused by pulmonary oedema)
- Hyperdynamic apical impulse and pansystolic murmur
- Apical impulse displaced laterally and inferiorly
- The chest X ray demonstrates cardiomegaly and left atrial enlargement (a double density on the right heart border and elevation of the left main bronchus)
- The ECG demonstrates left atrial enlargement (broad bifid P waves in lead II and a prominent negative component to the P in V1) and left ventricular hypertrophy
- Signs of pulmonary hypertension (see below).

If there are features of severe mitral regurgitation, the child should be urgently referred for a paediatric cardiology opinion as surgery is likely to be necessary. Ideally all children

with mitral regurgitation should be evaluated by echocardiography annually, as progressive left heart dilation may result in irreversible left ventricular dysfunction if referral is delayed until symptoms develop. Medical treatment should be given for heart failure (captopril is particularly useful) but children who are unwell enough to require this often need either a mitral valve repair or a mitral valve replacement with a mechanical valve or bioprosthesis.

### Mitral stenosis

If there is effective antibiotic prophylaxis, mitral stenosis usually develops slowly over 5–10 years and is often not sufficiently severe to cause symptoms in childhood. The reality in countries where there is inadequate prophylaxis and recurrent attacks of rheumatic fever are common is that mitral stenosis may progress much more rapidly and symptoms may be evident 6 months to 3 years after the first attack. Mild stenosis does not cause symptoms, moderate stenosis causes shortness of breath on exertion and severe stenosis causes easy fatigue, shortness of breath at rest, orthopnoea, paroxysmal nocturnal dyspnoea and haemoptysis. Mitral stenosis may be diagnosed by the presence of a low frequency mid-diastolic murmur maximal at the apex. The murmur may be accentuated by exercise and is often accompanied by a loud first heart sound and a diastolic opening snap. The murmur becomes longer as the severity of the stenosis increases. In severe cases there are also signs of pulmonary hypertension.

Signs of pulmonary hypertension:

- Left parasternal heave
- Loud second heart sound
- Early diastolic murmur of pulmonary regurgitation at the upper left sternal border
- Elevated JVP and hepatomegaly if there is right heart failure.

The chest X ray and ECG often show left atrial enlargement when there is moderate mitral stenosis. Radiographic signs of pulmonary oedema may be evident when stenosis is severe. ECG changes of right ventricular hypertrophy and right axis deviation are present when there is pulmonary hypertension. Symptoms should be treated with diuretics and a low-sodium diet. Digoxin is only indicated in rare cases where there is atrial fibrillation secondary to left atrial enlargement. Symptomatic children and children with signs of pulmonary hypertension should be referred for paediatric cardiology review as surgery is often necessary. The options for treatment are open or closed mitral commissurotomy, mitral valve replacement and percutaneous catheter balloon mitral commissurotomy.

### Aortic regurgitation

Aortic regurgitation is less common than mitral regurgitation and frequently occurs in combination with mitral valve disease. Affected children usually remain asymptomatic for many years as symptoms only become evident when left ventricular dysfunction develops secondary to chronic left ventricular volume overload. Severe symptomatic aortic regurgitation may however become established within 1–2 years of the initial attack of rheumatic fever if recurrence is not prevented. Once symptoms appear deterioration is often rapid. Symptoms include exercise intolerance, shortness of breath on exertion and chest pain in a few severely affected cases. Examination reveals a blowing decrescendo

early diastolic murmur maximal at the mid to lower left sternal border. The murmur is loudest sitting forward with the breath held in expiration.

Signs of moderate to severe aortic regurgitation:

- The murmur lengthens and may be throughout diastole
- Hyperdynamic apex
- Apical impulse displaced laterally and inferiorly
- Wide pulse pressure
- Collapsing pulses
- Visible pulsations in the suprasternal notch and neck vessels
- Systolic murmur at the upper right sternal border (from increased aortic valve flow).

If patients are symptomatic or have signs of severe aortic

regurgitation they should be referred for paediatric cardiology assessment as surgery may be necessary. Marked cardiomegaly on the chest X ray or multiple ventricular ectopics on the ECG should also prompt referral. Ideally all children with aortic regurgitation should have an echocardiogram at least annually as it is important to assess left ventricular dilation and function to ensure that surgery is carried out before irreversible left ventricular dysfunction develops. Exercise tolerance may be improved by captopril treatment and medical treatment for heart failure may be necessary in severe cases. Surgical options include aortic valve reconstruction, aortic valve replacement with an aortic homograft or mechanical valve and transferring the patient's own pulmonary valve to the aortic position (Ross procedure).

## 5.4.B The child with heart failure and cardiomyopathy

### BOX 5.4.B.1 Minimum standards

- Electrocardiograph.
- Chest X-ray.
- Furosemide.
- Spironolactone.
- Anticoagulant.

### Introduction

Heart failure occurs when the heart is unable to pump enough blood to meet the metabolic needs of the body. The term is often used to indicate the clinical changes that occur when the cardiac pump cannot meet the workload it is presented with. This may occur either because the pump is weak (due to a primary abnormality of the cardiac muscle) or because the workload imposed on the heart is higher than normal. The latter is the case in congenital heart disease, where heart failure occurs because the heart is pumping against a high resistance (in the case of obstructive lesions) or because it is volume loaded (commonly in left-to-right shunting cardiac lesions).

Left-to-right shunting cardiac defects are the commonest cause of heart failure in infancy identified in well-resourced countries.

In resource-poor countries most heart failure is related either to severe anaemia or to fluid overload when treating infections or severe malnutrition, particularly with IV fluids or during blood transfusion (see below).

### The physiology of left-to-right shunts

A large defect between the ventricles or great arteries allows free communication between the left and right sides of the heart. Left and right heart pressures therefore equalise, and pulmonary artery pressure is maintained at systemic level. The pulmonary vascular resistance then determines the pulmonary blood flow. In the newborn period the pulmonary vascular resistance is high, which limits the pulmonary blood flow and therefore the left-to-right shunt across the defect. Over the first 6 weeks of life, the pulmonary vascular resistance gradually falls, allowing pulmonary blood flow and the left-to-right shunt to increase. This gives rise to heart failure, which usually appears after 4 weeks of age. If the pulmonary

arteries are exposed to high pressure and flow for a prolonged period, pulmonary vascular disease develops. This normally becomes significant between 12 and 18 months of age. High pulmonary vascular resistance secondary to pulmonary vascular disease reduces the left-to-right shunt, and symptoms of heart failure gradually resolve. Eventually, pulmonary resistance becomes so high that flow across the defect becomes right to left, and cyanosis develops (Eisenmenger's syndrome). The pulmonary artery pressure remains high throughout, and it is only the amount of flow through the lungs that changes.

### Is heart failure present?

**TABLE 5.4.B.1** Diagnosis of heart failure secondary to congenital heart disease in infancy

Symptoms	Signs
Easily tired	Failure to thrive
Poor feeding	Tachypnoea
Breathlessness (particularly during feeds)	Increased respiratory effort
Sweaty (particularly during feeds)	Tachycardia > 160bpm
	Sweating
	Pallor
	Hepatomegaly
	Gallop rhythm

### What type of cardiac defect is present?

**Heart failure in the first few weeks of life is a medical emergency.**

The following causes should be considered:

- supraventricular tachycardia
- complete atrioventricular block
- high-output cardiac failure
- left heart obstruction.

Perform an ECG to detect supraventricular tachycardia and heart block. Check the haemoglobin level, as severe anaemia may cause high-output cardiac failure. Also examine the baby for cranial and hepatic bruits, as cranial and hepatic arteriovenous malformations are a potential (although very rare) cause of high-output cardiac failure.

If these tests are negative, refer the child to a paediatric cardiologist, as a left heart obstructive lesion is likely and there may be duct-dependent systemic circulation. Consider the use of prostaglandin to keep the ductus arteriosus open until the referral can be achieved (see Section 5.4.A).

Heart failure in infancy presenting after the first few weeks of life may be caused by any of the following:

- the left-to-right shunting lesions listed in Table 5.4.B.2
- cyanotic congenital heart defects with high pulmonary blood flow
- the same causes that present in the first few weeks of life
- myocarditis or cardiomyopathy.

**TABLE 5.4.B.2 Common left-to-right shunting lesions that cause heart failure**

Large ventricular septal defect (VSD)
Atrioventricular septal defect with large ventricular component (AVSD)
Large persistent ductus arteriosus (PDA)

Examine the child for cyanosis and measure the oxygen saturation. It should be possible to detect those children with cyanotic defects immediately (note, however, that children with AVSD are sometimes mildly desaturated). Next, attempt to detect the children with left-to-right shunts, looking for the following features which are present in significant shunts:

- hyperdynamic precordial impulse
- apical impulse displaced laterally and inferiorly
- apical mid-diastolic murmur (from increased flow across the mitral valve)
- loud second heart sound (from increased pulmonary artery diastolic pressure)
- cardiomegaly and increased pulmonary vascular markings on the chest X-ray
- signs of heart failure and pulmonary oedema on the chest X-ray in severe cases.

If these examination findings are not present and there is no evidence of SVT or a hyperdynamic circulation (see above), a left heart obstructive lesion should be considered. **Some of these are eminently treatable conditions** and if they are suspected the child should be referred for paediatric cardiology review without delay.

**If there is evidence of a large left-to-right shunt, refer the child to a paediatric cardiologist within a few weeks. These signs must not be missed, as a remediable cardiac defect is rendered inoperable by delay.**

Although it is not imperative to make a more specific diagnosis, the following clinical features discriminate between the three most common left-to-right shunts:

- The persistent arterial duct has a continuous murmur that is maximal in the left infraclavicular area.
- A large ventricular septal defect has a quiet pansystolic murmur that is maximal at the lower left sternal border radiating to the lower right sternal border. There may also be a soft ejection systolic murmur at the upper left sternal border from increased flow across the pulmonary valve.
- An atrioventricular septal defect with a large ventricular component may have a blowing pansystolic murmur at the lower left sternal border or apex from atrioventricular

valve regurgitation. The ECG shows a characteristic superior QRS axis (between  $-30$  and  $-180$  degrees).

### Heart failure in later infancy and childhood

In addition to the symptoms seen in early infancy (easily tired, poor feeding, breathlessness particularly during feeds, excess sweating particularly during feeds), older children may have decreased exercise tolerance, shortness of breath on exertion and when lying flat.

The signs of heart failure are cyanosis or  $\text{SaO}_2 < 94\%$ , basal lung crepitations, failure to thrive, tachypnoea  $> 50$  breaths/minute for children aged 2–12 months, tachypnoea  $> 40$  breaths/minute for children aged 12 months to 5 years and the cut-offs for tachycardia are  $> 120$  bpm aged 1–5 years and  $> 100$  bpm after age 5 years.

There is usually increased respiratory effort, sweating, pallor and hepatomegaly.

In older children the hepatomegaly may be tender, a gallop rhythm may be heard and a raised jugular venous pressure may be observed.

In addition to the congenital heart defects described in Section 5.4.A the following causes of heart failure should be considered:

- Severe anaemia
- Severe malnutrition
- Excessive intravenous fluids
- Rheumatic fever
- Myocarditis
- Cardiomyopathy
- Infective endocarditis
- Constrictive pericarditis (rare and most often caused by tuberculosis) (see Section 6.1.N).

Anaemia is a common and often severe problem in poorly resourced settings (see Section 5.11.A). When the haemoglobin falls below 7 g/dl cardiac output must increase to maintain oxygen delivery and heart failure frequently develops with a haemoglobin  $< 5$  g/dl). The treatment is careful blood transfusion, but the increase in intravascular volume may precipitate worsening heart failure. Blood must therefore be infused slowly in small boluses and an exchange transfusion may be needed if there is clinical deterioration. Furosemide 1 mg/kg IV may be given during transfusion (see Section 5.11.A).

Protein-calorie malnutrition is also an important cause of cardiac failure in disadvantaged countries (see Section 5.10.B) with specific contributions from certain vitamin deficiencies (see Section 5.10.A). Although cardiac failure is unusual at presentation, it may occur after several days of refeeding. Rapid refeeding can cause a hypermetabolic state, demanding an increase in cardiac output which cannot be met by the malnourished heart which has a decreased cardiac reserve. The problem is exacerbated by coexisting anaemia, blood transfusion, inappropriate intravenous fluid administration and high sodium diets.

The other common causes of cardiac failure are dealt with individually in the sections below.

### Management of heart failure

Monitor heart and respiratory rates, respiratory distress and oxygenation regularly during treatment of acute heart failure. It is necessary to both control the symptoms of failure and to determine and treat the underlying cause.

- Treat severe anaemia if present, be careful with IV fluids and ensure adequate nutrition.
- Nasogastric feeding if there is inadequate oral intake.
- For older children nurse sitting up with legs dependent
- Treat hypoxaemia with oxygen to keep SaO<sub>2</sub> > 94%.
- In an emergency where there is pulmonary oedema, give furosemide 1 mg/kg IV which should produce a diuresis within 2 hours. If the initial dose is ineffective, give 2 mg/kg IV and repeat after 12 hours if necessary.
- For chronic heart failure give oral furosemide 1 mg/kg once a day, twice a day or three times a day.
- Spironolactone 1 mg/kg once a day or twice a day in combination with furosemide, matching the dose frequency, to enhance diuresis and prevent furosemide-related hypokalaemia.
- If furosemide is used without spironolactone, oral potassium 3–5 mmol/kg/day, should be given (supplemental potassium is not required if furosemide is given for less than 4 days).

If more than twice daily diuretics are required, consider using captopril. Captopril should be commenced in hospital with a 100 microgram/kg test dose. The dose should then be increased gradually over a number of days 100–300 microgram/kg 2–3 times a day to a maximum total dose of 4 mg/kg daily. After the test dose and each increment monitor the blood pressure carefully, as hypotension is common. Reduce the dose if significant hypotension occurs. Monitor urea and electrolytes daily while building up the dose, as renal failure is a well-recognised side effect. Stop spironolactone when the captopril dose is greater than 500 micrograms/kg per day as both drugs cause potassium retention. Do not give captopril if there is left heart obstruction.

### Cardiomyopathy and myocarditis

Myocarditis and dilated cardiomyopathy both cause impairment of myocardial contractility. This results in a dilated poorly functioning heart. Children present with heart failure, sometimes in association with shock. They may also more rarely present with ventricular arrhythmias.

The unexpected onset of heart failure in a previously well child should suggest the diagnosis. However, in the first 3 months of life, heart failure associated with cardiomegaly is more likely to be caused by congenital heart disease than by heart muscle disease. Echocardiography is therefore particularly important in this age group, to discriminate between the two potential causes of heart failure.

In addition to the features of heart failure listed earlier in Table 5.4.B.1, signs may include lateral displacement of the apex beat and an apical pansystolic murmur from mitral regurgitation. The chest X-ray often demonstrates cardiomegaly. It is not essential to identify whether the child has cardiomyopathy or myocarditis, as the management of both conditions is the same. However, the latter may be suggested by a preceding viral illness or evidence of acute myocardial damage with elevated blood levels of creatinine kinase or troponin. Myocarditis may be confirmed by identifying enterovirus by polymerase chain reaction (PCR) or serology.

In most cases, the cause of the cardiomyopathy remains unknown. However, it is important to perform a 12-lead ECG in all cases of cardiomyopathy, as it may reveal two

particular conditions that are reversible causes of poor heart function:

- Incessant tachyarrhythmias may cause cardiomyopathy. In cardiomyopathy there is often sinus tachycardia, which appears on the ECG as a heart rate faster than that expected for the child's age, with each QRS complex being preceded by a P wave that is positive in both lead I and lead aVF. If the QRS complexes are not preceded by P waves, or P-wave morphology is unusual, the rhythm is not sinus rhythm and a tachyarrhythmia must be suspected. Sometimes the tachyarrhythmia heart rate is only marginally higher than that expected for the child's age, but many months of mild tachycardia have resulted in poor function. If the arrhythmia is successfully controlled with anti-arrhythmic drugs or radiofrequency ablation, the heart function should normalise.
- Anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA) presents with severely impaired cardiac function at around 3 months of age. The ECG will show transmural anterolateral myocardial infarction in most cases. If the coronary artery is reimplanted in the aortic root the function will usually recover.

Post-intervention management is aimed at supporting the heart while function spontaneously recovers. It includes the following:

- Furosemide and spironolactone (see above, under heart failure)
- Captopril (see above, under heart failure)
- Digoxin:
  - 5 micrograms/kg orally twice a day (in children under 5 years old).
  - 3 micrograms/kg orally twice a day (in children over 5 years old).
  - Plasma levels should be in the range 0.8–2.0 micrograms/litre (check the level after 5 days, and at least 6 hours after giving a dose).
- Aspirin 3–5 micrograms/kg once a day if function is poor, to prevent thromboembolism.
- Anticoagulation if cardiac function is very poor:
  - Heparin IV, initially 20 U/kg/hour, titrated to APTT 2–3 times normal.
  - Warfarin if anticoagulation is needed long term.
- Intubation and ventilation if pulmonary oedema is severe.
- Inotropic support (dobutamine 5–10 micrograms/kg/minute, dopamine 5–10 micrograms/kg/minute, milrinone maximum dose of 0.7 micrograms/kg/minute). Ventilation and inotropic drugs should be a last resort if the child is deteriorating despite other measures, as it can be difficult to wean them off intensive care support once these steps are taken.
- Once the child is stabilised, introduce carvedilol at a dose of 50 micrograms/kg (maximum dose 3.125 mg) twice a day, doubling the dose at intervals of at least 2 weeks up to an upper limit of 350 micrograms/kg (maximum 25 mg) twice a day. Use echocardiography to check that cardiac function has not deteriorated before each dose increment, and monitor blood pressure for 4 hours after every dose increment. Carvedilol promotes myocardial remodelling.

### Bacterial endocarditis

Endocarditis should always be suspected in a child with

a cardiac defect when there is a fever without a focus. Infection develops on injured areas of endothelium or on abnormal or damaged heart valves. In some cases the onset may be sudden with obvious signs of sepsis and cardiac failure (secondary to valve damage). However, in most cases the onset is insidious and the diagnosis is unclear. There may be fever, malaise, fatigue, arthralgia, anorexia and weight loss. It may occur in a child previously thought to have a normal heart but with an undiagnosed congenital heart defect or undiagnosed episode of rheumatic fever.

Signs of endocarditis:

- Pyrexia
- Microscopic haematuria
- Splenomegaly
- Changing heart murmur
- Petechiae
- Neurological abnormalities (caused by cerebral abscess or infarction)
- Splinter haemorrhages, Janeway lesions, Osler's nodes and Roth's spots (characteristic but rare).

The diagnosis is made by isolating bacteria from the blood. At least three sets of blood cultures must be obtained from different puncture sites. If possible, antibiotics should be withheld until multiple blood cultures have been obtained and should only be started when the diagnosis is clear or there is a pressing clinical urgency. Blood cultures will be

negative in 10–15% of cases. Echocardiography helps to make the diagnosis if vegetations are seen, but a negative echocardiogram does not exclude the diagnosis.

Organisms most commonly isolated in endocarditis:

- *Streptococcus viridans* (commonest overall)
- *Staphylococcus aureus* (most cases of fulminant endocarditis)
- Coagulase-negative staphylococci (if the patient has a central venous line or is immunocompromised e.g. with HIV).

If the organism is *Streptococcus viridans*, IV benzylpenicillin 25 mg/kg 6 hourly and gentamicin 7.5 mg/kg once daily are given for two weeks, followed by a further two weeks of oral amoxicillin. If the organism is *Staphylococcus aureus*, IV flucloxacillin 25 mg/kg 6 hourly is given for 4 weeks, coupled with IV gentamicin 7.5 mg/kg once daily (or sodium fucidate) 6–7 mg/kg 8 hourly for the first two weeks. Vancomycin 10 mg/kg 6 hourly is used in place of flucloxacillin if the organism is a coagulase negative *Staphylococcus* or the patient is allergic to penicillin.

The effectiveness of treatment is monitored by symptoms and inflammatory markers (WBC, ESR and CRP).

Surgery is necessary when the organism cannot be eradicated, when there is evidence of embolisation, where there is a large mobile vegetation at risk of embolisation or when there is severe cardiac failure from valve damage.

## 5.4.C The child with a cardiac arrhythmia

### BOX 5.4.C.1 Minimum standards

- Electrocardiograph.
- Defibrillator.
- Adenosine.
- Beta-blockers.
- Flecainide.
- Amiodarone.
- Atropine.

### Supraventricular tachycardia

Supraventricular tachycardia (SVT) is the commonest tachyarrhythmia in childhood.

It may present with poor systemic output and heart failure in infancy, or palpitations and dizziness in later childhood. SVT can be distinguished from sinus tachycardia because the rate is usually more rapid (200–300 beats/minute) than can be explained by the child's level of activity, fever, agitation or pain. The ECG in most cases shows narrow QRS complexes without a preceding P wave. The commonest cause of SVT in childhood is an accessory pathway, which is an abnormal bundle of muscle fibres bridging from the atrium to the ventricle. In accessory pathway-mediated tachycardia, depolarisation passes down from the atrium to the ventricle through the atrioventricular node, and then returns back up to the atrium using the accessory pathway. If the electrical wavefront then passes down the atrioventricular node again and once again returns up to the atrium via the accessory pathway, SVT has initiated. Some, but not all, accessory pathways are evident

on the resting ECG because forward conduction across the accessory pathway in sinus rhythm causes a slurred stroke just before the QRS complex, known as a delta wave. The condition is often known as the Wolff–Parkinson–White (WPW) syndrome. The best method of treating this condition is by radiofrequency ablation of the abnormal pathway by means of a catheter passed into the atria, but this is a skilled technique that is only available in specialist centres.

Some patients have a different type of SVT, where the electrical wavefront loops back on itself to form a 'short circuit' entirely within the atrioventricular node. This is less often seen in early childhood, but becomes more common towards adolescence. A totally different mechanism of tachycardia occurs when there is an abnormally rapid atrial discharge (atrial flutter or atrial ectopic tachycardia). This is relatively rare in childhood.

### Management of SVT

- 1 Record a 12-lead ECG in tachycardia,
- 2 While attempts are made to terminate the tachycardia, record a rhythm strip (this can often be easily run off a standard defibrillator).
- 3 In the infant, try to terminate the SVT by facial immersion in ice-cold water.
- 4 To terminate symptomatic or prolonged attacks of SVT in the older child, try vagal manoeuvres such as ice-cold packs on the face, the Valsalva manoeuvre or carotid sinus massage.
- 5 If tachycardia persists, obtain IV access (via a large antecubital vein if possible) and give a rapid bolus of

adenosine 100 micrograms/kg followed by a rapid crystalloid flush.

- 6 If the SVT is not terminated, give larger doses of adenosine, doubling the dose until a maximum dose of 400 micrograms/kg is reached.
- 7 If adenosine terminates the tachycardia transiently, and then SVT re-initiates, anti-arrhythmic drug treatment needs to be initiated straight away to prevent constant recurrence of the arrhythmia.
- 8 If adenosine successfully terminates the tachycardia, it is not compulsory to initiate anti-arrhythmic treatment. As SVT is not dangerous beyond infancy, anti-arrhythmic drugs are only given if the child wants to avoid further attacks (this decision is usually influenced by the frequency and duration of attacks). In infancy, SVT may cause serious haemodynamic compromise. In view of this, all infants who present with SVT should be started on anti-arrhythmic medication, which should be continued until the child's first birthday.
- 9 If adenosine does not terminate the tachycardia at all, carry out synchronised DC cardioversion, after anaesthesia, intubation and ventilation with 0.5 joules/kg, rising to 2 joules/kg in steps if the first shocks are unsuccessful.
- 10 In rarer cases, adenosine causes only transient block of the atrioventricular node, revealing rapid atrial activity in the form of P waves or sawtooth flutter waves. When atrioventricular nodal conduction returns after a few seconds, the tachycardia is re-initiated. These tachycardias require either anti-arrhythmic drug treatment to be initiated straight away or DC cardioversion.

FIGURE 5.4.C.1 Supraventricular tachycardia (SVT).

FIGURE 5.4.C.2 Termination of supraventricular tachycardia (SVT).

FIGURE 5.4.C.3 Administration of adenosine during atrial tachycardia shows underlying rapid P waves.

## Ventricular tachycardia

FIGURE 5.4.C.4 Ventricular tachycardia.

Ventricular tachycardia (VT) is normally diagnosed when there is a broad complex tachycardia. However, the latter is more often seen in childhood when there is SVT with bundle branch block. In view of this, adenosine should be given if a child presents with regular broad complex tachycardia. If the adenosine terminates the tachycardia, this proves that SVT was the correct diagnosis. If there is irregular broad complex tachycardia, do not give adenosine (this pattern indicates a dangerous arrhythmia). If the tachycardia persists even after high-dose adenosine, ventricular tachycardia is likely. Not all childhood ventricular tachycardia is dangerous. If the child is haemodynamically stable, attempts can be made to terminate the tachycardia with anti-arrhythmic drugs (see below). If there is haemodynamic compromise, immediate DC cardioversion is required.

### Direct current (DC) cardioversion

Sedate or anaesthetise the child unless they are in extremis. Use paediatric paddles if the child weighs less than 10 kg. Place one paddle over the apex of the heart in the mid-axillary line and the other immediately below the clavicle just to the right of the sternum. If there are only adult paddles and the child weighs less than 10 kg, place one on the back and one over the lower chest anteriorly. The first shock should be 0.5 joules/kg, and subsequent shocks should be increased stepwise to a maximum of 2 joules/kg.

### Anti-arrhythmic drugs

This is only a guide, and other types of drug within a class can be given.

#### First choice

**Beta-blockers** (oral doses given)

**Infants:** propranolol 1 mg/kg/dose three times a day.

**Children** (when cannot swallow tablets): atenolol 1–2 mg/kg once a day.

**Older children** (when can swallow tablets): bisoprolol 0.2–0.4 mg/kg once a day (tablets come as 2.5 mg, so use multiples of this amount).

#### Second choice

**Flecainide** (oral doses given)

**Under 12 years of age:** initially 2 mg/kg/dose twice a day. It is possible to increase to 3 mg/kg/dose if tachycardias persist (maximum of 8 mg/kg/day).

**Over 12 years of age:** 50–100 mg twice a day (maximum of 300 mg a day).

It is preferable to measure the flecainide level after 5 days just before the next dose is due to be administered, to check that the plasma level has not exceeded 800 micrograms/litre.

Avoid feeds for 30 minutes before or after giving oral flecainide, as the absorption of the drug is significantly affected by milk and dairy products.

#### Third choice

**Beta-blocker and flecainide together**

If the tachycardia does not respond to the above drugs in the acute setting, or the child's haemodynamic status is borderline, IV amiodarone is the safest option.

#### IV amiodarone

Give a loading dose of 5 mg/kg over 2 hours (dilute with 5% dextrose only). Then continue infusion at a rate of

5–20 micrograms/kg/minute (maximum of 1.2 grams in 24 hours).

Consider stopping the infusion 4–8 hours after the SVT has resolved.

If tachycardia recurs after stopping amiodarone, give a further loading dose and recommence infusion, continuing for at least 1 day after tachycardia resolution.

As amiodarone has a large number of side effects, consider switching to either a beta-blocker or flecainide once the tachycardia has been controlled and the child is haemodynamically stable.

Make up the amiodarone infusion as follows:

15 mg/kg in 50 mL of 5% dextrose (1 mL/hour = 5 micrograms/kg/hour: such a slow infusion will need an electrically driven syringe pump).

Amiodarone is incompatible with sodium chloride. Therefore do not make up with and do not flush lines with this solution.

Amiodarone can be given through a peripheral line, but serious tissue damage may be caused by the drug if extravasation occurs, so central access is preferred. If peripheral access is used, dilute the infusion to a concentration between 600 micrograms/mL and 2 mg/mL. This dilution will be more appropriate in situations where

electrically driven syringe pumps are not available, but the infusion needs close monitoring.

### Congenital complete heart block

- Consider this in any newborn who has a consistent bradycardia without apparent cause, such as terminal respiratory failure or very severe shock.
- P waves are dissociated from QRS complexes on the 12-lead ECG.
- Perform an echocardiogram to exclude structural heart disease.
- Check for anti-Ro and anti-La antibodies in the child's mother (the underlying cause in the majority of cases).
- Monitor the heart rate for 24–48 hours.
- Assess perfusion and blood pressure, and examine for signs of heart failure.
- Arrange for a permanent pacemaker if there is inadequate cardiac output, heart failure, structural heart disease or the heart rate is < 50 beats/minute.
- Atropine 20 micrograms/kg or isoprenaline infusion 0.02–0.2 micrograms/kg/minute can be used for emergency treatment of severe bradycardia with inadequate cardiac output.

## 5.5 Shock

### 5.5.A Shock

#### Introduction

'Shock' occurs when the circulatory system fails to deliver adequate amounts of primarily oxygen, but also nutrients, to the tissues, and fails to remove unwanted metabolites from the tissues for excretion.

#### Pathology at cell level

At a cellular level, the end result of shock is anaerobic metabolism (oxygen-depleted metabolism). This is an inefficient mechanism and requires much more energy than aerobic metabolism (the normal oxygen-dependent system). In addition, anaerobic metabolism builds up excess toxic acid products in the cells which cannot be removed by the failed circulation. Cellular function deteriorates and there is a downward spiral of increasing loss of homeostasis, the onset of disseminated intravascular coagulation, and after a short while so much cell death occurs in vital organs that recovery is impossible and the patient dies.

In the early stages of shock the body has mechanisms to try to combat this process. The circulatory system is under the control of the sympathetic nervous system. This system regulates the flow of blood in health and in disease to all organs so as to respond to demands on different

organs. In health, more blood is sent to muscles if a person is exercising, more to the digestive system if they are eating, and more to the skin if their body is too warm.

In shock, the sympathetic nervous system attempts to protect the vital organs by diverting blood away from muscle, skin and the digestive system and directing it to the heart, brain and kidneys. This gives rise to some of the earlier signs of shock, such as cold peripheries, increased capillary refill time, cerebral anxiety or agitation, tachycardia to increase cardiac output, and reduced urine output as the kidneys conserve fluid.

Later signs such as depressed consciousness, weak pulses, falling blood pressure and acidotic breathing show that the body's compensation mechanisms are failing. It can be seen that it is vital to recognise and treat shock in the patient as soon as possible, as this will give the best chance of patient recovery.

#### Clinical diagnosis of shock

The signs of shock are listed below, although not all of them are present in all types of shock.

- **Tachycardia** (best measured with a stethoscope).

- **Weak pulse** (ideally central – brachial, femoral or carotid, but difficult to gauge).
- Low blood pressure (this is a **late sign** and very difficult to measure in young children).
- Extreme central pallor (severe anaemia).
- Raised respiratory rate (due to acidosis).
- **Cold skin with poor circulation.**
- **Prolonged capillary refill time (CRT) > 3 seconds.**
- Increased skin sweating in some cases.
- Agitation and anxiety (this is an early sign).
- **Reduced conscious level.**
- Reduced urine output (this is an early sign).

The WHO diagnosis of shock includes all of the above signs that are highlighted in bold type.

The problem is that shock is quite difficult to diagnose in the early stages, as some signs also occur as a result of medical causes other than shock. The diagnosis in the early stages depends on the following:

- tachycardia, which is a very useful sign of shock, but also occurs with fever and with anxiety or fear
- anxiety and/or agitation
- prolonged capillary refill time, which also occurs in dehydration and is influenced by environmental temperatures and by how hard the nail bed or sternum is pressed
- cold skin, which is also dependent on environmental temperature
- reduced urine output, which is also dependent on fluid intake.

**It is vital that if any of these early signs are noted in a patient that they are not dismissed as some unrelated cause, but are seriously considered as likely to be indicating the development of shock.**

**This is why it is so useful to have regular vital signs (pulse, respiration, conscious level, temperature and blood pressure) observations on patients, so that abnormal trends can be detected early.**

**It is also important to note that shock is not diagnosed on the basis of one physical sign alone, but on the basis of several signs occurring together. For example, a tachycardia alone does not diagnose shock, but if you note a tachycardia, you should look for cold limbs, prolonged capillary refill time, or a history suggestive of a cause of shock, such as a fever, severe diarrhoea or bleeding.**

### Pathological mechanisms that can cause shock

The circulatory system is complex, so there are many causes of shock. The organs, systems and pathologies that can be the primary cause of the shock include the heart itself, the blood vessels, restriction to the flow of blood, failure of the oxygen-carrying capacity of the blood, and loss of blood or fluid from the body. The main mechanisms of shock can be summarised as follows:

- loss of fluid or blood: **hypovolaemic shock** (e.g. diarrhoea, blood loss)
- failure of the heart pump: **cardiogenic shock** (e.g. dysrhythmias, cardiomyopathy, myocarditis, malnutrition)
- abnormal function of vessels supplying nutrients and oxygen to tissues: **distributive shock** (e.g. sepsis, anaphylaxis)
- inadequate capacity of the blood to release oxygen:

**dissociative shock** (e.g. severe anaemia, carbon monoxide poisoning)

- restriction of circulation to the tissues: **obstructive shock** (e.g. some congenital heart diseases, tension pneumothorax, cardiac tamponade, pulmonary embolus).

In an individual with shock, often several of these mechanisms may coexist. Therefore the clinician must consider which emergency treatments will be effective **and which will be harmful** for any particular patient. One of the most difficult situations is in the anaemic malnourished child with sepsis, where fluid is required to expand the circulating volume, but the heart is already failing and cannot cope with a rapid fluid infusion (see Section 5.10.B).

### Basic management of shock

Shock is managed according to the following principles:

- High concentrations of oxygen are safe and must be given regardless of the cause of shock.
- Airway and breathing stability or support must be established promptly first (the only exception is to control exsanguinating external bleeding in trauma or major obstetric haemorrhage concurrently with airway and breathing; see Sections 7.3.A, 2.5.D.i and 2.5.D.iv).
- Frequent reassessment, at least after every therapeutic manoeuvre, is vital to avoid both under-infusing and over-infusing fluids.
- The underlying pathology must be treated to arrest the pathological process.

**The clinical diagnosis of the cause of shock is not easy or definitive. Shock is a spectrum of conditions and mechanisms, and it is a clinical challenge.**

**Immediate resuscitation is needed to maintain oxygenation and perfusion of vital organs. Once this is under way, the cause of shock needs to be found and treated.**

Diagnosis depends on history, clinical examination, and response to treatment given. It is often possible to identify the cause of shock with a good history and a careful examination.

### Investigations

- Haemoglobin measurement is essential.
- Blood glucose measurement is essential, as some signs of shock are the same as signs of hypoglycaemia.
- Plasma electrolyte measurements are helpful, especially sodium and bicarbonate.
- Lactate measurement is helpful (if available).
- Central venous pressure (CVP) measurement is useful, if skilled staff are available to undertake the procedure and measurement (not an emergency procedure, but helpful if in high-dependency care).

### Choice of intravenous fluid

**Fluid infused into the circulation should approximate to plasma in its electrolyte content, osmolality and pH.**

### Dextrose-only fluids

It is clear that although glucose or dextrose is necessary to prevent or manage hypoglycaemia, fluids containing only dextrose should **never** be used for IV fluid replacement

**TABLE 5.5.A.1** Diagnostic pointers to the clinical causes of shock (each is discussed in the sections indicated)

Diarrhoea and/or vomiting with signs of severe dehydration	Gastroenteritis ( <i>see</i> Section 5.5.B and Section 5.12.A), volvulus, intussusception ( <i>see</i> Section 5.19)
Fever, non-blanching (purpuric) rash	Meningococcal septicaemia ( <i>see</i> Section 5.5.C and Section 6.1.G), dengue haemorrhagic fever ( <i>see</i> Section 6.2.B)
Urticaria, wheeze, oedema, exposure to allergen	Anaphylaxis ( <i>see</i> Section 5.1.B)
Trauma	Blood loss, tension pneumothorax, internal bleeding, spinal cord transection ( <i>see</i> Section 7.3.A)
Major obstetric haemorrhage in children who are pregnant	Blood loss: ruptured ectopic pregnancy, antepartum haemorrhage, postpartum haemorrhage ( <i>see</i> Section 2)
Burns	Fluid loss from burns ( <i>see</i> Section 7.3.1.b)
Pallor, tachycardia, severe malaria, severe acute malnutrition	Severe anaemia, often with malnutrition ( <i>see</i> Section 5.10.B) and malaria ( <i>see</i> Section 6.3.A.d)
Fever, signs of shock and a very sick child	Septicaemia ( <i>see</i> Section 5.5.C) and malaria ( <i>see</i> Section 6.3.A.d)
Baby < 4 weeks old: cyanosis, with no response to oxygen, very weak pulses	Congenital heart disease ( <i>see</i> Section 5.4.A)
Very fast pulse, heart failure	Arrhythmia ( <i>see</i> Section 5.4.C) and cardiomyopathy ( <i>see</i> Section 5.4.B)
Dehydration, polyuria, polydipsia, high glucose levels	Diabetic ketoacidosis ( <i>see</i> Section 5.8.A)
History of sickle-cell disease or diarrhoeal illness and low haemoglobin levels	Haemolysis with severe anaemia ( <i>see</i> Section 5.11.C)

or maintenance, or for the emergency management of shock.

The reason for this is that the dextrose is rapidly metabolised, so the effect of a dextrose-only IV fluid on the child's body is as if pure water had been given. The outcome of this treatment would be severe hyponatraemia, which could quickly lead to brain damage or death.

In addition, this pure water is rapidly moved out of the circulation and into the cells, and the state of shock is then worse than before the infusion.

### Sodium-containing fluids

The fluid traditionally infused into the circulation for the management of shock has been 'normal saline' (0.9% sodium chloride, NaCl). This fluid has increasingly been shown to be potentially dangerous, especially in the sick patient. An infusion of normal saline causes a hyperchloraemic acidosis (a high chloride concentration leading to an acidosis), which in the shocked patient, who is already acidotic, causes a deterioration in the health of cells in vital organs, even though perfusion of the cells has been improved by the increased circulating volume.

There are sodium-containing alternatives to normal

saline which are safer as they approximate more closely to human serum in content (*see* Table 5.5.A.2), although they are a little more expensive. We recommend the use of either of these alternatives (**Ringer-lactate and Hartmann's solution** are widely available) for all fluid replacement. Recognising that not all hospitals will have access to these solutions immediately, there may sometimes be no alternative but to start fluid replacement with normal saline. However, if more than 20 mL/kg needs to be given, one of the safer alternatives should be used in these very sick children if at all possible.

**Note that hospitals and clinics will need to have access to some 0.9% NaCl (normal saline)**, usually in 5 mL or 10 mL ampoules. This will be used for dissolving or diluting drugs for IV injection. If a specific fluid is indicated as the diluent for a particular drug (e.g. 0.9% NaCl, 5% dextrose, water for injection), **this fluid must be used**. If drugs are infused using the wrong fluid, their effect on the patient may be altered.

**Clinicians should try to ensure that their hospital facility does have access to these safer infusion fluids, such as Ringer-lactate or Hartmann's solution.**

**TABLE 5.5.A.2** Comparison of electrolytes, osmolality and pH levels in IV fluids with those in human serum

Fluid	Na <sup>+</sup> (mmol/litre)	K <sup>+</sup> (mmol/litre)	Cl <sup>-</sup> (mmol/litre)	Ca <sup>2+</sup> (mmol/litre)	Lactate or bicarbonate (mmol/litre)	Osmolarity (mOsm/litre)	pH
Human serum/plasma	135–145	3.5–5.5	98–108	2.2–2.6	22–30	276 to 295	7.35–7.45
Ringer-lactate or Hartmann's solution	131	5.0	111	2.0	29	279	6.0
0.9% 'normal' saline	154	0	154	0	0	310	5.4

### Initial management of shock

Even though it may be clear on initial inspection that the child is in shock, the first priority must still be to call for help,

manage the airway, manage breathing and then manage the circulation.

Call for help.

## Airway

At this stage also stop any obvious exsanguinating bleeding.

Assess the airway by the simple technique of asking the child 'Are you all right?'

Any vocalisation such as a reply or crying indicates an open airway and some ventilation. In the absence of a response, formally open the airway with a head tilt/chin lift or a jaw thrust manoeuvre (see Section 1.12), and assess breathing by looking, listening and feeling for its presence.

Stop any obvious exsanguinating bleeding by applying external pressure (or in the case of postpartum haemorrhage, see Section 2.5.D.iv).

## Breathing

**All children with suspected shock must receive high-flow oxygen.**

In the absence of spontaneous breathing, give assisted ventilation with a bag-mask (see Section 1.13).

## Circulation

**Intravenous access** with a short wide-bore venous cannula, or placement of **an intra-osseous line** (see Section 8.4.B), is vital. More than one line is preferable, as rapid fluid resuscitation may be needed, although always start treatment as soon as the first access has been achieved and insert the second line when possible. Take blood samples for the

FIGURE 5.5.A.1 Pathway of care for the child with shock that is not cardiac in origin.

following investigations: full blood count, glucose levels, electrolytes, blood culture (and, if relevant, cross-matching and malarial parasite test).

### **Nutritional status**

**While starting to give fluid, assess the child's nutritional status** (see Section 5.10.B). Look for visible severe wasting or **marasmus**. The WHO recommended criteria are as follows: 'Look at the arms, legs and chest. The marasmic child does not look just thin, but appears to be all skin and bone. The skin looks too large for the body, there is no fat on the child and you will see the outlines of the ribs. There is also severe muscle wasting of the arms, legs and buttocks. The head may appear relatively large because of wasting of the body.' Use the mid upper arm circumference (MUAC) (see Section 9) to assess marasmus, as the urgency of the child's need for treatment precludes a weight and height measurement.

**Look also for kwashiorkor.** Check for oedema of both feet. Look at the bare feet. Press the top of the foot gently with your thumb for a few seconds. Oedema is present if a definite dent is left in the tissues. Look and feel to determine whether the child has oedema of both feet.

**Some assessment of weight will be necessary to calculate the amounts of fluid and antibiotics to be given. If the child is not malnourished, use the following formula:**

$$\text{weight in kg} = 2 (\text{age in years} + 4).$$

**If the child is malnourished, this formula can still be used, but perhaps a percentage such as 25–50% subtracted from the result.**

### **Severe anaemia**

In very anaemic children (with either obviously pale palms or haemoglobin levels of less than 3–4 grams/dL), crystalloid alone will worsen oxygen delivery to the tissues. These children need blood, either packed cells or a partial exchange transfusion, in addition to initial **slow** fluid resuscitation (see Section 5.10.B, Section 5.11.A and Section 8.4.B).

The next step is to **give fluid intravenously**. In most cases this should be a crystalloid such as Hartmann's or Ringer-lactate solution, but give normal saline (0.9%) if this is all that is available. In children, the volume of fluid to be given is usually 20 mL/kg, which is 25% of the child's circulating volume (10 mL/kg in severe anaemia or severe malnutrition while awaiting blood for transfusion). Shock is not usually clinically evident until 25% of the circulation has been lost, so any child with signs of shock must have lost at least this amount of fluid from the circulation.

The concept of **targeted crystalloid fluid resuscitation** is important if the cause of hypovolaemic shock in a child is haemorrhage from a penetrating injury. Here the initial boluses of IV crystalloids required to treat shock should only be given to keep the vital organs (especially the brain, heart and kidneys) perfused before life-saving surgery and blood transfusion can be undertaken. Fresh blood is particularly useful to combat the coagulopathy that occurs in major blood loss if specific coagulation components such as platelets are unavailable.

Giving too large a volume of IV fluids can increase the blood pressure and thus increase bleeding by disrupting early clot formation. IV crystalloid also dilutes the red cells in the circulation, but whether or not this could reduce oxygen-carrying capacity requires further research.

We suggest that when giving boluses of crystalloid or blood to patients in shock due to bleeding, only the amount needed to keep the blood pressure at a level sufficient to perfuse the vital organs should be given. There is no clear evidence to indicate the precise blood pressure that should be achieved in a child in shock due to haemorrhage from penetrating injury. **Adequate perfusion of vital organs may best be indicated by the following: in the child over 2–3 years of age, a radial pulse that can be palpated and a conscious level of A or V on the AVPU scale (i.e. the child is either awake or will respond by opening their eyes when spoken to). In children under 2–3 years of age the radial pulse may be difficult to feel, and in children with shock due to haemorrhage the presence of a palpable brachial pulse may be the best available indicator at present.**

In this situation, therefore, and to maintain a palpable radial or brachial pulse, start with IV boluses of 10 mL/kg of crystalloid, or ideally blood, and reassess after each bolus.

**The next very important step is to reassess the patient's vital signs to see whether the fluid has helped, and to ensure that circulatory overload has not given rise to a situation where more IV fluids may produce very dangerous heart failure (see below for clinical signs of this).**

During this reassessment, give IV antibiotics, as shock without obvious fluid loss is probably sepsis (see Section 5.5.C).

At this point, some children will need more crystalloid fluid, while others will not, or they will need other fluids (e.g. plasma expanders such as albumin or blood). Many will need additional treatments. The next two sections (Sections 5.5.B and 5.5.C) deal with two of the commonest causes of shock in children, and the reader is referred to the sections indicated in Table 5.5.A.1 for details of the various other causes of shock.

## 5.5.B The child with shock from dehydration

### BOX 5.5.B.1 Minimum standards

- Oral rehydration solution (ORS), including ReSoMal.
- Crystalloid infusion fluids (preferably Hartmann's solution or Ringer-lactate solution, but normal saline may be used if it is the only available alternative).
- Blood transfusion.
- Antibiotics.
- Furosemide.
- MUAC tapes.

### Dehydration

- Dehydration is loss of water, sodium and other essential electrolytes.
- The most common cause in resource-limited countries is gastroenteritis (from a number of different organisms; see Section 5.12.A).
- Most cases can be treated with low-osmolarity oral rehydration solution (ORS) administered by mouth or nasogastric tube.
- In children with severe malnutrition, use a solution with lower sodium content, such as ReSoMal.
- It is important to also consider diabetic ketoacidosis (see Section 5.8.A) and surgical causes of dehydration, such as intussusception and volvulus (see Section 5.19).

### Dehydration classification

Dehydration is classified by estimating the percentage of body water lost according to clinical criteria (except in malnutrition, where clinical signs are more difficult to interpret; see below).

#### 'No dehydration'

If there is less than 3% weight loss there are **no clinical signs**.

#### 'Some dehydration'

If there is 3–9% weight loss, the following signs are seen:

- increased thirst
- drinks eagerly
- dry mucous membranes
- loss of skin turgor, tenting when pinched
- sunken eyes
- sunken fontanelle in infants
- restless or irritable behaviour
- decreased capillary refill time (> 3 seconds)
- decreased urine output.

#### 'Severe dehydration'

If there is ≥ 10% weight loss, the following signs are seen:

- more pronounced signs than those seen in moderate dehydration
- lack of urine output
- lack of tears when crying
- inability to drink or drinking poorly (because of reduced conscious level)
- lethargy

plus

- hypovolaemic shock, including:

- rapid and weak low-volume pulse (radial pulse may be undetectable) (use a stethoscope for measuring heart rate)
- altered consciousness or coma
- low or undetectable blood pressure
- cool and poorly perfused extremities
- severe nail bed or sternum decreased capillary refill time
- peripheral cyanosis
- rapid deep breathing (from acidosis).

It is important to realise that the above classification is made only to guide the start of treatment. **Levels of dehydration are a continuous spectrum, not three separate and distinct categories.** The only way to be absolutely certain about the percentage dehydration of a child is to compare an accurate weight measured just before the onset of the diarrhoeal illness with an accurate current weight. It is very unlikely in most cases that the former weight will be available. In the case of the shocked patient, immediate treatment takes precedence over weighing the child (estimate the child's weight from the formula:

$$\text{weight (kg)} = 2 (\text{age in years} + 4)$$

for previously well children before puberty, or read it from a weight/age chart (see Section 9)).

However, if the clinical situation is not so critical, the weight of the child on presentation is very helpful for subsequent management, and should be measured and recorded as a daily routine.

### Emergency treatment of severe dehydration: principles of treatment

- Recognise and treat shock.
  - Give a fluid bolus, 20 mL/kg IV of Hartmann's or Ringer-lactate solution (0.9% saline, or 'normal' saline, can be used if there is no alternative; see Section 5.5.A).
  - A second bolus may be needed if the child does not respond (see the 'shock' pathway in Figure 5.5.A.1).
  - It is unusual to need more than two boluses in cases of dehydration due to gastroenteritis alone, unless they are due to cholera (see Section 5.12.A). Consider other causes, such as septicaemia, diabetic ketoacidosis (check blood sugar levels), volvulus or intussusception (check whether vomit is bile-stained, and whether there is fresh blood in stools; see Section 5.19).
  - If septicaemia is suspected, treat with IV antibiotics.
- Think of the most likely cause of the dehydration.
- Estimate the level of dehydration (see above) to calculate the fluid deficit, maintenance needs and ongoing losses (see below).

### Shock recognition and treatment

**Children with shock associated with dehydration will have a high and increasing heart rate, weak pulse, poor**

**skin circulation time with prolonged capillary refill time (> 3 seconds), depressed conscious level, and low or even unmeasurable blood pressure.**

These children require immediate resuscitation (ABC) and emergency treatment.

**Call for help (summon an anaesthetist if possible).**

**Airway (in cases of reduced conscious level)**

Use an opening manoeuvre if the airway is not open or if it is partially obstructed. Keep the airway open. If there is immediate improvement but the airway closes without active opening support, consider airway adjuncts to support the airway.

Suction if necessary under direct vision, but not routinely.

If the child is deeply unconscious (P or less on the AVPU scale), the airway may need to be secured by intubation using experienced senior help (if available).

**Breathing**

Give 100% oxygen (using a mask with reservoir and a flow rate of at least 6 litres/minute) regardless of SpO<sub>2</sub> (this increases oxygen delivery as well as improving tissue oxygenation). For inadequate ventilation or depressed conscious level (check with the AVPU scale) with hypoventilation, respiration should be supported with oxygen via a **bag and mask**, and experienced senior help should be summoned (if available).

**Circulation**

- Obtain vascular access to give IV boluses quickly. Insert an IV cannula and send blood for a full blood count, urea and electrolytes, cross-matching (if the patient is anaemic) and clotting. If peripheral veins are difficult to access, the **external jugular vein** or **long saphenous vein cut-down** are good alternatives, as is an **intra-osseous infusion** (see Section 8.4.B). If a skilled operator is available, an internal jugular or femoral vein central line is ideal, as it can also allow **central venous pressure (CVP)** measurements (if available).

Some assessment of weight will be necessary to calculate the amounts of fluid and antibiotics to be given. If the child is not malnourished, use the formula:

$$\text{weight (kg)} = 2 (\text{age in years} + 4).$$

If the child is malnourished, this formula can still be used but perhaps a percentage such as 25–50% subtracted from the result.

**Children with normal nutrition**

- **If the child is not malnourished**, give an initial **rapid** bolus of 10–20 mL/kg of Ringer-lactate or Hartmann's solution, but give normal saline (0.9%) if this is all that is available. It is essential that the bolus is given as rapidly as possible. **Do not use 5% glucose or 0.18% saline/4% glucose solutions for resuscitation, which can be dangerous (risk of hyponatraemia and cerebral oedema).** Boluses should be manually pushed in using a 20- to 50-mL syringe (with a three-way tap and linked to an IV giving set).
- When this bolus of fluid has been given, review the child's condition, looking to see whether there has been any improvement in pulse rate, conscious level,

respiratory rate, capillary return and limb warmth, and blood pressure.

- A further 10–20 mL/kg bolus will be required if signs of shock remain. Once a **total** of 40 mL/kg of boluses has been given IV, complications such as pulmonary oedema are more likely to occur. In a child with shock from severe dehydration caused by diarrhoea, it would be unusual to need more than 40 mL/kg to improve the child's circulation, unless cholera was the cause. In severe cases, where more than a total of 40 mL/kg is considered essential, intubation, ventilation, CVP monitoring and inotrope support might be indicated (if available), but **the diagnosis should be reviewed as this need is unusual in straightforward gastroenteritis.** Reconsider the diagnosis. For example:
  - surgical abdominal pathology, such as intussusception, peritonitis or volvulus (bile-stained vomiting, abdominal distension or tenderness) (see Section 5.19)
  - additional pathology, severe anaemia, septicaemia or a cardiac problem.

**Children with severe malnutrition or severe anaemia**

- **If the child is malnourished and/or has severe anaemia, fluid must be given much more carefully.** Give 15 mL/kg IV over 1 hour. The recommended solution is Ringer-lactate or Hartmann's solution, each with 5% glucose (insert 50 mL of 50% dextrose into a 500-mL bag of the bolus fluid, ideally after first removing 50 mL from the bag: not essential), but give normal saline (0.9%) if this is all that is available, also with 5% dextrose. At the same time, insert a nasogastric tube and give ReSoMal, 10 mL/kg/hour. Monitor carefully for signs of over-hydration: reassess the respiratory and heart rates every 15 minutes. It is also wise to give IV antibiotics in this situation, as it can be very difficult to distinguish septic shock from dehydration shock in children with malnutrition.

**Nutritional status**

- **While starting to give fluid, assess the child's nutritional status** (see Section 5.10.B). Look for visible severe wasting or **marasmus**. Follow the WHO criteria: 'Look at the arms, legs and chest. The marasmic child does not look just thin, but appears to be all skin and bone. The skin looks too large for the body, there is no fat on the child and you will see the outlines of the ribs. There is also severe muscle wasting of the arms, legs and buttocks. The head may appear relatively large because of wasting of the body.'
- Use the mid upper arm circumference (MUAC) (see Sections 5.10.B and 9) to **assess marasmus**, as the urgency of the child's need for treatment precludes a weight and height measurement.
- **Look also for kwashiorkor.** Check for oedema of both feet. Look at the bare feet. Press the top of the foot gently with your thumb for a few seconds. Oedema is present if a definite dent is left in the tissues. Look and feel to determine whether the child has oedema of both feet.

**Severe anaemia**

In very anaemic children (with either obviously pale palms or haemoglobin levels less than 3–4 grams/dL), crystalloid

alone may worsen oxygen delivery to the tissues. These children need blood, either packed cells or a partial exchange transfusion, in addition to initial **slow** fluid resuscitation (see Section 5.10.B and Section 8.4.B).

- **If after 1 hour** the child is improving but still severely dehydrated, stop the IV fluids, but continue nasogastric ReSoMal 10 mL/kg/hour for up to 5 hours (see Section 5.10.B for further details).
- A child with a haemoglobin level of less than 5 grams/dL will also need a transfusion of 10 mL/kg of packed cells over 4 hours, watching continuously for evidence of pulmonary oedema. If pulmonary oedema develops, furosemide 1 mg/kg IV may be required, but if possible pulmonary oedema of severity requiring diuretics should be avoided by a slow and vigilant approach to therapy in these very sick children.
- Keep the patient warm, but do not overheat them, as this will cause peripheral vasodilatation and reduce the blood supply to vital centres. Hypothermia will exacerbate poor peripheral perfusion, acidosis and coagulation abnormalities.
- Elevate the patient's legs (raise the foot of the bed).
- A central venous pressure (CVP) line is potentially helpful for avoiding under-transfusion or fluid overload. Insertion should not delay initial resuscitation, but if peripheral access is inadequate this route may be used for volume replacement. If disseminated intravascular coagulation (DIC, a clotting disorder) has become established, CVP insertion is hazardous, must be undertaken by an expert, especially via the subclavian vein.
- If the child has a reduced level of consciousness or has a convulsion, particularly if they are an infant or a young child, hypoglycaemia may be present. Always measure the blood glucose concentration in this situation. However, if blood glucose measurement is not possible, always treat as for presumed hypoglycaemia and, in addition to the IV fluids given above, give 5 mL/kg of 10% glucose IV or, if there is no IV access, by intra-osseous needle.

While treating shock, reassess the child, ideally continuously, until signs of shock have resolved.

### When signs of shock have resolved

**When shock has resolved and the patient's level of consciousness has returned to normal, the remaining estimated fluid deficit MUST be taken by mouth or by gastric tube, especially if there is malnutrition and/or anaemia (due to the danger of a large IV fluid volume). Use WHO Plan B (see Appendix to Section 5.12.A).**

- Check the serum sodium concentration, and if it is higher than 155 mmol/litre, reduce it **slowly** with oral rehydration solution over 48 hours. Too rapid a reduction in sodium levels leads to cerebral oedema.
- Further tests might include abdominal X-ray or ultrasound scanning, if there is concern about a distended abdomen.
- A surgical opinion is needed if there is bile-stained vomiting or abdominal signs.

### Fluid requirements

WHO Plans A, B and C for gastroenteritis in children (see Appendix to Section 5.12.A) include estimates of total fluid

requirements, and assume that most children will be drinking by 4 hours into treatment and thus able to 'self-regulate'. For patients for whom this is not the case, the following guidelines can be used.

### Estimating fluid requirements

The amount of fluid needed in a 24-hour period must be calculated. It is the sum of:

#### estimated fluid deficit + maintenance requirements + ongoing losses.

#### Deficit

If an accurate recent pre-illness weight is available, subtract the current weight to estimate lost fluid (1 kg = 1 litre of fluid).

For example, a child who weighed 9.2 kg is seen with diarrhoea and a weight of 8.3 kg. The estimated fluid loss in this case is  $(9.2 - 8.3) \text{ kg} = 0.9 \text{ kg} = 900 \text{ mL}$  deficit, i.e. 10% dehydrated.

If no recent reliable weight is available:

- 1 Estimate the degree of dehydration.
- 2 Weigh the child or estimate their weight from their age as follows:

$$\text{weight (kg)} = 2 [\text{age (years)} + 4].$$

- 3 Use the formula: percentage dehydration  $\times$  weight (kg)  $\times 10 =$  deficit (in mL).

For example, a child whose weight is estimated to be 10 kg is 10% dehydrated. The estimated fluid loss in this case is  $10 \times 10 \times 10 = 1000 \text{ mL}$  (i.e. 40 mL/hour if replaced over 24 hours).

#### Maintenance

The estimated maintenance fluid requirements based on body weight for a child are shown in Table 5.5.B.1.

**TABLE 5.5.B.1** Fluid requirements per day

Body weight	Volume of fluid needed per day	Volume of fluid needed per hour
First 10 kg of body weight	100 mL/kg	4 mL/kg
Second 10 kg	50 mL/kg	2 mL/kg
Subsequent kg	20 mL/kg	1 mL/kg

#### Ongoing losses

Estimated ongoing fluid losses are shown in Table 5.5.B.2.

**TABLE 5.5.B.2** Estimates of ongoing fluid losses in gastroenteritis

For each diarrhoea stool	Age < 2 years: give 50–100 mL Age $\geq$ 2 years: give 100–200 mL
For each vomit	2 mL/kg oral rehydration solution: give small frequent volumes (e.g. 5 mL every minute for a child) via a spoon, syringe or cup
For nasogastric tube aspirates	Replace volume for volume with either oral rehydration solution or Hartmann's or Ringer-lactate solution with 5% or 10% glucose or normal saline with 5% or 10% glucose and 5 mmol/litre of potassium chloride

**Over-hydration**

Signs of over-hydration, especially if there is cardiac failure (e.g. in severe malnutrition) are as follows:

- tachycardia, increased respiratory rate, oedematous (puffy) eyelids, crepitations at lung bases, enlarged liver and raised jugular venous pressure (JVP)
- pulmonary oedema on chest X-ray.

**Management**

- Stop giving IV fluids or oral rehydration solution, but give breast milk or plain water and food.
- Do not give a diuretic unless there is pulmonary oedema

(crepitations in lungs), in which case give furosemide 1 mg/kg IV.

**Reassess:**

- ABC.
- The state of intravascular rehydration.
- Plasma electrolytes (if possible).
- Urine output and urine electrolytes.
- Glucose levels.

Reduce fluid intake and continue to monitor, responding to changes in the child's condition as described above.

**5.5.C The child with septic shock****BOX 5.5.C.1 Minimum standards**

- High-dependency care.
- Ringer-lactate or Hartmann's solution (or 0.9% saline if no other crystalloid is available).
- Urgent blood transfusion.
- Antibiotics: cefotaxime, flucloxacillin, gentamicin, metronidazole and penicillin.
- Dopamine and adrenaline.
- MUAC tapes.

**Introduction**

Septic shock develops when a number of different mechanisms of shock operate in the context of an invasive bacterial infection (an exception is dengue, which is caused by a viral agent; see Section 6.2.B). These mechanisms are as follows:

- **hypovolaemic:** there is abnormal capillary permeability, fever and accompanying vomiting and diarrhoea
- **distributive:** there is loss of the normal sympathetic nervous system control of vascular tone, so that blood is lost from vital organs into non-vital areas
- **cardiogenic:** there is impaired cardiac function secondary to hypovolaemia and the toxic effects of the pathogen.

These multiple factors make septic shock difficult and complex to treat, and they contribute to a high mortality rate in these conditions.

The bacteria that cause septic shock include *Meningococcus*, *Staphylococcus*, *Streptococcus pneumoniae* and *Streptococcus pyogenes*, together with Gram-negative organisms such as *E. coli* which particularly affect **patients who are at risk due to lower immunity**, such as the newborn, those with HIV/AIDS, and the malnourished.

**Diagnosis of septic shock**

The early recognition and treatment of septic shock is key to a good outcome, so a high degree of vigilance for this condition is necessary.

In a child who has an infection, with a fever (although the **at-risk** group mentioned above may have a normal or subnormal temperature), the development of a change in

mental status, such as irritability, drowsiness, lack of interaction or reduced or absent eating or breastfeeding is often the first feature to alarm parents, and is the result of the effect of poor cerebral perfusion and possible accompanying hypoglycaemia on the child's brain.

The signs which should then be sought include the following:

- tachycardia (best measured with a stethoscope)
- weak pulse (ideally central – brachial, femoral or carotid, but difficult to gauge)
- reduced urine output (this is an early sign)
- cold skin with poor circulation, or sometimes peripheral skin vasodilatation
- prolonged capillary refill time (CRT) > 3 seconds
- agitation and anxiety
- increased skin sweating in some cases
- extreme central pallor (in cases with severe anaemia)
- raised respiratory rate (due to acidosis)
- reduced conscious level (**this is a serious and dangerous sign**)
- low blood pressure (this is a **late sign** and difficult to measure in young children; the correct-sized cuff is needed).

**Difficulties in managing septic shock**

In well-resourced countries or well-resourced areas of countries with specialist paediatric intensive care units (PICUs) or high-dependency units, some cases of septic shock are still difficult to manage and some children die.

In resource-limited countries the following additional difficulties need to be taken into account:

- **Severe malnutrition:** this makes the diagnosis of septic shock more difficult, as the child's malnourished body does not respond with the same physical signs as that of a well-nourished child. In addition, malnourished children may have poor myocardial function and almost always have severe anaemia. This will result in cardiac failure and probable death if rapid infusions of large and repeated boluses of fluid (an important part of septic shock management) are given (see Section 5.10.B).
- **Severe anaemia:** as shock is a failure of oxygen delivery to the tissues, clearly anaemia will make this worse. Rapid crystalloid fluid infusion will dilute the blood further and worsen the heart failure which may be present in severe anaemia. These children need early **fresh**

whole blood transfusion, where the red blood cells will improve oxygen-carrying capacity, and the plasma will support the circulation and supply coagulation factors. If only stored blood is available, it should be packed to provide predominantly red blood cells. In the absence of a suitable centrifuge, hanging the bag vertically allows the red cells to fall to the bottom of the pack and these can be transfused first.

- **HIV/AIDS:** again diagnosis may be difficult, as physical signs and laboratory tests may be unreliable. A low threshold for treatment of suspected sepsis with broad-spectrum antibiotics is recommended (see Section 6.2.D).
- **Lack of PICU or high-dependency care facilities:** even in children with good nutrition, no severe anaemia and no other long-term debilitating condition, the amount of fluid infusion required to successfully treat some cases of septic shock is sufficient to induce heart failure and pulmonary oedema. If facilities are available, intubation and ventilation, IV infusion of inotropic drugs such as dopamine and adrenaline, invasive cardiovascular monitoring, renal dialysis and other aspects of paediatric intensive care are required. The absence of these facilities limits the treatment that can be offered to children with septic shock.

### Initial management of septic shock

Even though it may be clear on initial inspection that the child is in shock, the first priority must still be to call for help, manage the airway, manage breathing, and then manage the circulation.

Call for help.

#### Airway

Assess the airway by the simple technique of asking the child 'Are you all right?'

Any vocalisation such as a reply or crying indicates an open airway and some ventilation. In the absence of a response, formally open the airway with a head tilt/chin lift or a jaw thrust manoeuvre (see Section 1.12), and assess breathing by looking, listening and feeling for its presence.

#### Breathing

**All children with suspected shock must receive high-flow oxygen.**

If possible, this should be given through a mask with a reservoir to achieve the higher concentrations. In the absence of spontaneous breathing give assisted ventilation with a bag-mask (see Section 1.13).

#### Circulation

Some assessment of weight will be necessary to calculate the amounts of fluid and antibiotics to be given. If the child is not malnourished, use the following formula:

$$\text{weight in kg} = 2 (\text{age in years} + 4).$$

If the child is malnourished, this formula can still be used, but perhaps a percentage such as 25–50% subtracted from the result.

**Intravenous access** with a short wide-bore venous cannula, or placement of **an intra-osseous line** (see

Section 8.4.B), is vital. More than one line is preferable, as rapid fluid resuscitation may be required, and other drugs may need to be given simultaneously, but start IV treatment as soon as the first line is in place before seeking additional IV access (unless sufficient staff are available). Take blood for the following investigations: full blood count, glucose levels, electrolytes (including calcium and lactate levels if possible), blood grouping and blood cross-matching in all cases. Treat hypoglycaemia if it is identified (see Section 5.8.B).

#### **Nutritional status: severe malnutrition**

**While starting to give fluid, assess the child's nutritional status** (see Section 5.10.B). Look for visible severe wasting or **marasmus**. Follow the WHO criteria: 'Look at the arms, legs and chest. The marasmic child does not look just thin, but appears to be all skin and bone. The skin looks too large for the body, there is no fat on the child and you will see the outlines of the ribs. There is also severe muscle wasting of the arms, legs and buttocks. The head may appear relatively large because of wasting of the body.' Use the mid upper arm circumference (MUAC) (see Section 9) to **assess marasmus**, as the urgency of the child's need for treatment precludes a weight and height measurement.

**Look also for kwashiorkor.** Check for oedema of both feet. Look at the bare feet. Press the top of the foot gently with your thumb for a few seconds. Oedema is present if a definite dent is left in the tissues. Look and feel to determine whether the child has oedema of both feet.

#### **Severe anaemia**

In very anaemic children (with either obviously pale palms or haemoglobin levels of less than 3–4 grams/dL), crystalloid alone will worsen oxygen delivery to the tissues. These children need blood, either packed cells or a partial exchange transfusion, in addition to initial **slow** fluid resuscitation (see Section 5.10.B, Section 5.11.C and Section 8.4.B).

#### **First fluid**

**The next step is to give fluid and antibiotics intravenously.**

#### **Malnourished and/or severely anaemic children**

- **If the child is malnourished and/or anaemic (haemoglobin concentration < 5 grams/dL), fluid must be given much more carefully.** Give 10 mL/kg IV over 30–60 minutes. The recommended solution is Ringer-lactate solution or Hartmann's solution, each with 5% glucose (insert 50 mL of 50% dextrose into a 500-mL bag of the bolus fluid), but give normal saline (0.9%) if this is all that is available, also with 5% dextrose. For antibiotic treatment, see below.
- Give a bolus of 10 mL/kg of **fresh blood** (if available) or stored blood over 15 minutes as soon as possible.
- Assess the child and **if they are not in clinical heart failure**, give another 10 mL/kg bolus of fresh or stored blood over 15 minutes.
  - **If the child is in heart failure**, give 10 mL/kg of blood as packed red cells over 2–3 hours, or use a partial exchange transfusion as follows: using a cannula in a large vein, withdraw 5–10 mL of the patient's anaemic blood (depending on the child's size) and infuse 10–20 mL, respectively, of new blood over 5 minutes and repeat 10 times.
- If the child is not improving after having been given the above treatment and antibiotics (see below), further

clinical interventions must be determined by the individual situation.

### Normal nutrition

- **If the child is not malnourished**, infuse a crystalloid such as Hartmann's or Ringer-lactate solution as quickly as possible, but give normal saline (0.9%) if this is all that is available. In well-nourished children, the initial bolus volume of fluid to be given is usually 20 mL/kg, which is 25% of the child's circulating volume. Shock is not usually clinically evident until 25% of the circulation has been lost, so any child with signs of shock must have lost at least this amount of fluid from the circulation. For example, a child weighing 12 kg would need 240 mL of crystalloid. This fluid should be given as quickly as possible, usually over 5–10 minutes. It is easily given by pushing the fluid in using a 50-mL syringe.

### Antibiotics

- While giving the first bolus of IV fluid, also give IV antibiotics if sufficient staff are available to avoid introducing delays with the first fluid bolus. The choice of antibiotics will depend on the clinical clues as to the infecting organism. In the presence of a purpuric rash (and in a non-endemic dengue area), meningococcus is the likely organism. Otherwise *Streptococcus* or *Staphylococcus* or Gram-negative organisms are candidates. A third-generation cephalosporin such as ceftriaxone or a combination of gentamicin and a penicillin would be advisable. Flucloxacillin should be added if *Staphylococcus* is suspected (e.g. if there are boils or a known abscess). In newborn infants or children with suspected intra-abdominal sepsis, Gram-negative organisms are likely. Metronidazole should be given to cover anaerobic organisms if clinically appropriate.

### Reassessment

- The next very important step before a second IV bolus is given is to **reassess the patient's vital signs** to see if the fluid has helped. Check the pulse rate, capillary return, limb temperature and blood pressure, and pay particular attention to the child's mental status. Observe the parent–child interaction. Is the child more or less responsive to the parent? Look for signs of heart failure (i.e. raised jugular venous pressure, enlarged liver, and crackles in the lung bases).
- If the child still shows the signs of shock, give further fluid. If there are signs of fluid overload with or without heart failure, stop the IV fluid.

### Further fluid

- If there has been a little improvement or no improvement, give **a further bolus of 10–20 mL** of fluid. Reassess the child after each 10 mL/kg of fluid, checking the pulse rate, capillary return, limb temperature, blood pressure and alertness, and looking for signs of heart failure, raised jugular venous pressure, enlarged liver, and crackles in the lung bases.
- Once a total of 40 mL of fluid have been given, there is an increasing risk that you will cause fluid overload with pulmonary oedema, which will make the child worse, not better. The problem is that there may still be leakage of fluid out of the circulation (into which you have been infusing the crystalloid or other fluid), which makes

the tissues oedematous but leaves the circulation still hypovolaemic and the tissues under-perfused.

### Inotropes

- One response to this situation is to give an infusion of a drug that stimulates the heart to pump harder and supports the circulation (an inotrope). **Dopamine is a very potent drug and must be given carefully.** It should be given into a peripheral vein or intra-osseously at a starting dose of 5 micrograms/kg/minute. The dose can be increased in steps up to 20 micrograms/kg/minute if lower doses do not help.

### Dopamine infusion

- Make up 0.3 mg/kg of dopamine in 500 mL of Ringer-lactate or Hartmann's solution or normal saline. This will give 0.1 microgram/kg/minute if run at a rate of 1 mL/hour. Use an 100-mL paediatric burette in the infusion line for this fluid. The burette can then be filled with a further 100 mL and a further dose of dopamine added when necessary. To give 5.0 micrograms/kg/minute, give 50 mL/hour of this dilution for a child. Do not forget that the fluid that you are using for the infusion must be included in your calculations of total fluid given. If higher doses of dopamine are needed, a more concentrated solution of dopamine should be used or too much fluid will be given.
- If dopamine is not available or is not having any significant effect in the larger doses, then adrenaline, which is more potent than dopamine, may be tried.

### Intermittent adrenaline infusions

- Dissolve 0.1 mL of 1 in 1000 adrenaline or 1 mL of 1 in 10000 adrenaline in 10 mL of 0.9% saline and give 1 mL IV in a child (100 microgram) or 0.2 mL in an infant (20 micrograms). Check the response (in particular of blood pressure), and repeat after 15–30 minutes if it helps to improve perfusion. Then intermittently give further doses as required (1 mL of this solution contains 100 micrograms).
- It must be emphasised that in the absence of paediatric intensive care, the above infusions of inotropic (circulation-supporting) drugs are an attempt to save a child in extremis, and may not be effective.
- Once the infusion of inotropes has been started and the child's vital signs reassessed, fluid may cautiously be continued, reassessing frequently and stopping the infusion if signs of heart failure appear.
  - If there is a skilled operator (an anaesthetist or surgeon) available, the placing of a central venous line would be very helpful for monitoring the venous pressure (around + 8 mmHg is a good target) and for infusing the dobutamine or adrenaline centrally.
  - Once 60 mL/kg have been given in total along with inotropes, further fluid is unlikely to be beneficial unless skilled ventilation is available.
  - In this situation, provided that adequate facilities and expertise are available, positive pressure ventilation through an endotracheal tube (usually with positive end-expiratory pressure) can assist the circulation and help to manage the effects of any pulmonary oedema.

### Reviewing the full blood count and biochemistry

- Blood tests were taken at the beginning of treatment, but it is useful to check the blood tests again (taking the blood from a vein with no IV in place).
  - Check the haemoglobin level to see whether there is now a need for a blood transfusion (fresh blood would be best). Studies have shown that the haemoglobin concentration should ideally be above 10 grams/dL when treating shock in children.
  - Check the blood glucose level and treat with 2 mL/kg of 10% dextrose in a neonate and 2–5 mL/kg of 10% dextrose in an older infant or child if the level is less than 2.5 mmol/litre. Also add glucose to any infusion fluid.
  - Check the calcium level, and if the concentration of ionised calcium is less than 1 mmol/litre, give 0.3 mg/kg of 10% calcium gluconate IV slowly (over 30 minutes, as calcium can cause cardiac arrest if given too quickly).
- Consider giving 0.5–1 mmol/kg of sodium bicarbonate (0.5–1 mL/kg of 8.4% sodium bicarbonate) over

15 minutes IV for refractory acidosis that is not responding to fluid resuscitation and effective ventilation.

### Steroids

- There is some evidence that IV steroids can be helpful in some cases of septic shock. If the suspected organism is meningococcus or the child has previously been on a prolonged course of steroid treatment (e.g. for nephrotic syndrome), IV hydrocortisone can be given at a dose of 1–2 mg/kg/day in divided doses or as a continuous infusion. Occasionally higher doses up to 50 mg/kg/day have been used.

### Further treatment

- Many children with septic shock may respond to the above treatments. For those who have not done so, paediatric intensive or high-dependency care is needed. If this is available, contact should be made with the PICU team as soon as it becomes clear that the child has septic shock. Advice on their care can then be given by experts and arrangements made, if possible, for the child to be 'retrieved' by the intensive care team coming to stabilise and transfer them.

## 5.6 Renal disorders

### 5.6.A Medical renal disorders

#### BOX 5.6.A.1 Minimum standards

- Accurate weight-measuring scales.
- Fluid input and output charts.
- Urine microscopy, culture and sensitivity.
- Antibiotics: trimethoprim, cephalosporins, amoxicillin, nitrofurantoin, gentamicin, penicillin.
- Blood biochemistry: urea, creatinine, sodium, potassium, chloride, bicarbonate.
- Urinary electrolytes.
- Full blood count.
- Ultrasound scan.
- Blood pressure measurement.
- Furosemide and chlorothiazide.
- Nifedipine or amlodipine, hydralazine, propranolol or atenolol, captopril or enalapril.
- Prednisolone, levamisole and cyclophosphamide.
- IV albumin.
- Analgesia: morphine.
- IV Ringer-lactate solution, Hartmann's solution, phosphate and 5% albumin.
- IV glucose 10% and insulin.
- Sodium bicarbonate, calcium gluconate, calcium resonium and calcium carbonate.
- Antihypertensive drugs.

### Introduction

#### Common renal investigations: plasma or serum biochemistry

#### Electrolytes

Sodium (Na<sup>+</sup>) and potassium (K<sup>+</sup>) assays are essential for the logical management of children with kidney dysfunction. Bicarbonate (HCO<sub>3</sub><sup>-</sup>) is also extremely helpful, but more difficult to measure.

Problems with fluid and electrolyte balance are common in ill children. They can occur in a wide variety of clinical situations and with a wide range of underlying diagnoses. A methodical approach to history taking and clinical examination is therefore essential, and interpretation of biochemical results must always be done in the context of the clinical situation.

**TABLE 5.6.A.1 Maintenance water, sodium and potassium requirements**

	Age Preterm	Term	1 year	5 years	12 years
Sodium (mmol/kg/24 hours)	5	3	2	2	1
Potassium (mmol/kg/24 hours)	5	3	2	2	1
Water (mL/kg/24 hours)	200	150	100	75	50
Fluid (mL/kg/hour)	8	6	4	3	2

### Dehydration and hypovolaemia

Fluid within the body is distributed between the intracellular fluid (ICF) and extracellular fluid (ECF) compartments, the ECF being composed of the intravascular and interstitial components. Differential solute composition of the ICF and ECF compartments is maintained by cell membrane pump activity and solute size and electrical charge. Fluid movement is regulated by a balance between osmotically active solutes and hydrostatic pressure.

It is useful when clinically assessing the fluid volume status of a patient to try to consider which compartment has insufficient or excess volume.

The effects of ECF volume depletion are usually shared between the intravascular and interstitial compartments, and are seen as hypovolaemia and dehydration, respectively. However, assessment can be complex. For example, in a condition like nephrotic syndrome, on examination there may be weight gain and oedema. However, since there is hypoalbuminaemia, and albumin is the primary intravascular osmotic component, the intravascular fluid volume may be low but the total ECF volume is high. Conversely, in acute renal failure there can be weight gain and oedema in a situation where both the total ECF and the intravascular volume are high. In heart failure, oedema can be present with high, normal or low intravascular volume, depending on other additional pathologies. In summary, oedema can occur with high, normal or low intravascular fluid volume, which makes the clinical history and a full examination vitally important for understanding the individual patient.

Often, in dehydration, sodium and water have been lost in an approximately normal ratio and therefore the deficit should be replaced as Ringer-lactate or Hartmann's solution. Normal saline can be used if these two solutions are unavailable, but it is less satisfactory because large volumes cause the patient to develop a hyperchloraemic acidosis, due to the larger chloride load in normal saline than there is in plasma.

### Practical point

When prescribing rehydration fluids:

- Make an assessment of volume deficit and replace this as Ringer-lactate or Hartmann's solution.
- Calculate maintenance fluids and insensible losses.
- Initially estimate, and then measure, ongoing losses and replace them appropriately in volume and content.

Fluid prescription should consist of A + B + C.

Aim to treat cardiovascular collapse or 'shock' quickly over the first 1–2 hours. Infuse Ringer-lactate or Hartmann's solution to restore the circulating blood volume, reviewing to assess the response (see Section 5.5.A), and thereafter use a slow replacement rate so that the total deficit is replaced over at least 24 hours.

In hypernatraemic dehydration, after an acceptable

cardiovascular state has been restored, aim to reduce plasma sodium levels slowly over 24–48 hours by altering the sodium concentration of the infusion fluid appropriately, and repeatedly monitoring the rate of fall of the plasma sodium and urinary sodium concentration.

### Fluid and electrolyte disorders

Good management depends on measurement of input and output, plus **repeated**:

- clinical examination
- biochemical data on urine and blood
- weight measurements.

### Hyponatraemia

Hyponatraemia is defined as a plasma sodium concentration of less than 130 mmol/litre, and it occurs when there is:

- sodium loss in excess of water loss
- or water gain in excess of sodium gain.

The total body sodium level may be high, low or normal, and therefore initial and ongoing clinical assessment of the extracellular fluid volume is essential.

### Hypernatraemia

Hypernatraemia is defined as a plasma sodium concentration greater than 150 mmol/litre, and occurs when there is:

- water loss in excess of sodium loss
- or sodium gain in excess of water gain.

Again, the total body sodium level may be high, low or normal.

**TABLE 5.6.A.2 Clinical estimation of ECF volume deficit in dehydration**

<i>Mild</i> 3–5% weight loss	Thirsty Mucous membranes dry Decreased skin turgor
<i>Moderate</i> 5–10% weight loss	Increased severity of the above Depressed fontanelle Sunken eyes Tachycardia
<i>Severe</i> 10–15% weight loss	Increased severity of the above Drowsiness, confusion or coma 'Shock' Cool peripheries Prolonged capillary refill time Hypotension

### Hypernatraemic dehydration: water loss in excess of sodium loss

Because sodium is the principle ECF osmole, the ECF volume is relatively well maintained, and signs of dehydration and hypovolaemia are less apparent.

### Creatinine

Plasma creatinine concentration is the best available, most clinically useful and relatively inexpensive guide to glomerular renal function. It is easily, quickly and cheaply measured on a small blood sample. Individual measurements are of use in determining whether renal function is within the normal range. Sequential measurements are useful for following deterioration or improvements in renal function over a short time scale of hours or days, or over a long time

scale of months or years. Although formulae can be used, the following guidelines allow the glomerular filtration rate (GFR) to be estimated in most clinical situations.

The plasma creatinine concentration depends on the bulk of the patient's muscle (where it is produced) and the patient's height, so on average men have higher values than women, and older children have higher values than babies, except in the first few days of life (see Table 5.6.A.3).

For example, a creatinine concentration of 150 mmol/litre in a well-nourished 5-year-old girl would be three times the upper limit of normal, indicating a GFR of one-third normal. The same creatinine concentration in a very undernourished girl with little muscle bulk would imply a GFR considerably lower than one-third.

TABLE 5.6.A.3 Upper limit of normal plasma creatinine concentrations

Subject	Plasma creatinine concentration (micromol/litre)	Plasma creatinine concentration (mg/dL)
Well-nourished average man	100	1.15
Well-nourished average woman	75	0.85
Well-nourished average 10-year-old child	60	0.70
Well-nourished average 5-year-old child	50	0.65
Well-nourished average baby or toddler	40	0.45
Baby aged 3 days to 3 weeks	Variable	
Baby in first 2 days of life	Maternal	

### Urea

Although useful for managing children with renal failure, urea concentration is an inaccurate way of measuring renal function because it is also highly dependent on hydration, and on carbohydrate and protein intake.

that P and U creatinine values are expressed in the same units), using the following formula:

$$\text{FE Na (\%)} = \text{U/P sodium} \times \text{P/U creatinine} \times 100.$$

## Urine biochemistry

### Concept of fractional excretion

Clearance of any substance which is filtered by the glomerulus and then reabsorbed by the tubules can be compared to the clearance of creatinine which is filtered and then excreted largely unmodified by the tubule. The fractional excretion is that fraction of substance *x* that has been filtered at the glomerulus that actually reaches the urine.

$$\text{Fractional excretion (FE) } x \text{ \%} = \frac{\text{urine } x}{\text{filtered } x} \times 100$$

### Fractional excretion of sodium

Normally, most of the filtered sodium ( $\text{Na}^+$ ) is reabsorbed; the majority of this reabsorption occurs in the proximal tubule. When plasma sodium is normal and the patient is not shocked, physiologically fractional excretion of sodium can vary. However, calculating FE Na can give useful clues in pathological states.

The normal renal response to intravascular fluid volume reduction is to excrete urine with a low sodium content. It does this by a number of mechanisms, including reduction of glomerular filtration rate (GFR) and aldosterone-stimulated sodium reabsorption, which requires intact tubules.

**Fractional excretion** of sodium (FE Na) is calculated from the urine (U) and plasma (P) concentrations (check

TABLE 5.6.A.4 Interpretation of excretion of sodium in pathological processes

	FE Na	Interpretation
Shock	< 1%	Tubules functioning = pre-renal failure
	> 1%	Acute tubular necrosis (ATN)
Hyponatraemia	< 1%	Salt loss or water overload (appropriate renal response)
	> 1%	Renal salt wasting (tubular disease)
Hypernatraemia	< 1%	Renal concentration defect
	> 1%	Salt overload (may be abuse)

### Urine collection and examination

Collecting urine from babies can be time consuming, but is important in establishing a diagnosis.

#### Methods of urine collection

- Clean catch into a sterile pot.
- Sterile collecting pads are cheaper and easier to use than an adhesive bag.
- For toddlers it is fine to use a potty or equivalent which has been thoroughly washed in hot water and detergent (using antiseptics or bleach, or scalding with boiling water, are unreliable).
- Suprapubic or catheter urine sampling is useful in ill children when antibiotics need to be started without delay.

### **Stick testing of urine and protein measurement**

- Dipstick testing for blood, protein and glucose is useful and reliable.
- Stick testing for nitrite to identify urinary tract infections (UTIs) is useful when positive to rule in UTIs, but unreliable when negative because it remains negative in 50% of cases.
- Stick testing for white cells to diagnose UTIs is unreliable because they may occur without white cells, and because white cell numbers also increase in the urine of febrile children without UTIs.

### **Laboratory measurement of protein in urine**

Urine protein should be < 20 mg protein/mmol creatinine in an early-morning sample of urine.

In nephrotic syndrome there is typically > 500 mg protein/mmol creatinine.

### **Microscopy of urine**

Microscopy of unspun fresh urine can provide a cheap and reliable way of rapidly diagnosing UTIs (by identifying bacteria directly, rather than by counting white cells), and of diagnosing schistosomiasis.

Red blood cells can be identified as being due to glomerulonephritis (when they are small, fragmented and of varied and distorted shapes), or due to other causes, such as trauma, stones or bladder inflammation (when they are all similar, and typically biconcave).

A standard light microscope with a magnification of × 400 is sufficient. Using a counting chamber (or a microscope slide with a scratched surface) and cover slip ensures that the microscope is focused at the correct plane, otherwise it is not possible to tell when microscoping a normal urine. A counting chamber with a mirrored surface is not essential, but makes identification of bacteria easier. Phase contrast makes identification even easier. A highly reliable, almost pocket-sized microscope (McArthur) is available with phase contrast.

### **Urinary tract imaging techniques**

All renal imaging techniques are relatively expensive, and many will have limited availability.

#### **Ultrasound scanning**

Useful information can only be obtained from ultrasound scanning by a skilled operator using an adequate machine. It demonstrates anatomy, but not function. It is ionising radiation free, and, when available, is now the first choice for initial imaging of most renal conditions in children. It is excellent at demonstrating cysts, stones and dilatation, and has a similar sensitivity to the intravenous urogram (IVU) for demonstrating long-standing or extensive scarring. Nephritis causes echo brightness of the kidneys. Tumours and cysts are easily seen, usually before they are visible by other modalities. Stones can be easily identified, but may be misinterpreted by the inexperienced because the whole stone is not seen; a bright line identifies where the ultrasound hits the front edge of the stone, and an acoustic shadow is thrown behind it. Nephrocalcinosis can be detected easily as white renal pyramids long before it can be seen on X-rays.

Ultrasound scanning during the acute phase of the UTI will often show dilatation of the ureters. It is therefore

suggested that this investigation should be undertaken 2–3 weeks after the infection. Any dilatation of the ureters should then be regarded as significant.

#### **Micturating cystogram (MCUG)**

This is still the most reliable way to assess vesico-ureteric reflux (VUR), but unfortunately depends on invasive urethral catheterisation, and depending on the equipment used it may require a relatively high dose of radiation. It should be reserved for use when the result will affect management. (Reflux is less commonly found in Afro-Caribbean children.)

This investigation is very important to confirm posterior urethral valves, one of the commonest obstructive uropathies seen in Afro-Caribbean children. The age of presentation is variable. When it presents in the neonatal period there is usually severe renal involvement.

#### **Plain abdominal X-ray**

This demonstrates radio-opaque stones, but these and nephrocalcinosis are usually easier to see on an ultrasound scan.

## **Urinary tract infections (UTIs)**

### **Background**

UTIs are very common. The risk of UTI is increased in babies with anatomical nephro-urological abnormalities, those with obstruction, those with VUR, and in girls. Management of VUR is controversial (see Section 5.6.B). Recent studies have shown that about 10% of girls and 3% of boys will have had a UTI diagnosed by the age of 16 years in the UK. Most children with UTIs have no underlying renal tract problem and suffer no serious consequences. However, UTI may be the first indicator of underlying renal tract abnormality, and may be associated with acquired renal scarring. Distinguishing the small group of children with important findings in this common condition remains a challenge, and the question of how intensively to investigate children after UTI remains controversial.

Large scars may cause renal failure, but even small ones can cause hypertension, often in later childhood or in adulthood. **To prevent serious sequelae of hypertension, children with scars should have lifelong blood pressure monitoring, as symptoms do not occur until serious irreparable disease is present.**

Infants are the most vulnerable to scarring, and most children who will acquire scarring will have started to do so by the age of 4 or 5 years. Animal studies and case series suggest that a UTI in a vulnerable individual may cause permanent scarring rapidly, in a matter of a very few days.

### **Diagnosis Symptoms**

Older children may present with typical 'cystitis' symptoms, typically due to bladder and urethral irritation, such as frequency and dysuria. Loin pain suggests likely upper renal tract involvement, but some children have few or no symptoms. Younger children (under 2 years of age) often only have non-specific symptoms such as anorexia, failure to thrive, unexplained fever or prolonged jaundice. Therefore all young children with an unexplained illness, particularly with a fever, should have a UTI excluded.

### Urine testing

A diagnosis is usually made by culture of a pure growth of one species of bacteria (most commonly *E. coli*) at a concentration of more than  $10^5$ /mL. Any concentration of bacteria in a suprapubic urine sample suggests infection. White blood cells ( $> 50$ /microlitre) are usually considered helpful in making the diagnosis, but UTIs can occur without any white cells (sometimes because they lyse in minutes), and urinary white blood cells can be found in children with fever who have some other cause and do not have a UTI.

As stated above, the organism most commonly involved is *E. coli*. If unusual organisms such as *Pseudomonas* are cultured at the first episode of UTI, it is mandatory to rule out an underlying urinary tract abnormality.

### Microscopy

Microscopy of freshly voided unspun urine is a quick, reliable and cheap way to diagnose UTIs if a  $\times 400$  microscope is available, and it enables an immediate diagnosis to be made. This allows the best-guess antibiotic to be started at once. Infected urines need to be cultured to obtain antibiotic sensitivities. Infected urine will contain many bacteria, up to thousands per high-power field, depending slightly on the depth of urine under the cover slip. The bacteria will all look the same, and are typically rods of identical length. Occasionally, UTIs are caused by streptococci, which are seen as long chains of dots. Separate small dots that appear to be swimming are not streptococci, but are phosphate crystals (the shimmering movement is due to Brownian motion). Most but not all children with UTIs will also have  $> 50$  white blood cells/microlitre, or at least 1 per 10 high-power fields.

If no bacteria are seen in about 5 high-power fields, the urine is not infected; the samples therefore need no further testing and can be discarded. Urine samples containing less than 1 bacterium per high-power field, or mixtures of rods and cocci, are likely to have been contaminated. Because this can be identified quickly, further samples can and should be collected until a clearly uninfected or infected one is obtained.

FIGURE 5.6.A.1 Rods seen in 10 high-powered fields.

### Imaging

Imaging after the first UTI is controversial. Young children and infants warrant more intensive investigation, as do those with a family history of renal disease.

### Ultrasound scanning

This should be undertaken for all children after their first recognised UTI in order to identify structural abnormalities,

and to try to identify scars. The likelihood of detecting a scar is much greater if it is large, involving multiple renal segments, or several years old, so that it will have had time to shrink and distort. Negative scans in young children (under 4 years) therefore need to be interpreted with caution.

Ultrasound scanning during the acute phase of the UTI will often show dilation of the ureters. It is therefore suggested that this investigation be undertaken 2–3 weeks after the infection. Any dilation of the ureters should then be regarded as significant.

### Micturating cystogram (MCUG)

It is probably ideal to perform an MCUG on very young children who have had a definite UTI. It is recommended that an MCUG be performed on all those under 1 year of age, because about a third will have an anatomical abnormality detected, usually vesico-ureteric reflux (VUR). However, there is not universal agreement about this, as there is a high percentage of normal results.

Posterior urethral valves may present with a UTI, especially in parts of the world where there is little or inadequate antenatal scanning. Thus in baby boys who have had a UTI, a good view of the urethra is essential.

Children with VUR are at risk of developing scars with UTI. Therefore finding VUR should make you suspect that the child may have a scar that was not identified by ultrasound.

Management of VUR is controversial (see Section 5.6.B). Prophylactic antibiotics may reduce the recurrence of infection; awareness and rapid treatment of infection is important. Most VUR is self-resolving and the aim of medical treatment is to keep free of UTI while allowing natural resolution (over a period of years). The possibility of VUR should be considered and, if possible, tested for if scarring is identified on ultrasound scanning.

Most VUR resolves with time; the lower the grade, the more likely it is that resolution will occur (80–90% resolution of grade 1–2 over 5 years).

### Treatment of UTIs

Encourage a high fluid intake to produce dilute urine and reduce the symptoms of dysuria.

Treat the child for 7 days initially with:

- oral trimethoprim (4 mg/kg twice daily)
- or cephalexin (10 mg/kg three times daily)
- or amoxicillin (1 month to 1 year 62.5 mg: 1–5 years 125 mg: 5–18 years 250 mg, all three times daily)
- or nitrofurantoin (3 months to 5 years: 750 micrograms/kg 4 times daily, 12–18 years: 50 mg 4 times daily).

Intravenous antibiotics may be necessary for very unwell children (particularly under 2 years of age) for as long as they are unable to tolerate oral medication. This may include **gentamicin** 7.5 mg/kg as a loading dose and then 7.5 mg/kg once daily only after confirmation that the plasma creatinine concentration is normal. If there is renal failure, no more should be given after the single dose, unless blood levels are available to guide the dosage. If necessary, change the antibiotic according to the laboratory sensitivity testing, when and if it is available.

Use of prophylactic antibiotics is controversial. Use may reduce recurrence of UTI and should be considered when there is VUR. A night-time dose of trimethoprim (2 mg/kg) or cephalexin (12.5 mg/kg maximum 125 mg) or nitrofurantoin

(1 mg/kg) may be used. Do not use amoxicillin for prophylaxis, because resistant organisms are likely to emerge.

In many resource-limited countries where there may be inadequate procedures for ensuring that antibiotics are used appropriately and where disposal of body fluids containing antibiotics may contaminate drinking water supplies, UTIs are resistant to trimethoprim but remain sensitive to cephalosporins and amoxicillin. Ideally, where available, cultures for antibiotic sensitivity should be undertaken.

## Hypertension

### Background

There is a steady increase in blood pressure with age, and definitions of hypertension are arbitrary. However, in most children with hypertension the blood pressure becomes very much higher than normal (unlike the majority of adult hypertension patients, whose blood pressure is only moderately elevated, causing a skewed frequency distribution curve). Primary hypertension is rare in children, and in more than 80% of them hypertension is secondary, and in at least 75% it is renal in origin. Diagnosis of the underlying cause is therefore very important in management. Children are

relatively intolerant of hypertension, so they are at major risk of sequelae, especially encephalopathy, blindness and death.

### Measurement

Blood pressure is best measured with a simple sphygmomanometer, as automatic blood pressure machines may be unreliable. It is more reliable to use the largest cuff that will fit on to the upper arm, rather than using 'formulae' that relate the cuff size to the child's size. A cuff that is too large will not significantly underestimate the blood pressure, but one that is too small will overestimate it. In children, it is best to use systolic blood pressure; it is just as important as diastolic pressure for diagnosis and treatment, and is easier and more reliable to measure. In most children, palpating the reappearance of the pulse at the wrist is as accurate as using a stethoscope at the antecubital fossa, or a Doppler (if available) may be used at the wrist to detect the reappearance of the pulse. High values should be confirmed with the child relaxed to reduce the effects of anxiety. Measurements should be repeated several times if they are abnormal. Table 5.6.A.5 shows the upper limit of normal blood pressure ranges according to age.

**TABLE 5.6.A.5 Mean, upper limit of normal and dangerous levels of systolic blood pressure in children of different ages**

Value	1 month	1 year	5 years	10 years	15 years
Mean (mmHg)	75	85	95	105	115
Upper limit of normal (mmHg)	80	90	100	110	125
Needing urgent treatment (mmHg)	100*	120	130	140	150

\*In infants, the likeliest cause of hypertension is coarctation of the aorta.

**TABLE 5.6.A.6 Oral hypotensive drugs\* for children, with maximum doses**

Class of drug	Example	Maximum dose (mg/kg/day)
Calcium-channel blocker	Nifedipine	1
Vasodilator	Hydralazine	10
Beta-blocker	Atenolol	1
Angiotensin-converting-enzyme (ACE) inhibitor <sup>†</sup>	Captopril	5

\* These are often given in combination to achieve a powerful effect with fewer side effects.

<sup>†</sup> ACE inhibitors must be started by giving a very low test dose first and building up slowly. They must be used with great care if renal artery stenosis is suspected.

### Causes and diagnosis

It is important to find the underlying cause of the hypertension to guide management. Sometimes the cause is clear from the history, examination or urine testing, and sometimes it requires diagnostic imaging. Ultrasound is the most useful screening technique, but is quite operator dependent. Hypertension can be caused by renal scarring that is difficult to detect with ultrasound.

### Treatment

If the hypertension is known to be of recent onset, as in acute glomerulonephritis, it is safe to reduce the blood pressure quickly. Usually salt and water overload is a major factor; if so, restrict sodium and give furosemide 1–2 mg/kg (the oral route is as effective as the intravenous one).

In other cases, treat the blood pressure slowly because cerebral arterial vasoconstriction may have occurred to protect the brain parenchyma from the impact of the

hypertension, and made the cerebral blood flow dependent on a high blood pressure being sustained.

**A rapid fall in blood pressure may cause cerebral infarction and blindness.** Reduction over 2 days or more allows the vascular tone to return to normal. **Slow control may be achieved by introducing oral hypotensive drugs slowly at well below the maximum dose.**

### Glomerular disease

Glomerular disease is characterised by proteinuria with or without haematuria. It may be caused by a primary glomerular disease or be secondary to a systemic illness, and it can cause a wide spectrum of clinical pictures, including the following:

- nephrotic syndrome
- acute glomerulonephritis
- chronic glomerulonephritis
- asymptomatic proteinuria or haematuria.

TABLE 5.6.A.7 Renal and arterial causes of hypertension in childhood

Diagnosis	Notes	Renal ultrasound
Reflux nephropathy	Also called pyelonephritis ( <i>see</i> UTI)	Focal scars or shrunken kidney
Glomerulonephritis Post-infective Other causes	Typically have proteinuria and glomerular haematuria. Typically after a streptococcal infection, sore throat/skin infection. Give a 10-day course of penicillin May have evidence of Henoch–Schönlein purpura or lupus; if not, renal biopsy is needed	Echo bright
Inherited polycystic disease Infantile type (recessive) Adult type (dominant)	Kidneys large at birth, typically severe hypertension, renal failure in early life Seldom causes renal failure in childhood, but may cause hypertension. Screen blood pressure of children of affected parents	Huge, homogeneous, echo bright Discrete cysts develop through childhood
Narrowed arterial supply Coarctation of the aorta Renal artery stenosis	Check femoral pulses; may need surgical treatment or balloon angioplasty Requires long-term medical treatment. May occur with neurofibromatosis; screen for this	May be small, and difficult to diagnose without expensive imaging

### Nephrotic syndrome

#### Background and clinical features

The clinical picture is of proteinuria, hypoalbuminaemia and oedema.

It must be differentiated from other causes of hypoalbuminaemia, such as protein malnutrition (*see* Section 5.10.B) and protein-losing enteropathy (*see* Section 5.12.D).

It is traditionally classified as early-onset (congenital, diagnosed at under 6 months of age) and later-onset types.

#### Early onset

Children with congenital nephrotic syndrome frequently do not survive, many of them dying early of protein malnutrition, infection or thrombosis unless they are aggressively treated.

Those with severe proteinuria, including the recessively inherited Finnish type, tend to fare worst. Diffuse mesangial sclerosis is a similar condition, but is usually less acute. Congenital syphilis can cause neonatal nephrotic syndrome which may respond to penicillin treatment. Some early nephrotic syndromes are self-resolving, but this is uncommon.

Treatment is often difficult. Early-onset nephrotic syndrome is generally not responsive to steroids. Treatment may be supportive, including frequent albumin infusions, and in the most severe cases may require early unilateral or even bilateral nephrectomy, leading to dialysis and transplantation. Reduction of proteinuria by the use of ACE inhibitors or indomethacin may be attempted, but very careful monitoring is required.

#### Later onset

Most children with nephrotic syndrome presenting in childhood (after the age of 1 year and before the teenage years)

are steroid responsive, losing their proteinuria within 1 to 2 months of treatment. They share clinical characteristics (*see* Table 5.6.A.8). Children with steroid-resistant nephrotic syndrome may have a range of diagnoses, including focal segmental glomerulosclerosis, Henoch–Schönlein purpura, lupus and mesangiocapillary glomerulonephritis. There is a strong association with infections, especially malaria and hepatitis B, as well as hepatitis C and HIV.

#### Acute management

It is reasonable to attempt to induce a remission with steroids, unless the clinical picture virtually excludes the possibility of steroid sensitivity.

- Use prednisolone 60 mg/m<sup>2</sup> daily (*see* Section 9 to convert from body weight to surface area) for up to 6 weeks (about 95% of children who are going to respond do so within 1 month). Monitor carefully for the development of hypertension on steroids.
- Limit fluid retention by imposing a tight dietary sodium restriction.
- Prevent secondary pneumococcal infection with prophylactic penicillin V (125 mg twice daily up to 5 years of age, and 250 mg twice daily thereafter).
- Avoid the sequelae of hypovolaemia (thrombosis).
- Intravascular hypovolaemia is a high risk and should be monitored clinically by the appearance of cold peripheries and sometimes abdominal pain. There may be initial paradoxical hypertension, and hypotension may not occur until late. The best laboratory test is a urinary sodium concentration of less than 15 mmol/litre, especially if combined with a urine osmolality of over 800 osmol/kg. Blood tests are seldom helpful.
- Treatment of hypovolaemia should be with 1 gram/kg

TABLE 5.6.A.8 Clinical characteristics of steroid-sensitive and steroid-resistant nephrotic syndrome

Feature	Steroid-sensitive nephrotic syndrome	Steroid-resistant nephrotic syndrome
Gender	Male > female	Varies with condition
Age	1–3 years	Usually older
Blood pressure	Normal	Often elevated
Speed of onset	Rapid (days or weeks)	Usually weeks or months
Haematuria	Microscopic	Often macroscopic
Plasma creatinine concentration	Normal or low unless hypovolaemic	May be elevated

of IV 20% albumin over 4 hours, preferably with 2 mg/kg of IV furosemide given halfway through. If shocked, give 10 mL/kg of 4.5% albumin.

- Avoid the use of furosemide in the acute situation without adequate volume replacement.

### **Subsequent management if steroid-sensitive**

This is ideally based on daily home monitoring of the morning urine protein level by stick testing. A common definition of a relapse is ++ proteinuria for 7 consecutive days, or +++ for 3 days, and it should be responded to by reintroducing salt restriction, penicillin V and prednisolone.

Protocols for doses and duration of use of prednisolone and steroid-sparing agents vary. The following is a proposed example:

**First presentation:** give prednisolone 60 mg/m<sup>2</sup> daily (see Section 9), and if the patient responds (by loss of proteinuria), complete 6 weeks of 60 mg/m<sup>2</sup> daily, followed by 40 mg/m<sup>2</sup> on alternate days for a further 6 weeks.

**Subsequent relapse:** restart 60 mg/m<sup>2</sup> daily until there is no proteinuria for 3 days, then give 40 mg/m<sup>2</sup> on alternate days for a further 4 weeks.

**Frequent relapses:** give prophylactic low-dose (e.g. 200 micrograms/kg) alternate-day prednisolone. Titrate the dose up until either relapses are prevented, or steroid side effects develop.

If steroid prophylaxis causes unacceptable side effects, add prophylactic levamisole 2.5 mg/kg on alternate days (approximately 50% of cases will benefit), which can be used relatively long term.

If levamisole is ineffective, consider giving cyclophosphamide 2.5–3 mg/kg daily for 12 weeks, monitoring weekly with white blood cell count, and reducing the dose if the absolute neutrophil count falls below  $1 \times 10^9$ /litre, or stopping if it falls below  $0.5 \times 10^9$ /litre. Or give 6 × monthly cyclophosphamide infusion (600 mg/m<sup>2</sup>). Note that this is potentially dangerous in resource-limited circumstances where infections are frequent.

### **Subsequent management if steroid resistant**

Persistent haematuria and hypertension at the first presentation may be early warning signs of steroid resistance. Steroids should be used with caution, as the hypertension may be aggravated.

There is a wide range of conditions that may induce steroid-resistant nephrotic syndrome. These include infective agents, autoimmune diseases, some drugs and poisons, and unknown causes. The cause may be apparent from the history and examination and other tests, but **in most cases the diagnosis relies on the accurate interpretation of a kidney biopsy.**

The infective causes include hepatitis B, HIV, *Schistosoma mansoni*, leprosy, tuberculosis and malaria. These conditions should be sought in those parts of the world where they are likely to be found, and treated appropriately. Hepatitis B typically causes a membranous nephropathy which tends to improve spontaneously. Post-streptococcal glomerulonephritis may cause nephrotic syndrome, but it is seldom the presenting feature. Although it is not the only cause of this clinical picture, **it is sensible to treat any child who develops nephrotic syndrome after an acute nephrotic illness with 10 days of oral penicillin V, 1–6 years 125 mg, 6–12 years 250 mg, 12–18 years 500 mg per dose 6-hourly.**

The autoimmune causes of nephrotic syndrome include Henoch–Schönlein purpura and IgA nephritis, lupus, mesangiocapillary glomerulonephritis, and some cases of membranous nephropathy. The commonest cause of steroid-resistant nephrotic syndrome in many parts of the world is focal segmental glomerulosclerosis (FSGS), the pathophysiological mechanism of which is unknown. In some of these conditions (including lupus, mesangiocapillary glomerulonephritis and FSGS), some children do respond to steroids. However, many children with steroid-resistant nephrotic syndrome do not respond to any treatment at all. Most of those who do only respond to more powerful immunosuppressants, such as cyclophosphamide or cyclosporine. Some conditions have been treated with plasmapheresis, but in most conditions the evidence for this is purely anecdotal. These treatments are difficult to use because they are expensive, and they require close monitoring for side effects. Even under ideal medical conditions with considerable resources, many cases still progress to end-stage renal failure.

### **Protein in the diet**

Children with nephrotic syndrome may lose huge quantities of protein in their urine. If they are on a low-protein diet they will quickly lose muscle mass as the body proteins are utilised to synthesise plasma albumin. A relatively high-protein diet will be muscle sparing, but will make no significant difference to the plasma albumin concentration.

### **Glomerulonephritis**

Glomerulonephritis (GN) strictly refers to inflammation of the glomeruli with cellular proliferation, although it is often used to include other glomerulopathies such as FSGS and membranous nephropathy, both of which typically cause steroid-resistant nephrotic syndrome.

The commonest cause of childhood glomerulonephritis varies widely across the world. In resource-limited countries, acute post-streptococcal glomerulonephritis is the commonest type. In wealthier countries this is now becoming more unusual, and IgA nephropathy predominates.

### **Post-streptococcal glomerulonephritis**

This is caused by antibodies produced in response to specific strains of streptococci. These bacteria typically cause throat and skin infections. The antibodies then form complexes and are deposited within the glomeruli along with C3. Because it takes time for antibody production to occur, the signs and symptoms of nephritis do not usually begin to appear until 10–20 days after the start of the infection.

The inflamed glomeruli leak blood and protein, so the first symptom is usually the child passing smoky or frankly bloody urine. The glomerular filtration rate usually falls slightly, so the plasma creatinine concentration is typically slightly elevated. Also the tubules reabsorb sodium and water excessively, which causes water retention out of proportion to the fall in glomerular filtration rate. This leads to swelling, which is most easily noticed around the eyes and face, and in the legs, but which does not pit as easily as oedema does in the nephrotic syndrome. The water retention also leads to hypertension. Most children with acute post-streptococcal glomerulonephritis do not lose enough protein into the urine to cause nephrotic syndrome as well, although some do, producing a mixed nephrotic–nephritic picture.

A presumptive diagnosis is made by examination of the urine for the presence of protein (using stick tests) and glomerular red cells and casts (by microscopy; see Section 8.S), in a child with a history of a recent sore throat or skin infection. Culture of a specific strain of *Streptococcus* from a throat or skin swab may confirm the diagnosis.

It is not reliable to make a diagnosis from a single titre of an anti-streptococcal antibody such as the ASOT or the anti-DNase B, because many children have an elevated level from previous exposure to other strains of streptococci. Confirmation requires a significant rise between two titres taken at least 10 days apart.

If plasma complement levels (C3 and C4) can be measured, they may give a clue to the underlying diagnosis but are not confirmatory. In post-streptococcal glomerulonephritis the plasma C3 concentration is reduced, and often stays subnormal for up to 6 weeks before rising back to normal. The plasma C3 level is usually low in mesangiocapillary glomerulonephritis, and the C3 and C4 levels are often both low in lupus, and these conditions may present clinically identically to post-streptococcal glomerulonephritis.

### Treatment

If post-streptococcal glomerulonephritis is suspected, immediately start penicillin V, 1–6 years 125 mg, 6–12 years 250 mg, 12–18 years 500 mg per dose four times daily for 10 days, to eradicate the organism. There is always a delay in obtaining bacteriological confirmation, either from culture or from paired titres, so it is best to start the penicillin at once, and use these tests as retrospective confirmatory evidence.

It is essential to measure the child's fluid intake and losses accurately as well as daily weighing, and restrict the amounts of sodium and water allowed. This should be to balance the losses, or to cause net fluid reduction if the child is significantly fluid-overloaded. The insensible loss is about 300 mL/m<sup>2</sup> daily, but will be higher in a hot dry climate. (Estimate the surface area from Table 9.16 in Section 9.) **Salt restriction is far more important than water restriction**, and is sometimes all that is required for a child to maintain fluid balance. This is because the tubules retain sodium avidly, so any salt that is eaten will be retained in the body and cause hypernatraemia. This drives an intense thirst, and it then becomes almost impossible to stop the child drinking. By contrast, a tight salt restriction will minimise the thirst, which aids management.

If the plasma albumin concentration is normal or only slightly reduced, it is safe to give an oral dose of furosemide, 1–2 mg/kg. This will increase the urinary excretion of sodium and water, and thus improve fluid overload and hypertension. It will also increase potassium loss, which is helpful if the fall in glomerular filtration has led to hyperkalaemia. It may be repeated as needed. However, if the child has a very low plasma albumin concentration from a mixed nephrotic–nephritic picture, giving furosemide may precipitate hypovolaemia. Because of this, either give intravenous albumin combined with furosemide (see section on acute management of nephrotic syndrome), or give furosemide under close observation and be prepared to give albumin if hypovolaemia occurs. Cold peripheries and abdominal pain (from splanchnic vasoconstriction) are important signs of this.

The raised blood pressure is frequently fully controlled

by salt and water restriction and furosemide, but in some cases hypotensive agents are also needed (see Table 5.6.A.5). Under such acute conditions it is safe to reduce the blood pressure rapidly.

In children with post-streptococcal glomerulonephritis, the kidneys usually make a full recovery, and progression to renal failure is rare. Therefore most of these children will have no sequelae, provided that their fluid and electrolyte balance and blood pressure are carefully managed.

### IgA nephropathy (Berger's disease)

The typical presentation is of a child aged 5–15 years who develops an acute upper respiratory tract illness, and simultaneously has heavy haematuria that lasts for several days. Urine microscopy reveals distorted 'glomerular' red cells (see above). Usually the urine then clears completely, but the haematuria may return with subsequent illnesses. Some children with IgA disease have a more insidious illness with little or no macroscopic haematuria.

The diagnosis is suggested in children who present with recurrent heavy glomerular haematuria. There may be a family history. The plasma IgA concentration may be elevated in affected children, but this test is a poor discriminator. In children with a less obvious clinical picture the diagnosis can only be made on a kidney biopsy. Antibody staining will show granular deposits of IgA in glomeruli that have mesangial proliferation. Histologically, IgA disease is identical to Henoch–Schönlein nephritis.

The best prognostic indicator in IgA nephropathy is the amount of proteinuria that persists between the acute episodes of haematuria. Most children have heavy haematuria but little or no proteinuria between attacks, and virtually all of these grow out of the condition, usually without any sequelae. Often the ones with the most dramatic haematuria recover particularly well. The children with a more insidious onset are more likely to have persistent proteinuria, and to continue with the condition into adulthood, eventually developing end-stage renal failure by middle age. There is no good evidence for treatments to prevent this happening. However, adequate blood pressure control is important in slowing the progression of renal disease.

Rarely, IgA disease first presents as a severe rapidly progressing glomerulonephritis. The picture is one of an acute nephritis in which the creatinine level rises rapidly and inexorably. It is therefore clinically indistinguishable from any other rapidly progressive glomerulonephritis, other than by renal biopsy. Treatment options include various immunosuppressive drugs and plasmapheresis. These have not been subjected to controlled trials, are expensive and may lead to serious complications.

### Haematuria

- Urine test sticks are highly sensitive and detect the smallest traces of blood.
- **For most conditions that can cause haematuria, the clinical significance is best predicted by the quantity of protein present, so always test for that, too.**
- **The most important test for determining the cause of haematuria is to check the shape of the red cells, ideally under phase-contrast microscopy (see above).**

### Macroscopic glomerular haematuria

The presence of distorted red cells may be due to any

form of glomerulonephritis, as listed above. The history of a simultaneous infection may suggest IgA nephropathy, while a recent infection points to post-streptococcal glomerulonephritis. The presence of a rash, or joint involvement, or abdominal pain might suggest Henoch–Schönlein or lupus nephritis as causes, but most other types can only be diagnosed on renal biopsy.

### **Macroscopic non-glomerular haematuria**

The presence of red cells with a normal biconcave appearance indicates bleeding into the urine, and excludes glomerulonephritis as a cause. This may be due to trauma, but this would have to be major, because the renal tract is physically well protected. Minor trauma will only cause bleeding if the kidney is enlarged with cysts, as in adult-type (dominantly inherited) polycystic kidney disease, or if it is vulnerable due to being ectopically positioned. Urinary tract stones can also cause bleeding.

The cystitis caused by a urinary tract infection or by *Schistosoma mansoni* may cause frank haematuria. These can be distinguished on phase-contrast microscopy of a fresh sample, when either bacteria or ova are easily visible.

Although bleeding into the urine can be due to a malignancy, this is rare in childhood, and is then usually from a Wilms' tumour. Frank haematuria in a newborn suggests a renal vein thrombosis, which may be unilateral or bilateral, and the affected kidney is usually easily palpated.

Trauma, stones, an ectopic kidney, adult polycystic disease, a Wilms' tumour and renal vein thrombosis can each be identified by their characteristic appearance on ultrasound scanning. In cases for which no cause has been found, cystoscopy should be considered.

### **Microscopic glomerular haematuria**

Blood may be detected in urine that looks completely clear. Rarely, the red cells appear normal on microscopy; these children should be investigated as for frank non-glomerular haematuria. Most children with microscopic haematuria have distorted 'glomerular' red cells. In this group, management depends on how much proteinuria they have. Those with massive nephrotic-level proteinuria should be assessed and managed in the same way as for other children with nephrotic syndrome. Those with moderate proteinuria are likely to have a form of glomerulonephritis. The vast majority of children will not have any proteinuria with their microscopic haematuria. Investigation of this group is unlikely to identify a cause. If the renal ultrasound scan is normal, these children should be monitored annually with just a urine stick test and blood pressure measurement. If the blood disappears, follow-up may be discontinued. If it persists without proteinuria or hypertension developing, continue the annual reviews. If proteinuria or hypertension appears, the child needs to be investigated accordingly.

## **Haemolytic uraemic syndrome (HUS)**

HUS is a common cause of established (parenchymal) acute renal failure (see above). Children with HUS fall broadly into two groups, according to their pathophysiological mechanisms. It is important to divide them clinically into diarrhoea-associated HUS (D + HUS) and diarrhoea-negative HUS (D – HUS).

### **D + HUS**

This is the common type, and it occurs in otherwise normal children, often in outbreaks or clusters of cases. It is triggered by a toxin that is produced by some colonic bacteria, including *Shigella* and some strains of enteropathic *E. coli*. Infection is from ingestion of contaminated food or fluids. Public health measures to identify a source of the organism are important in preventing and limiting outbreaks. Typically the child has several days of bloody diarrhoea, and then becomes pale and mildly jaundiced (from haemolytic anaemia), may bruise and have petechiae (from thrombocytopenia), and develops oligo-anuria. A blood film shows fragmented red blood cells and a low platelet count.

Antibiotics are not of benefit, and may worsen the condition by causing the acute release of more bacterial toxin. Blood transfusion may be needed (usually when the haemoglobin level falls below 6 grams/dL). Platelet transfusion may exacerbate the condition, and should only be used in the face of uncontrolled bleeding. There is no evidence that any specific medication is of benefit. Management is as for other children with acute renal failure (see above). Mortality from this condition has decreased with active management of fluid and electrolyte imbalance and dialysis.

In a minority of cases, D + HUS can affect other organs, sometimes severely. Effects can include bowel perforations, pancreatitis with diabetes mellitus, and cerebral involvement, with fits, coma and death.

The long-term outcome for children who survive the acute episode of D + HUS is relatively good. Most appear to fully recover renal function, although up to 25% have persistent hypertension or proteinuria. Few develop end-stage renal failure.

### **D – HUS**

This variant is very rare, and is often associated with a functional or actual deficiency of factor H, so a minor trigger (such as a minor viral illness) can precipitate the typical clinical and haematological HUS picture, but without a diarrhoeal prodrome. Typically, D – HUS patients fare much worse long term than D + HUS patients.

### **Confusing findings**

Blood may be present on stick testing without any red cells visible on microscopy. This indicates acute haemolysis such as may occur in glucose-6-phosphate dehydrogenase (G6PD) deficiency or malaria.

Large quantities of urate make the urine brick red. Although families may think the colour resembles blood, it is easily distinguished visually. Porphyrinuria is a very rare cause of confusion. Ingestion of red vegetables, especially beetroot, causes red urine. Rarely, but this possibility must not be forgotten, a parent may place their own blood in a child's urine, leading to unnecessary investigations. This condition is called fabricated or induced illness (FI).

## **Urinary tract stones**

### **Background**

There is wide geographical variation in the frequency of stone disease, and there have been major changes in prevalence with time within populations. The incidence appears to be influenced by a wide range of factors, such as climate, race, diet, dehydration, infections and socioeconomic status.

### Causes

There are three broad causes of urinary tract stones (which may coexist in individual children).

#### ***Proteus urinary tract infections***

The mechanism is twofold. The infection results in turbid urine containing cells and debris, and secondly *Proteus* splits urea to form ammonia, which raises the urinary pH. Because calcium ammonium phosphate is relatively insoluble in alkaline urine, it will co-precipitate readily on to the urinary debris under these conditions to form thick sludge initially, and subsequently a stone. This explains why these stones take up the shape of the tract they form in ('stag-horns' in the pelvi-calyceal system, 'date stones' in the lower ureter, and round stones in the bladder). Preschool boys are affected much more than any other groups.

#### ***Relative dehydration and possibly dietary factors***

The mechanisms of stone formation are probably similar to those for infection stones, with chemicals normally found in the urine reaching relatively high concentrations due to low urine volumes, and high dietary intake and consequent excretion rates of relatively insoluble chemicals.

#### ***Rare inherited metabolic conditions***

These result in excessive urinary excretion of poorly soluble chemicals. Calcium stones are most commonly caused by isolated hypercalciuria (without hypercalcaemia), and more rarely by hypercalciuria combined with hypercalcaemia in hyperparathyroidism. Cystine stones are seen due to an inherited (dominantly or recessively) failure of the proximal tubules to reabsorb this amino acid. Oxalate stones may be due to excessive gut absorption of oxalate when the calcium is unavailable to precipitate it, such as with steatorrhoea. Rarely it is also produced and excreted in excess due to a recessive liver enzyme deficiency.

#### **Presentation and diagnosis**

Children may pass a stone or present with severe colicky abdominal pain (typically in one loin), often with frank haematuria. Ultrasound scanning is a sensitive imaging tool, showing the front edge as a bright line, with an acoustic shadow thrown behind it, rather than showing the whole stone. Nephrocalcinosis associated with hypercalciuria is seen as white (echo-bright) renal pyramids.

A plain abdominal X-ray will show radio-opaque stones, and is thus useful for distinguishing the type. Similarly, the appearance of a passed stone or fragment may aid identification. Infection and dehydration stones are usually grey, and only moderately X-ray dense, and take up the shape of the collecting system. Calcium (white) and cystine (yellow) stones are very X-ray dense, may grow up to 2 cm or

more in diameter, and are typically smooth, and round or oval wherever they form. Oxalate stones are yellowish-buff coloured and typically grow to 5 mm, with irregular spiky edges. A high oxalate load will result in many small stones rather than large individual ones.

If the type of stone is not clear from the history, chemical measurements can be made and compared with urinary creatinine measurements on an untimed 'spot' urine sample collected during the morning (but not the overnight sample).

The **upper normal limits** of the ratio of the chemical x to creatinine concentrations, both in mmol/litre, are as follows:

- calcium:creatinine ratio of < 0.8
- cystine:creatinine ratio of < 25
- oxalate:creatinine ratio of < 0.18.

These ratios will be normal in children with infection stones, or those secondary to dehydration.

### Treatment

#### ***Removal of stones***

Small stones may be passed spontaneously. Ureteric colic may be excruciatingly painful and should be treated with powerful opiate analgesia (see Section 1.15). Spasmolytics such as hyoscine butylbromide (age 6–12 years: 5–10 mg IV or orally; age > 12 years: 20 mg IV or orally) are sometimes used, but are often not effective. Larger stones may need surgical removal by open surgery or cystoscopy. Percutaneous nephrostomy or lithotripsy may be used where specialist facilities exist.

#### ***Preventing recurrences***

Infection stones should not recur in the absence of infection. Stones due to metabolic causes and those related to dehydration are all helped by a consistently high fluid intake, but it is probably even more important to avoid episodes of acute dehydration (e.g. with vomiting or diarrhoea) than increasing daily fluid intake.

Chlorothiazide up to 10 mg/kg twice daily reduces urinary calcium excretion; its dose can be titrated in hypercalciuria to keep the urinary calcium:creatinine ratio in the normal range. Furosemide should be avoided because it increases urinary calcium excretion.

Children with hyperparathyroidism may require parathyroidectomy.

In cystinuria, it is essential to maintain a lifelong high fluid intake. Alkalinising the urine increases the solubility of cystine. Give oral sodium bicarbonate supplements (start with 1 mmol/kg daily) until the urine pH is usually  $\geq 7$  on home testing with strip test paper.

With oxalate stones due to malabsorption, treat the underlying bowel problem. Inherited hyperoxaluria typically leads to renal failure and widespread calcification of soft tissue.

## 5.6.B The child with vesico-ureteric reflux

### BOX 5.6.B.1 Minimum standards

- Ultrasound scanning.
- Micturating cystogram.
- Antibiotics: trimethoprim, nitrofurantoin, nalidixic acid.
- Paediatric surgery.

### Introduction

Vesico-ureteric reflux (VUR), which is the abnormal flow of urine from the bladder into the upper urinary tract, occurs in about 1 in 100 members of the general population and is more common in girls. Reflux nephropathy is a cause of hypertension and chronic renal failure in children and young adults.

Renal scarring is an acquired phenomenon that usually occurs during the first few years of life, and rarely after the age of 5 years.

### Grades of VUR (International Reflux Study Group classification)

These are as follows:

- Grade I: partial filling of an undilated ureter.
- Grade II: total filling of an undilated upper urinary tract.
- Grade III: dilated calyces but sharp fornices.
- Grade IV: blunted fornices and degree of dilatation greater than in lower stages.
- Grade V: massive hydronephrosis and tortuosity of the ureters.

Figure 5.6.B.1 illustrates the different grades of VUR.

### Clinical presentation

- VUR almost always occurs in conjunction with an associated UTI.
- It is rarely a cause of flank pain.
- Fever is the single most important symptom for differentiating children with upper tract infections (pyelonephritis) from those with lower tract infections (cystitis).

### Investigations

The minimal acceptable standards of investigation would include the following:

- ultrasonography (useful for detection of dilatation, but not for demonstrating scars or reflux)
- micturating cystourethrogram

**FIGURE 5.6.B.1** The different grades of vesico-ureteric reflux (VUR) according to the International Reflux Study Group classification.

- investigations in siblings: VUR occurs in up to 30% of siblings, and families should be made aware of this.

### Medical management

- Spontaneous resolution occurs most often in the first 2–3 years after diagnosis and then at the rate of 10–15% per year.
- The main goal is the prevention of ascending UTI and renal scarring.

The following measures should be used to prevent UTI:

- Proper wiping techniques (girls should be taught to wipe their bottoms backwards, and to avoid using soap on the vulva if possible; they should be discouraged from wearing nylon knickers).
- Frequent voiding.
- Avoidance of constipation.
- Low-pressure voiding.
- Continuous antibiotic prophylaxis, usually maintained for 2 years. Trimethoprim, 2 mg/kg/day, is the usual prophylactic agent. If breakthrough infections that are resistant to this occur, a suitable alternative prophylactic such as nitrofurantoin (1 mg/kg/day) or nalidixic acid (7.5 mg/kg twice daily) may be used.

In children of all ages the preferred initial treatment is medical, but they need regular follow-up. The need for surgery is becoming increasingly uncommon, but re-implantation of the ureters is occasionally necessary if the VUR is not resolving, is bilateral, in late presentations and in children, or with higher grades of VUR and with antenatally detected hydronephrosis.

## 5.6.C Acute renal failure

### BOX 5.6.C.1 Minimum standards

- **Peritoneal dialysis.**
- ECG monitoring.
- Nebulised salbutamol.
- Vitamin D with serum calcium monitoring.
- Blood transfusion.
- Low protein and sodium diet.
- Furosemide.
- Antibiotics.

### Types of acute renal failure

Acute renal failure (ARF) may be caused by a wide variety of insults to the renal tubule cells. Each type of ARF has a different management. It is therefore important to distinguish them clearly.

#### *Pre-renal failure*

This is caused by poor perfusion and hypovolaemia secondary to gastroenteritis, septic shock, haemorrhage, burns, nephrotic syndrome or cardiac failure.

#### *Established (intra-) renal failure*

Established renal failure most commonly results from more extreme or more prolonged versions of the same insults that cause pre-renal failure, leading to acute damage to the kidney cells. Other causes include haemolytic-uraemic syndrome and drug toxicity and acute rapidly progressive glomerulonephritis. The prognosis for recovery depends on the underlying cause, whether only the tubule cells are damaged, and whether the glomeruli are also involved.

#### *Post-renal failure*

Acute complete obstructions of the renal tract causing failure of urine production are rare, but include posterior urethral valves, obstruction of a single kidney, bilateral stones and trauma.

### Diagnosis and initial management of ARF

#### *Pre-renal ARF*

Pre-renal failure is essentially a reversible renal dysfunction due to the kidneys being under-perfused, but where the perfusion is still sufficient to prevent necrosis of the renal tissue.

The clinical diagnosis is made by recognising the signs of shock, the commonest of which are a delayed capillary refill time, cool peripheries, a weak pulse, and usually a low blood pressure. However, the blood pressure may also be unexpectedly high because of the powerful renin drive in response to hypovolaemia. An important feature is that the child may complain of abdominal pain (induced by splanchnic ischaemia as blood flow is diverted from the gut to more vital organs).

Laboratory support of the clinical diagnosis is made by measuring the fractional excretion of sodium (FE Na; see Section 5.6.A). This requires measurement of the sodium and creatinine concentrations in a sample of blood and urine. If the FE Na is less than 1% this indicates that the renal tubule cells are still alive, and able to respond to shock by reabsorbing sodium avidly. This therefore confirms a diagnosis of pre-renal failure. No other tests, including

measurements of osmolality, urinary sodium concentration alone, or urine microscopy, can reliably differentiate pre-renal from established renal failure. Ultrasound scanning is useful to exclude obstruction, but cannot differentiate pre-renal from established renal failure.

#### **Treatment**

**This consists of urgent volume expansion followed by furosemide.** Percentage dehydration should be estimated, and rehydration should be with Hartmann's or Ringer-lactate solution, plasma, 4.5% albumin or other similar isotonic fluid or plasma substitute. Give 10–20 mL/kg as rapidly as possible initially, and repeat if necessary. If urine output does not commence after adequate volume replacement and furosemide, consider whether this is actually established renal failure, and **do not continue repeating fluid boluses**. Thereafter give Hartmann's or Ringer-lactate solution to fully correct the fluid deficit within 2–4 hours. The deficit can be estimated by multiplying the child's weight by the estimated percentage dehydration. For example, a 6 kg infant estimated to be 10% dehydrated is deficient of approximately 600 mL. According to the above guidelines he would receive 60–240 mL of plasma or plasma substitute very rapidly, and the rest of the 600 mL as Hartmann's or Ringer-lactate solution over a few hours.

Once rehydration has started, give furosemide 2 mg/kg orally or IV. **If there is a urine output response to furosemide this will usually indicate that the renal failure can recover.** If the blood pressure remains markedly depressed after rehydration, it may be due to cardiogenic shock, so consider administering inotropes (see Section 5.5.C).

#### *Established ARF*

Established failure is due to acute parenchymal damage to the kidneys. In most cases the causes are exactly the same as for pre-renal failure, but an increased severity or duration of the insult has led to death of some of the renal cells. Therefore the pertinent history and clinical signs are usually the same as for pre-renal failure. Other cases are due to directly toxic effects of drugs such as gentamicin, or poisons to the tubular cells. Some forms of glomerulonephritis may lead to ARF (see Section 5.6.A), as may the arteriolar disease, haemolytic-uraemic syndrome.

The laboratory diagnosis of established renal failure due to under-perfusion or an ischaemic insult can be made reliably by calculating the FE Na from a measurement of the sodium and creatinine concentrations in a plasma sample and a spot urine sample. The FE Na is typically greater than 2% because the damaged tubules are usually unable to reabsorb sodium avidly. Again, attempts to use other laboratory criteria are unreliable. The history, clinical examination and laboratory confirmation of glomerulonephritis and haemolytic-uraemic syndrome are described in Section 5.6.A.

The most vulnerable region of the kidney is the highly metabolically active mass of proximal tubule cells. If these cells alone die from the insult, this causes acute tubular necrosis (ATN), which will fully recover in 2–4 weeks if the child is maintained in good health during that period of renal failure (likely to require dialysis). More severe insults

may result in damage to some or all of the glomeruli as well, which are in the renal cortex. Glomerular damage is irreversible, and acute cortical necrosis may therefore result in chronic or end-stage renal failure.

Fluid repletion and furosemide administration will not result in recovery of renal function. If an FE Na is not available to distinguish between pre-renal and established ARF, it is sensible to give a trial of fluid bolus and furosemide. Management consists of correcting the dehydration, as for pre-renal failure, and thereafter careful maintenance of fluids (usually restriction) and electrolyte balance and nutrition (restricting potassium intake) while it is hoped that some recovery of tubule cells will lead to recovery of kidney function. **This is likely to require dialysis.** If recovery is going to happen it is likely to have begun by 4 weeks, but can occur up to 2 or even 3 months later. There are no reliable imaging techniques for determining whether the child has recoverable ATN or irrecoverable cortical necrosis, but renal biopsy if available may distinguish between these.

### Post-renal ARF

Post-renal causes are due to obstruction to all of the urinary flow, and are uncommon. This will not occur if the flow from just one kidney is blocked (unless a single kidney is present). Causes in a child with two kidneys include congenital urethral valves, or a bladder stone obstructing the urethra. Causes in a child with a single kidney include a ureteric stone, or a pelvi-ureteric junction narrowing (which is congenital, but often blocks intermittently and presents late).

All of these pathologies cause severe acute colicky abdominal pain. This is well localised in older children to either unilateral pain with ureteric obstruction, or lower abdominal pain with bladder neck obstruction. An ultrasound scan will reveal stones and dilatation of the urinary tract proximal to the site of the obstruction.

### Treatment

The treatment of post-renal ARF is to remove or bypass the obstruction. For a bladder neck stone obstruction, catheterise the child. Giving pain relief with an opiate analgesic may allow time for an obstructing urethral stone to pass, or for the intermittent blockage from a pelvi-ureteric junction narrowing to clear. If not, the stone may need to be removed cystoscopically or by ureterolithotomy, or the upper renal tract can be drained by insertion of a percutaneous nephrostomy under ultrasound guidance. Once removal of the obstruction has allowed the renal function to recover, procedures such as surgical repair of the pelvi-ureteric junction may be performed.

### Ongoing management of persistent ARF

#### General management

The management of ARF consists of the provision of good general care for an acutely ill child, plus the specific management of fluid and electrolyte balance, blood pressure, and the adjustment of some drug dosages. In many instances the limitations that need to be imposed to keep in metabolic balance compromise the care that can be given in other areas.

**The safe management of these children requires the maintenance of meticulous fluid balance. To achieve this it is necessary to accurately measure all intake and losses.** For babies, stool and urine losses are best estimated by weighing their clean and dirty nappies. Insensible

water losses need to be estimated. This is done most reliably by assuming it to be 300 mL/m<sup>2</sup> in temperate conditions, and higher in hotter climates and at low humidity (for estimation of body surface area, see Table 9.16, Section 9). The best guide to the overall changes in fluid balance is to weigh the child twice daily.

### Nutrition, fluid and electrolyte balance

Adequate nutrition is important for recovery, but may be difficult to provide. If a child is old enough and well enough to eat solid food they are relatively easy to manage because they can obtain their requirements with little water. Aim to provide their normal calorie intake from carbohydrates and fats, and limit their protein intake to about 1 gram/kg/day to minimise uraemia. It is necessary to limit the salt intake to prevent sodium retention and hypernatraemia, which leads to insatiable thirst and hence fluid overload. It may be necessary to provide some of the sodium as bicarbonate to prevent acidosis, typically at a starting dose of 1 mmol/kg/day (note that 1 mL of an 8.4% sodium bicarbonate solution contains 1 mmol, and 1 gram of powder contains 12 mmol).

**Dietary potassium must be restricted (avoid in particular bananas, tomatoes, coconut, citrus fruits or juices, and chocolate) to decrease the risk of hyperkalaemia. Dietary phosphate must be restricted (restrict milk and dairy products but not breastfeeding) to reduce the risk of hyperphosphataemia.**

Giving calcium carbonate with the food (e.g. 0.5–2 grams with each meal) will bind the intestinal phosphate and reduce hyperphosphataemia as well as reducing the tendency to hypocalcaemia.

Young infants who normally take milk, and children who are too ill to eat solid food, or who have gastrointestinal involvement, will need either nasogastric tube feeding **or intravenous nutrition. The enteral route should always be used if possible.** However, adequate nutrition has to be delivered in a relatively large fluid volume. If the child has polyuric renal failure, or has high non-renal water losses (e.g. from diarrhoea or drain fluids), this can be achieved. However, if the child is oligo-anuric it is very difficult (and often impossible) to give sufficient nutrition without causing fluid overload, which can lead to hypertension and pulmonary oedema. Concentrated fat-based oral feeds can be made up from ingredients such as double cream. **Specialist parenteral nutrition solutions will be required if they are to be used for a child in renal failure.**

### The need for dialysis

Although severe fluid and electrolyte restriction is possible for short periods of time while awaiting spontaneous recovery of renal function, it is not possible to both provide adequate nutrition and maintain stable water and chemical balance over a prolonged period in a child with oligo-anuria. If such a child does not start to regain renal function, they will die unless they are dialysed.

The main indications for starting dialysis (where available) are as follows:

- Hyperkalaemia: this is discussed below.
- Fluid overload causing pulmonary oedema and/or hypertension.
- Severe metabolic acidosis: this is another important reason for dialysis (if available). Treatment with sodium bicarbonate is limited because this may lead to massive

sodium overload, and thus to dangerous levels of hypernatraemia, and to greater fluid retention. Fluid overload is worsened if hypoglycaemia occurs (this needs to be treated with IV glucose solutions) and if other fluids are required (e.g. platelets).

- **Uraemia:** clinical symptoms are apparent at concentrations above 40 mmol/litre, but uraemia is not as acutely life-threatening as hyperkalaemia or pulmonary oedema. It needs to be reduced by providing more non-protein calories.

## Hyperkalaemia

Hyperkalaemia causes life-threatening arrhythmias, especially in acute renal failure, where other metabolic changes may exacerbate the risk (e.g. hypocalcaemia). Aim to keep the plasma potassium concentration below 6.5 mmol/litre in older children and below 7.0 mmol/litre in neonates (who appear to tolerate hyperkalaemia better).

**There are three pharmacological approaches to managing children with hyperkalaemia.**

- 1 **Reduce the risk of it causing arrhythmias.** Reduce the effect of hyperkalaemia by increasing the plasma calcium concentration. Give 0.5 mL/kg (0.1 mmol/kg) of calcium gluconate 10% IV.
- 2 **Remove potassium from the body.** Give calcium resonium 1 gram/kg orally or rectally, and repeat with 0.5 grams/kg 12-hourly. This ion-exchange resin exchanges potassium for calcium. It is not well tolerated. If volume status and urine flow permit, furosemide will increase urinary potassium excretion.
- 3 **Push potassium into the cells.** This last option only results in a temporary improvement, because as soon as the treatment stops the potassium moves back out of the cells. Essentially this approach is only a holding treatment while a more effective therapy such as dialysis is prepared:
  - Give a beta-2-adrenergic agonist, such as salbutamol. Nebulise 2.5 mg for children under 25 kg, and 5 mg for larger children, or give 4 micrograms/kg IV. This works rapidly, but the potassium will move back out of the cells within a few hours.
  - Alternatively, infuse a high concentration of glucose. Monitor the plasma glucose concentration and be prepared to infuse insulin beginning at a dose of 0.05 units/kg/hour if it exceeds 12 mmol/litre. It is unsafe to mix the glucose and insulin and infuse them together in children, as this may cause hypoglycaemia. This necessitates close monitoring, an inevitable fluid load, and only lasts while it is continued.
  - Bicarbonate infusions push potassium into the cells. A dose of 2.5 mmol/kg may be infused over 15 minutes. If a solution of 8.4% is used, containing 1 mmol/mL, it will increase the plasma sodium concentration by approximately 5 mmol/litre very quickly, which may be hazardous. It is better to use a solution of 1.26% which is isotonic, but this requires that a volume of 17 mL/kg be infused, adding to fluid overload.

## Acute peritoneal dialysis

### Indications

Children with acute renal failure can be considered for peritoneal dialysis if their biochemical control is not safe

despite careful treatment (see section on management of acute renal failure above). Although the specific indications for initiating peritoneal dialysis vary from case to case, the commonest reason is a high and rising plasma potassium concentration (e.g. above 6.5 mmol/litre in an older child, or above 7 mmol/litre in a neonate). Other indications include a urea concentration above 40 mmol/litre, a phosphate concentration above 3.5 mmol/litre, or acidosis with a bicarbonate concentration below 12 mmol/litre, as well as hypertension or pulmonary oedema due to fluid overload.

The primary underlying reason for needing to proceed to dialysis is usually anuria or severe oliguria. This is because even a moderate urine flow will prevent fluid overload if the intake is restricted, and because it 'makes space' for biochemically appropriate replacement fluid. Even poor-quality urine contains potassium, so replacement with potassium-free fluid allows a net loss. Also, urinary sodium losses can be replaced with IV sodium bicarbonate to counter acidosis, and a high infused glucose concentration will reduce catabolism and so minimise urea, potassium and phosphate production. Take advantage of all fluid losses; diarrhoeal losses will 'make space' just as effectively as urine losses.

## Practical techniques

### PD Catheter

Ideally, a catheter with side holes should be inserted so that its tip lies in or near one of the iliac fossae. The ideal catheter is a cuffed silastic Tenckhoff which has a series of side holes and an end which is cut off straight, but these are expensive and need to be inserted through a peel-away sheath (usually in the midline below the umbilicus). It is possible to dialyse adequately using other more readily available catheters that have side holes, such as chest drains. These are usually inserted over a metal trocar, and have a tapered tip with an end hole that is considerably smaller than the diameter of the tube lumen, which can lead to difficulties with blockage with omentum (see below).

### Insertion of catheter

- This must be a strictly aseptic technique performed either under general anaesthetic, or under sedation/systemic analgesia (see Section 1.15) and local anaesthetic. The catheter may be placed directly percutaneously or with a subcutaneous tunnel or with full surgical procedure.
- If the catheter is not tunnelled, to prevent fluid leakage it is essential that it is inserted through the skin with a very tight fit; using a larger skin hole and stitching it closed will inevitably result in leakage in time. Cut a skin slit that is obviously smaller than the tube, and stretch it with a surgical clip or stitch holder.
- Before introducing the catheter, insert an IV cannula through the skin cut and fill the abdomen with about 40 mL/kg of Ringer-lactate solution or 0.9% saline until the abdominal wall is fairly tense.
- To insert the catheter through a tight hole requires some force, and this is best done by pushing the catheter and trocar tip into the dilated skin slit as far as possible, and then suddenly advancing it with a sharp force through the tense abdominal wall. Grip the catheter and trocar tightly about 3 cm from its tip to act as a stop as it pops into the abdomen (the risk of causing damage is greatly reduced by the presence of sufficient instilled fluid).
- To further minimise the risk of trauma, it is better to

enter the upper quadrant lateral to the rectus sheath, and aim towards the opposite iliac fossa, than to use an infra-umbilical approach. Be aware of the possibility of an enlarged spleen or liver.

- Once sited, test to check that fluid flows rapidly in and out, before securing with a skin stitch and sterile dressing.

### Problems with omentum

It is common for omentum to wrap around the end of the catheter, and for some to enter the end hole. This slows or stops drainage because the omentum is sucked further into the lumen, but has little effect on filling because the omentum is washed back towards the catheter tip, and the fluid exits through the side holes. Deal with it as follows:

- The omentum can often be forced out by rapidly injecting up to 50 mL of dialysis fluid, Ringer-lactate solution or 0.9% saline into the catheter under pressure.
- If this fails, withdraw the catheter from the abdomen using full aseptic technique. If the omentum has become detached, simply reinsert the catheter, and resume dialysis.
- If (as usually happens) the catheter comes out with the omentum attached, detach it, and gently pull more omentum out, tie round it with an absorbable suture near to the skin surface, cut off the excess, and return the omentum into the abdomen, using the stitch to obtain easy purchase, and replace the catheter.

### Fluid and cycles

- Run the dialysis fluid in through a giving set with a burette, and with the bag held about 1 metre above the patient, and leave it to dwell for 30 minutes. Allow it to drain by gravity through a Y-connector into a sealed bag for about 10–15 minutes; by then, it should have drained about as much as was instilled, and the flow should have stopped.
- The osmolality of the dialysis fluid determines the amount of water that is drawn off (ultra-filtered) during each peritoneal dialysis cycle, and this is adjusted by varying the glucose content. Typical glucose concentrations available are 1.36% (standard) and 3.86% (high-osmolality) bags. Start with 1.36% glucose.
- Add heparin, 1000 units/litre, to the fluid initially to prevent any blood from the insertion clotting the catheter. Discontinue it once the effluent fluid looks clear.
- Start with 10 mL/kg cycles of dialysis fluid for the first 2 days. Using this small volume minimises the risk of a peritoneopleural leak of dialysate.
- The first cycle balances are unreliable because there is always a sump of fluid left, but after that the ultra-filtrate required is the volume of fluid that needs to be removed to correct any overload, plus an amount equivalent to the urine that would normally be passed (so just a little less than the normal fluid intake).
- If there is too little ultra-filtrate, increase the glucose concentration of the dialysate by giving some cycles of 1.36% glucose and some of 3.86% glucose. Continue to review the fluid balance, and vary the proportion of cycles of each strength as necessary.
- Increase the cycle volume by 10 mL/kg every 2 days until tolerance occurs, or a maximum of 40 mL/kg. As the cycle volume increases, it is not necessary to dialyse so intensively. Either continue with 30-minute dwells,

but just for part of the day (e.g. 8 hours overnight), or lengthen the dwells, eventually moving to chronic ambulatory peritoneal dialysis (CAPD), in which the fluid is left in the peritoneum all the time, and exchanged four to six times per day.

### Biochemical control

The sodium, calcium and magnesium content of the dialysis fluid is similar to that of plasma, and the fluid contains lactate, which is converted to base, so is equivalent to bicarbonate. Cycling therefore tends to keep the plasma concentrations stable. Peritoneal dialysis fluid contains no potassium, urea or creatinine, so these are removed.

- Urea equilibrates rapidly, so is cleared well, allowing the child to have a normal protein intake.
- Creatinine is removed slowly, so peritoneal dialysis never restores the plasma levels to normal. This is useful because creatinine is not toxic, and its plasma concentration continues to provide a measure of intrinsic renal function and renal recovery.
- Sometimes the dialysis required to control fluid or urea excretion is sufficient to cause hypokalaemia. If so, reduce the potassium dialysis clearance by adding up to 3 mmol/litre potassium chloride to the dialysate bags (do not use more than this; if the potassium concentration is still too low, give extra orally or intravenously).

### Peritonitis

Infection is the major hazard of peritoneal dialysis, and produces a cloudy dialysis effluent in the drainage bag due to white blood cells. Prevention is crucial, by scrupulous hand washing and avoiding touching the open tubing ends while changing peritoneal dialysis bags, and by changing connections as infrequently as possible.

- Monitor constantly by inspecting the clarity of the effluent fluid.
- Undertake daily microscopy for white blood cells (there should be < 50 white blood cells/mL; see Section 8.5).
- If the effluent fluid is cloudy, and microscopy confirms the presence of large numbers of white blood cells (over 100, but typically several hundred), culture a sample of fluid, and start treatment at once by adding heparin (to stop blockage of the tube holes with fibrin) and antibiotics to peritoneal dialysis bags and revert to continuous cycling if not still doing that. Start with vancomycin and ceftazidime, and adjust according to the culture and sensitivity results. Concentrations of antibiotics that may be added to peritoneal dialysis fluid are as follows:
  - vancomycin, 25 mg/litre
  - ceftazidime, 125 mg/litre
  - ampicillin, 125 mg/litre
  - flucloxacillin, 250 mg/litre
  - gentamicin, 8 mg/litre.
- Continue continuous cycling until a count of < 50 white blood cells/mL is obtained for two samples taken 12 hours apart. Then return to previous dialysis cycles, adding peritoneal dialysis antibiotics for 14 days.
- If accidental contamination occurs, such as touching the open dialysis catheter during a bag exchange, or a fluid leak from a connection or punctured bag, add vancomycin and either ceftazidime or gentamicin to the dialysis fluid for the next 12 hours.
- Fungal peritonitis is difficult to clear. It is best to remove

the catheter and treat systemically until the peritonitis resolves.

The urine output must be measured throughout the procedure.

**Analgesia** for the procedure and throughout the dialysis is likely to be required.

## Chronic renal failure

### Background

Chronic renal failure (CRF) is more frequent in boys than in girls. Its commonest cause is congenital renal abnormalities such as dysplasia associated with severe antenatal vesico-ureteric reflux, and often also with posterior urethral valves. It can also follow almost any form of acute renal failure.

It is relatively easy to improve the quality of life of children with milder forms of CRF by simple treatments, especially in the case of older children. In its more severe forms, CRF is very difficult to treat effectively, requiring expensive drugs and intensive laboratory monitoring.

Very young children with CRF are particularly difficult to manage, as they usually have marked anorexia and failure to thrive. Successful treatment requires a massive family and medical input, highly expensive drugs, and a complex medical infrastructure of a kind that has only limited availability worldwide at present. **Each country should have a specialised centre that can provide care for such children.**

### Progression of CRF

CRF tends to worsen progressively through childhood. This is mainly because dysplastic or damaged kidneys may not grow in parallel with body growth, and renal function becomes outstripped by demand. Deterioration is likely to be quicker if the child has hypertension, or has recurrent urinary infections with continuing reflux, both of which require active treatment.

### Management

#### **Water, sodium and potassium**

Children with dysplastic kidneys usually have **polyuric renal failure** in which they lose water and salt, and often potassium, in an uncontrolled way. Consequently, they have a persistent thirst, and can become dehydrated extremely rapidly if they vomit persistently. They need IV fluids early, particularly if there is an episode of gastroenteritis.

Hyperkalaemia due to severe CRF occurs relatively late in children with polyuria.

Supplementing with sodium bicarbonate or salt, as needed, can improve well-being and growth. For each of these, start by adding about 1 mmol/kg per day. For bicarbonate, increase daily until the plasma concentration is in the normal range. The total extra sodium needed is best judged by measuring lying and standing blood pressures to detect postural hypotension; a fall in plasma sodium concentration is a very late event. Note that:

- For bicarbonate, 1 mmol is equivalent to 84 mg, so 1 gram contains about 12 mmol bicarbonate. For intravenous use, 8.4% bicarbonate solution contains 1 mmol/mL.
- For sodium chloride (salt), 1 mmol is equivalent to 57 mg, so 1 gram contains about 18 mmol sodium. For intravenous use, each litre of 0.9% saline contains 150 mmol

(see Table 5.5.A.2 in Section 5.5.A on 'shock' for details of electrolyte concentrations in other more physiological infusion crystalloids, such as Ringer-lactate and Hartmann's solution), and strong sterile sodium chloride solutions can be used to increase the sodium concentrations of standard IV fluids (e.g. a 30% solution contains 5 mmol sodium/mL).

Children with **oliguric renal failure** are more difficult to manage because they require salt and water restriction to prevent hypertension, and potassium restriction to prevent hyperkalaemia.

**When dialysis is available, indications to begin this treatment are often multiple, and include an intolerable diet or fluid restriction, and symptoms such as poor growth and lethargy as important factors, rather than just specific biochemical parameters.**

### **Calcium and phosphate**

CRF can lead to abnormalities of the plasma calcium and phosphate concentrations, and these can cause rickets and hyperparathyroidism (renal osteodystrophy), which can result in bone pain, limb deformities, and fractures (especially slipped femoral capital epiphyses). The primary problem is phosphate retention due to a reduced glomerular filtration rate. This causes a high plasma phosphate concentration, which in turn leads to a low plasma calcium level by mass action, and by suppressing the enzyme 1-alpha-hydroxylase, thus lowering the concentration of circulating activated 1-alpha-hydroxyvitamin D. A primary lack of 1-alpha-hydroxylase enzyme from destruction of kidney tissue is rare except in very severe CRF.

Treatment is therefore aimed at reducing the phosphate intake, either directly by dietary restriction (reducing the intake of meat and dairy products), or by **giving calcium carbonate** with meals. This binds with the phosphate in the gut, and prevents its absorption. The dose needed is very variable. Start at about 50–100 mg/kg, divided among the day's meals, and titrate the dose (if biochemical monitoring is available) to keep plasma phosphate levels at the lower end of the normal range. This commonly also results in a rise in plasma calcium levels into the normal range. Because of this, it is seldom necessary to treat mild CRF with 1-alpha-hydroxyvitamin D<sub>3</sub>. If it is needed, in more severe CRF, start with about 20 nanograms/kg once daily, and titrate the dose up until the plasma calcium concentration is normalised. It is extremely potent, and using it without regular monitoring can easily lead to severe hypercalcaemia, which can result in permanent calcification of tissues, including the renal medullae.

### **Anaemia**

Severe CRF leads to anaemia because the kidneys fail to produce enough erythropoietin. Treatment by repeated transfusions is unsatisfactory because blood is often scarce, carries infective risks, is always expensive, and eventually leads to iron overload. **Recombinant erythropoietin (if available)** should be used, after adequate iron levels have been achieved (folate and vitamin B<sub>12</sub> supplementation is seldom required, but levels should be checked if possible).

### **Growth**

Many factors lead to growth failure in children with CRF.

In older children, attention to fluid and electrolyte intake,

prevention of acidosis with bicarbonate supplements, and control of the bone biochemistry help considerably. Control of uraemia by encouraging a diet containing about 1 gram of protein/kg daily and a high carbohydrate intake will also contribute to good growth.

In young children, the problems are much greater. They are often extremely anorexic; most babies with severe CRF virtually do not feed, and only survive if tube fed for months

or even years. Many also vomit excessively. Even when supplemented with tube feeds, very young children with CRF often remain small.

### Transplantation

Renal transplantation (if it is available) from a living or deceased donor gives the best quality of life for children with end-stage renal failure.

## 5.7 Liver disorders

### 5.7.A Acute liver failure

#### BOX 5.7.A.1 Minimum standards

- Vitamin K.
- IV glucose 10%.
- Oxygen.
- Lactulose.
- Blood transfusions and clotting factors.
- Ranitidine/antacids.
- Antibiotics and antifungal treatment.
- High-carbohydrate diet.
- N-acetylcysteine.
- Measurements of prolonged blood clotting times.

#### Introduction

In contradistinction to fulminant liver failure in adults, acute liver failure (ALF) in children may not be accompanied by encephalopathy, which tends to be a late feature, or if it occurs early in the course suggests a metabolic cause.

Prolonged prothrombin time (PT) or international normalised ratio (INR) indicates coagulopathy due to the absence of liver-synthesised coagulation factors, and is the basis of the definition of ALF. However, coagulopathy in the presence of liver dysfunction can also result from vitamin K deficiency (usually due to prolonged cholestasis) and consumption of coagulation factors due to disseminated intravascular coagulation (DIC).

#### Definition

Based on the above, ALF is present in children when coagulopathy accompanies liver disease but is not due to DIC or a lack of vitamin K (see Table 5.7.A.1). Administration of IV or IM vitamin K (300 micrograms/kg for children aged 1 month to 12 years; 10 mg for those over 12 years of age) ensures that remaining coagulopathy is due to failed production (liver failure) or excess consumption (DIC). Markers that suggest DIC, rather than ALF, include a low platelet count, compatible blood film (fragmented cells, schistocytes) and a serum bilirubin that is predominantly unconjugated.

TABLE 5.7.A.1 Clinical features of ALF

1.	Nausea and vomiting is a frequent early feature.
2.	Bruising, petechiae and bleeding secondary to deranged clotting (INR > 4 is associated with 90% mortality).
3.	Jaundice with tender hepatomegaly or a liver that is enlarged but reducing in size in days.
4.	Encephalopathy latterly complicated by features of raised intracranial pressure.
5.	Metabolic alkalosis from failure of the urea cycle associated with a low serum potassium concentration.
6.	Failure to maintain normoglycaemia.

#### Diagnosis of ALF

- The history may establish a recent episode of shock including severe dehydration, sepsis or heatstroke, evidence of ingestion of toxic mushrooms or drugs (including those bought over the counter or obtained from any non-conventional source), or exposure to infection such as *Salmonella typhimurium* (see Table 5.7.A.2).
- The possibility of bloodborne or other parenteral infection with hepatitis B up to 6 months previously should be explored.
- Examination may show features of acute portal hypertension with liver tenderness suggesting Budd–Chiari syndrome or a veno-occlusive disease, or lymphadenopathy suggesting malignancy.
- Urine should be tested for bilirubin, urobilinogen and reducing substances.
- Stools should be examined for colour.
- **Tests to establish many of the causes of ALF require sophisticated laboratory facilities which may not be available.**
- The cause may be diagnosed from local epidemiology.
- A blood film and an INR or prothrombin ratio should be measured.
- A full septic screen, **excluding lumbar puncture because of coagulopathy**, should be performed (including fungal cultures and chest X-ray).

TABLE 5.7.A.2 Causes of acute liver failure

Type	Cause
Infective Viral	Hepatitis A, B, C or D, HIV, parvovirus, herpes virus, enterovirus, adenovirus, echovirus, varicella, yellow fever, Lassa fever, Ebola virus, Marburg virus, dengue
Bacterial, protozoal	Leptospirosis, typhoid, malaria
Metabolic	Wilson's disease, tyrosinaemia, urea cycle disorders, galactosaemia, mitochondrial disorders, haemochromatosis, Niemann–Pick disease type C
Drugs	Paracetamol, anti-TB drugs, halothane, carbamazepine, sodium valproate
Toxins	<i>Amanita phalloides</i> , heatstroke, shock (all causes)
Autoimmune	Anti-smooth-muscle antibodies and anti-liver-kidney microsome (LKD) antibodies, antibody-positive giant cell hepatitis with haemolytic anaemia
Vascular	B Budd–Chiari syndrome, veno-occlusive disease (may follow bush tea ingestion)
Cryptogenic	Non-A, non-B hepatitis

### Complications of ALF

These include the following:

- Encephalopathy and raised intracranial pressure, convulsions.
- Hepatorenal syndrome.
- High-output cardiac failure.
- Hepatopulmonary syndrome.
- Acid–base disturbance; initially alkalosis with hypokalaemia, followed by metabolic acidosis from multi-organ failure.
- Gastrointestinal bleeding, including early development of oesophageal varices.
- Pancreatitis.
- Bone-marrow aplasia.
- Sepsis, particularly Gram-negative and fungal, pulmonary (including aspiration) and septicaemia.

### Fluids in ALF

- Fluids in ALF should be restricted to two-thirds of normal maintenance (see **Section 9 Appendix**).
- When albumin needs to be infused, the dose is 5 mL/kg of 20% albumin, and for fresh-frozen plasma the dose is 10–20 mL/kg.
- Do not give any potassium if the patient is anuric.
- Treat hypoglycaemia in the usual way (see **Section 5.8.B**).

### Management of children with ALF

- **In the absence of liver transplantation, conservative management relies on liver recovery, which will occur in many cases of ALF, taking place before irreparable damage occurs in another organ, particularly the brain. The best possible high-dependency care may improve the likelihood of this occurring.**
- Refer the child to a specialised centre if one exists in that country. Undertake frequent reviews and clinical observations and high-dependency nursing.

TABLE 5.7.A.3 Four grades of hepatic encephalopathy

<b>Grade I</b>
Irritable, inappropriate behaviour
Lethargy
Mildly depressed awareness
Tremor or flap (slow wave in outstretched extended hand)
<b>Grade II</b>
Aggressive outbursts, bad language
Unable to stay still
Pulling at IV cannulae, plaster, etc.
<b>Grade III</b>
Mood swings
Irritable, odd behaviour
Not recognising parents
Photophobia
<b>Grade IVa</b>
Mostly sleeping, but rousable
Incoherent, sluggish pupils
Hypertonia with or without clonus and extensor spasm
<b>Grade IVb</b>
Absent reflexes
Irregular gasps with imminent respiratory failure
Bradycardia
Unresponsive to painful stimuli

- Blood tests for coagulation, electrolytes, blood glucose levels and blood count should be performed frequently (ideally 8-hourly).
- Hypoglycaemia and hypokalaemia must be detected and corrected.
  - Maintain blood glucose levels in the range 4–9 mmol/litre using a restricted fluid volume (two-thirds of maintenance) consisting of a minimum concentration of 10% glucose (given IV or orally); 20% glucose is the preferred solution, but is irritant to peripheral veins and is best given into a central vein or, better still, if tolerated, orally or via a nasogastric tube.
  - A metabolic alkalosis resulting from a failure of the urea cycle may cause hypokalaemia as a result of a shift of potassium into the cells. This hypokalaemia can worsen encephalopathy, and should be corrected enterally or IV.
- Children with encephalopathy should be nursed with their head elevated at 30 degrees above the horizontal and without neck flexion (to decrease intracranial pressure and minimise cerebral irritability). Children with agitated encephalopathy of grade II or III represent a major management problem, as they may pull out monitoring equipment and IV lines. **Sedation will worsen their encephalopathy.**
- Strict fluid balance is essential.
  - Allowance should be made for a hot climatic environment by giving 10–20% extra fluid, and 10% extra fluid should be given for each degree of fever.
  - Strict monitoring of urinary output and fluid balance is required. Aim for a urine output of not less than

0.5 mL/kg/hour (determined by weighing nappies or measuring output).

- Daily weights are useful if the child can be moved, and will allow greater precision in fluid balance.
- If possible and appropriate, insert a central venous line and aim to provide a central venous pressure (CVP) of 6–10 cmH<sub>2</sub>O if necessary to give a normal blood pressure. Increased CVP may be required to compensate for an increased cardiac output, or to treat the reduced cardiac performance that is seen as liver failure progresses.
  - Patients who require inotropes despite adequate central venous filling are developing multi-organ failure and have a very poor prognosis.
- Stop oral protein initially, and during recovery gradually reintroduce 0.5–1 gram/kg/day in oral or nasogastric feeding.
- A high-energy intake, predominantly of dietary carbohydrate, should be promoted to prevent protein catabolism with an increased serum ammonia level. In the absence of products such as Maxijul, uncooked cornstarch may be used as a source of carbohydrate. It may be given up to 2-hourly to provide predicted energy requirements, and may also help to maintain normoglycaemia.
- Lactulose, 5–10 mL two to three times a day, is given to produce two to four soft and acid stools per day (it should be omitted if diarrhoea occurs).
- Maintain normothermia by environmental measures (**but NOT with paracetamol, aspirin or ibuprofen**).
- Give one dose of IV or IM vitamin K (300 micrograms/kg for children aged 1 month to 12 years: 10 mg for those over 12 years of age) to attempt correction of prolonged clotting time.
- If there is frank bleeding (gastrointestinal or other), consider giving fresh blood, fresh-frozen plasma or **cryoprecipitate** at 10 mL/kg IV.
- A prophylactic H<sub>2</sub>-blocking agent (e.g. ranitidine 2 mg/kg twice daily orally or IV) is given with oral antacid (e.g. sucralfate 250 mg four times a day for children aged 1 month to 2 years, 500 mg four times a day for those aged 2–12 years, 1 gram four to six times a day for those aged 12–18 years) to prevent gastric and/or duodenal ulceration.
- Treat any confirmed sepsis aggressively.
  - Broad-spectrum antibiotics, such as a cephalosporin plus amoxicillin, or penicillin plus gentamicin, should be used prophylactically.
  - Systemic fungal infection may require IV amphotericin (250 micrograms to 1 mg/kg/day) or oral fluconazole (10 mg/kg once daily).
  - Give prophylactic oral nystatin mouthwashes (100 000 IU (1 mL) four times a day).
- Manage hypotension with IV colloids and **possibly dopamine and nor-adrenaline infusions if central venous access has been obtained** (see Section 5.5.C).

### Paracetamol overdose

If paracetamol overdose is suspected or confirmed, N-acetylcysteine must be started immediately, whatever the time between the alleged overdose and the visit to the hospital. Histories after overdose are often misleading,

with multiple administrations and other drugs not immediately admitted. N-acetylcysteine is given IV at 150 mg/kg over 15 minutes as a loading dose, then 100 mg/kg over 12 hours, then 100 mg/kg/day as a continuous infusion until the INR is normal.

### Prognosis for ALF

The most important prognostic parameter for ALF is metabolic acidosis. Even in the presence of a very prolonged INR, a patient who is not acidotic will have an 80% chance of survival. A plasma pH of < 7.25 (if blood gas measurement is available) indicates a 95% risk of mortality.

Other factors that predict a poor outcome are grade III or IV hepatic encephalopathy and oliguric renal failure (usually occurring 3–4 days after onset).

### Risk factors

- Age < 2 years.
- INR ≥ 4 (associated with a mortality of > 90%).
- Serum bilirubin concentration > 350 micromol/litre.
- Grade III or IV encephalopathy.
- Non-A non-B hepatitis.
- Drug-induced ALF.

### Poisoning or toxic reactions associated with the development of ALF

These include the following:

- paracetamol
- mushrooms, particularly *Amanita phalloides* and similar species
- carbon tetrachloride
- copper
- iron
- halothane and other volatile anaesthetic agents
- sodium valproate
- carbamazepine
- phenytoin
- phenobarbitone
- isoniazid
- cytotoxic drugs
- irradiation.

### Galactosaemia

- A defect of galactose-1-phosphate uridyl transferase is revealed in the perinatal period when affected infants are first exposed to milk feeding.
- Infants present with vomiting, hepatitis, liver failure and DIC, often with septicaemia.
- Symptoms settle within 2–3 days when feeding with milk is discontinued.
- Hypoglycaemia is seen in the majority of cases.
- Cataracts may be detected.
- Fanconi's nephropathy explains the presence of galactose in the urine giving the characteristic 'Clinistix negative, Clinistix positive' side-room test pattern when the infant is receiving feeds.
- Management consists of the **removal of galactose from the diet** and standard management of liver failure and sepsis.

## 5.7.B Chronic liver disease

### BOX 5.7.B.1 Minimum standards

- Hepatitis B vaccine.
- Vitamin K.
- Fat-soluble vitamins (A, D, E and K).
- Cholestyramine.
- Specific nutritional support.

### Introduction

The liver is anatomically strategically positioned between the gastrointestinal tract and the systemic circulation to perform its nutritional homeostatic role. Through the portal system,

it filters organic and inorganic substances, microorganisms and their breakdown products, including endotoxins. It also stores and processes nutritional substrates and coordinates nutritional status through endocrine carrier proteins. The liver is therefore the major organ of nutritional homeostasis.

It can be helpful in diagnostic and prognostic terms to think of clinically evident liver dysfunction as having degrees of severity in three simultaneous dimensions: cholestasis, portal hypertension (with hypersplenism) and synthetic function (although homeostasis of ammonia and blood glucose levels may fit better into this synthetic group). The clinical features are summarised in Table 5.7.B.1.

## Clinical symptoms and signs of chronic liver disease (CLD)

TABLE 5.7.B.1 Clinical features of CLD

Clinical feature	Cholestasis	Portal hypertension	Cell dysfunction
Jaundice	Conjugated	–	Mixed if severe
Pruritis	+	–	–
Leuchonychia	+	–	–
Fat-soluble vitamin deficiency	+	–	–
Xanthomas	+*	–	–
Splenomegaly	–	+	–
Cutaneous shunts	–	+	+
Other cutaneous stigmata	–	+	+
Hypersplenism	–	+	–
Hepatopulmonary syndrome	–	+	+
Oesophageal varices	–	+	–
Ascites	–	+	+
Encephalopathy	–	+	+
Dependent oedema	–	–	+
Malnutrition	+	+	+

\*Not in familial intrahepatic cholestasis.

### Jaundice

Accompanied by dark urine and pale stools, jaundice is characteristic of cholestatic liver disease. The urine of infants should not contain significant colour or stain the nappy, and yellow urine strongly suggests bile obstruction. Yellow sclerae suggest cholestatic jaundice but are difficult to detect in small infants, and children with deep skin pigmentation may have some scleral pigmentation. There is no substitute for personal examination of stool and urine, as the history can be misleading. White stool, or stools the colour of cream cheese or uncooked pastry, are clearly abnormal, whilst pale yellow, pale green or pale brown stools may also raise concern about liver function. Comparison with a stool colour chart ([www.yellowalert.org/file\\_download.aspx?id=7358](http://www.yellowalert.org/file_download.aspx?id=7358)) can be extremely helpful if there is doubt.

### Hepatomegaly

Healthy infants may have up to 2 centimetres of liver edge palpable below the costal margin, but the texture is soft.

An abnormally hard texture or irregular inferior margin strongly suggests established liver disease with fibrosis/cirrhosis. Changed liver conformation with prominence in the mid-line but an impalpable right lobe suggests collapse, regeneration and the development of cirrhosis. Tenderness of a smoothly enlarged liver suggests a rapid recent increase in liver size (e.g. in acute hepatitis and also congestive cardiac failure).

### Splenomegaly

Newborns may normally have a palpable spleen tip. Later palpable spleen suggests splenomegaly, possibly from portal hypertension, but as children get older a larger spleen can be accommodated beneath the ribs, so the sign becomes less sensitive.

### Coagulopathy

With cholestasis, coagulopathy results from a failure of absorption of sufficient vitamin K. In infants this may present as haemorrhagic disease of the newborn, who should not

normally suffer spontaneous bleeding. Routine vitamin K is given to newborns in some countries. Fresh blood from sites such as the umbilicus or nares should always prompt a search for evidence of vitamin K malabsorption or liver disease even when jaundice seems trivial.

In liver disease and coagulopathy unresponsive to vitamin K, but without consumptive coagulopathy, liver synthetic failure must be present. **The degree of coagulopathy is the most sensitive index of liver impairment in children.**

### Hypoglycaemia

Hypoglycaemia may suggest a metabolic disease as a cause of liver dysfunction or profound failure of liver function.

### Encephalopathy

More common in acute liver failure (see Section 5.7.A), chronic hepatic encephalopathy may be insidious, with educational failure, poor impulse control, bizarre behaviour and absences noted intermittently over months or years. Improvement may be associated with a low-protein diet reduced to 1 gram/kg/day, with lactulose to give acid stools and change the gut flora in favour of organisms that are less likely to produce the amines associated with encephalopathy.

**TABLE 5.7.B.2 Laboratory features of CLD**

Laboratory feature	Cholestasis	Portal hypertension	Cell dysfunction
Serum bilirubin	Conjugated	Normal	Normal or mixed
Serum albumin	Normal	Normal	Low
Serum cholesterol	High <sup>†</sup>	Normal	Low
Prothrombin time/ratio	Normal <sup>‡</sup>	Normal*	Prolonged if severe

\* Implies minor prolongation seen in portal vein thrombosis.

<sup>†</sup> Except in familial intrahepatic cholestasis types 1 and 2.

<sup>‡</sup> If there is adequate vitamin K.

### Investigations into CLD

Consider liver dysfunction according to the following three categories (see Table 5.7.B.2):

- **cholestasis:** impairment of bile flow with a consequent reduction in intraluminal bile salt concentration and associated conjugated hyperbilirubinaemia and malabsorption
- **portal hypertension (PHT)** with associated hypersplenism and the effects of portosystemic shunting
- **hepatocellular impairment** (cell dysfunction) with failure of synthetic and homeostatic function, such as hyperammonaemia and hypoglycaemia.

Clinical findings (see Table 5.7.B.1) can be interpreted according to this classification, although some (e.g. ascites) are represented in more than one category. Serum albumin concentration reflects liver synthetic function but also depends on nutritional status and losses (e.g. via the gastrointestinal tract or kidneys). Thus it is necessary to consider all clinical features supported by basic laboratory parameters when possible to evaluate the severity of liver disease.

A precise diagnosis of the various causes of CLD is often not possible without specialised and expensive investigations, yet use of the above clinical assessment may allow a general if unconfirmed diagnosis.

### Ascites

This is seen in advanced CLD, being a function of the balance between plasma oncotic pressure, which is mostly contributed by serum albumin, and hydrostatic pressure from portal hypertension.

### Cutaneous manifestations

Pruritus, liver palms, cutaneous shunts, clubbing, white nails and xanthomas are well-recognised signs.

### Hepatopulmonary syndrome

Progressive cyanosis occurs without lung disease, associated with low pulmonary artery pressure. Exertional dyspnoea is a frequent early feature. Type 1 implies pulmonary capillary vasodilatation and improves at least in part with inspired oxygen, whereas type 2 implies fixed intrapulmonary shunts without a response to oxygen.

### Other presentations

Chronic liver disease may be present without detectable symptoms or signs. For example, chronic viral hepatitis B can be present for decades, proceeding to cirrhosis without any external evidence.

### Outcome of CLD

Although CLD can often only be cured in specialised centres in countries where transplantation is available (costs are over \$120 000 per case), much can be done to relieve suffering in children with CLD, and most notably Wilson's disease can be treated successfully for US\$1–2 per day depending on the patient's size and age.

### Cholestatic CLD: diagnosis and management

Cholestasis is most frequently seen as a complication of the neonatal hepatitis syndrome. The commonest defined diagnosis is **biliary atresia**, an obliterative inflammatory condition of the intra- and extrahepatic biliary system exclusive to the perinatal period. Infants typically present with jaundice, pale stools and dark urine. If left untreated, biliary atresia progresses to biliary cirrhosis and death from complications of decompensated liver function within 2 years in 95% of cases. It is the commonest individual cause of severe liver disease in childhood in all populations, occurring in 1 in 9000 to 1 in 16000 live births.

Causes of cholestatic CLD that are rare and difficult to treat include the following:

- **Alagille syndrome:** a condition characterised by

TABLE 5.7.B.3 Basic investigations in liver disease

Investigation	Role
Serum bilirubin, total and conjugated	Conjugated bilirubin is elevated in cholestasis Unconjugated bilirubin is elevated in hepatocellular injury
Urine bilirubin	Present in cholestasis
Serum aspartate aminotransferase, alkaline phosphatase, gamma-glutamyl transpeptidase	Elevated in hepatocellular injury plus cholestasis
Serum sodium, potassium, urea, creatinine, albumin and glucose	Hepatocellular injury
Full blood count, prothrombin time or INR	Coagulopathy in liver failure and in cholestasis from vitamin K malabsorption
Hepatitis A antigen, toxoplasma, rubella, herpes, CMV, syphilis antibodies	Congenitally acquired infection
Serum total protein and immunoglobulins	Abnormal in autoimmune disease
Alpha fetoprotein	Elevated in liver tumour
X-ray of spine, cardiac	Alagille syndrome, dextrocardia rarely in biliary atresia
Ultrasound scanning	Biliary, portal and parenchymal abnormalities
Eye review for Kayser–Fleischer rings and embryotoxon	Wilson's disease, Alagille syndrome

cholestasis of variable severity associated with syndromic features.

- **Progressive familial intrahepatic cholestasis (PFIC):** a series of clinical syndromes of cholestasis representing impairment of bile salt transport or handling that may present as neonatal giant-cell hepatitis or drug- or viral-induced cholestasis.
- **Neonatal sclerosing cholangitis:** a rare condition which may mimic biliary atresia, although stools may show variable pigmentation.

The consequences of cholestasis include **pruritus**. This is a particularly troublesome symptom, resulting in disruption for the whole household, especially at night. Persistent scratching can be complicated by secondary infection of broken skin and bloodstaining of clothes and bedclothes. Early onset, before 7 months of age, implies profound cholestasis and a poor prognosis. Treatment is often difficult. First-line management is with **cholestyramine**, at a starting dose of 1 gram/day for under 1 year olds, 2 grams (sachets)/day for children under 6 years, or 4 grams (sachets)/day for those over 6 years, up to 6 sachets/day according to response, but not given within 4 hours of vitamins or other medicine. Second-line treatment is **rifampicin**, 2–4 mg/kg (maximum 300 mg) twice daily, and third-line treatment is **ursodeoxycholic acid**, 5–10 mg/kg two to three times a day up to 15 mg/kg two to three times a day.

Fat-soluble vitamin deficiencies (A, D, E and K) are frequently encountered in cholestasis unless patients receive prophylactic treatment. Clinical features of **rickets**, such as splayed epiphyses, especially swollen wrists, rickety rosary and craniotabes should be sought regularly. Metabolic bone disease should, if possible, be screened for by measurements of serum phosphate, calcium and parathormone levels and regular wrist X-rays. Prothrombin time or INR should be measured to ensure adequate vitamin K repletion.

Vitamin A replacement is 5000–10 000 units per day or 100 000 units by deep IM injection every 2 to 4 months. Vitamin D deficiency may be refractory to oral calciferol (vitamin D<sub>2</sub>) tablets or cholecalciferol (vitamin D<sub>3</sub>), but 10 000–25 000 units (250 micrograms) for 1–12 years and

10 000–40 000 for 12–18 years per day of either may help. More water-soluble preparations such as 1-alpha-calcidol, 15–30 nanograms/kg for 1 month to 12 years and 250–500 nanograms for 12–18 years once daily, are more effective. **They may also cause hypercalcaemia.** Vitamin E deficiency is associated with hypotonia, peripheral neuropathy, developmental delay and haemolysis, and is the most frequently encountered vitamin deficiency in liver disease. The dose of vitamin E for all age groups is initially 100–200 mg/day adjusted according to response up to 200 mg/kg once daily, to increase until normal plasma levels are maintained. Vitamin K replacement for infants orally is 1 mg/day, and for children it is 5–10 mg/day.

Nutritional management applies to all three categories of CLD, and is discussed below.

### Portal hypertension (PHT): diagnosis and management

The complications of portal hypertension can be divided into:

- those related to the increased pressure (e.g. enteropathy, hypersplenism)
- those related to the anatomy of any collateral circulation (e.g. bleeding varices, haemorrhoids)
- those related to the effects of substances bypassing the liver by porto-systemic shunting (e.g. hepatic encephalopathy, hepatopulmonary syndrome, porto-pulmonary syndrome, hepatorenal syndrome). In this group complications may increase as shunting increases and portal pressure then falls.

The aetiology of PHT has conventionally been divided into the following:

- **pre-hepatic causes**, including portal vein thrombosis and other congenital and acquired portal vein anomalies, including arterioportal fistulae
- **hepatic causes**, including all causes of cirrhosis, especially cystic fibrosis and other biliary diseases, congenital hepatic fibrosis, and causes of non-cirrhotic portal hypertension, including portal vein sclerosis

- **post-hepatic causes**, including hepatic venous outflow obstruction such as Budd–Chiari syndrome, various causes of veno-occlusive disease and problems of inferior vena caval flow or right heart function; particularly difficult to detect are constrictive pericarditis and IVC webs.

## Treatment of bleeding varices

### BOX 5.7.B.2 Minimum standards: oesophageal varices

- Vitamin K.
- Blood transfusion (ideally fresh blood) and blood-clotting factors (if available).
- Propranolol.
- Antacids (aluminium hydroxide or magnesium carbonate).
- Ranitidine.

### Acute management

- 1 Advise the parents not to panic, but to stay with the child.
- 2 Unless the CLD is very advanced, or the child is vitamin K deficient, the bleed will probably stop spontaneously, although the child may be shocked by that time.
- 3 Give oxygen by face mask.
- 4 Gain IV access and obtain cross-matched blood if possible. Resuscitation with 10–20 mL/kg boluses of Ringer-lactate or Hartmann's solution is appropriate in the acute situation while waiting for blood for transfusion.
- 5 Give IV vitamin K slowly over 5 minutes 250–300 microgram/kg up to a maximum of 10 mg (or 1 mg for children under 1 year; 3 mg for those aged 1–4 years; 5 mg for those aged 5–12 years; 10 mg for those over 12 years). Repeat according to the results of clotting studies.
- 6 Start antacids (see below).
- 7 Arrange skilled endoscopy with sclerotherapy or banding (if available).

### Prevention

- Propranolol is beneficial as primary and secondary prophylaxis for variceal bleeding, particularly when given early in the course of PHT. Give 500 micrograms/kg orally twice daily (adjust according to the heart rate; aim to reduce the rate by up to 25%). Around 30% of patients who receive propranolol have side effects, including wheeze and systemic vasoconstriction.
- Antacids. If there is a tendency to diarrhoea, use aluminium hydroxide (children aged 6–12 years: 5 mL three to four times a day between meals; children over 12 years: 10 mL three to four times a day). If there is a tendency toward constipation, use magnesium carbonate in the same dosage. The two may be used in combination.
- Avoid aspirin, ibuprofen and other gastric irritants.
- H<sub>2</sub>-receptor antagonists are of no proven value but are often used (ranitidine 1 mg/kg for 1–6 months, 2–4 mg/kg 6 months to 12 years, 150 mg 12–18 years ALL twice daily).

## Hepatocellular liver disease: diagnosis and management

### Chronic viral hepatitis B, C and D

#### Hepatitis B

Millions of children worldwide are infected with hepatitis B virus (HBV), and many ultimately die in adulthood from its complications, particularly decompensated cirrhosis and hepatocellular carcinoma. The population prevalence may exceed 10%, making HBV a major international public health problem. Spread may occur vertically at the time of birth or shortly afterwards, but also horizontally, especially in poor communities. Unlike HIV infection, surface contact with very small amounts of infected blood (e.g. as a result of sharing toothbrushes) can result in infection. A neonate exposed to HBV for the first time has more than a 90% risk of becoming chronically infected, a child has a 25% risk, and an adult has a 10% risk.

Risk factors associated with the development of cirrhosis and hepatocellular carcinoma include eAg+, a high level of HBV DNA, and male gender. Once infected, children have about a 15% probability per annum of reducing a high-risk state to a low-risk state as defined by eAg/antibody status.

Vaccines based on the antigenicity of the S Ag are highly efficacious in generating antibody response and providing protection. Protocols that involve three subcutaneous immunisations given at 0, 1 and 6 months give adequate antibody levels in 95% of individuals. In neonates, vaccination with the same dose, or half the dose for economy, at birth, 1 month, 3 months and 1 year achieves similar protection. Up to 5% of individuals will not mount an antibody response despite repeated vaccination, but it is not clear whether they all fail to develop immunity. As implied above, all neonates of HBV-positive mothers should receive a course of vaccine, irrespective of the mother's eAg/antibody status, as infants of S Ag+/e Ab+ mothers may develop fatal liver failure.

The WHO has recommended universal HBV vaccination. If such a policy was to be implemented it is highly likely that HBV would become a rare disease of children within less than 10 years, with a corresponding reduction in cirrhosis and hepatocellular carcinoma in one generation, representing one of the current great unseized opportunities of international public health.

#### Hepatitis C

Hepatitis C virus (HCV) was responsible for at least 90% of post-transfusion hepatitis in early US studies. Around 5% of sexual partners may become infected. Around 4–5% of infants of viraemic mothers may become infected. The risk is related to the level of maternal viraemia, with HIV-positive mothers having the highest HCV viral loads and the highest risk of transmission. HCV is also a small but significant risk for healthcare workers.

Following exposure, viraemia in HCV occurs within 7 days, with antibody positivity appearing from 21–28 days. Less than 10% of affected individuals adequately remove the virus, and the remainder progress to chronic liver disease. The rate of progression to cirrhosis is unclear, but factors such as liver iron content, alcohol consumption and other viral infections (including hepatitis A) contribute. Around 5% of adults with HCV develop cirrhosis each year. The median timescale for developing cirrhosis in HCV is probably of the order of four decades.

Hepatocellular carcinoma is a recognised complication of HCV and cirrhosis, following the latter by 5–15 years typically. Treatment is becoming rapidly more effective, including that for the more resistant genotypes I and IV. Children should be treated after the age of 5 years in order to avoid the neurotoxic effects of interferon.

### **Wilson's disease**

This is an autosomal-recessive disorder caused by the accumulation of copper in the liver, brain, eyes, kidney and bone. The prognosis depends on the speed of diagnosis. Treatment with a low-copper diet and penicillamine is highly successful if started well before the onset of liver failure.

### **Drugs and the liver**

Drugs are a major cause of liver dysfunction. Over 600 drug hepatopathies have been documented; common examples are given below. Drug clearance may be reduced in liver disease, and liver disease increases the risk of drug injury to the liver.

Acute/subacute hepatocellular toxicity is caused by paracetamol, aspirin, ibuprofen, iron, isoniazid, sodium valproate, carbamazepine, methotrexate and ketoconazole.

Cholestasis is caused by rifampicin, penicillins, erythromycin, oestrogens and anabolic steroids.

Progressive fibrosis is caused by azathioprine.

### **HIV and the liver**

HIV is known to be associated with worsening of hepatitis due to other conventional causes and cholangiopathy, probably related to ascending infection with low-grade organisms such as *Cryptosporidium* or cytomegalovirus (CMV) infection (see Section 6.2.D). Hepatitis due to a conventional cause, especially CMV, may be particularly severe or progressive when associated with a low CD4 count.

### **Metabolic liver diseases**

These are rare and difficult, if not impossible, to treat without liver transplantation or expensive diets. Advice from a specialist unit should be sought.

## **The management of nutrition in CLD**

Malnutrition is a serious consequence of CLD. Thin limbs and a prominent abdomen are frequently seen, and malnutrition will be evident in anthropometric measurements. Triceps skinfold thickness tends to become reduced earlier in the course of progressive disease, followed by a reduction in mid upper arm circumference (MUAC). Stunting tends to occur later, unless severe rickets is present. Weight is affected by fluid balance abnormalities and organomegaly,

and is therefore an insensitive indicator of nutritional state. Lean body mass, and skeletal muscle in particular, is prone to depletion as a result of progressive liver disease.

Anorexia is attributed to organomegaly or pressure effects of ascites, but may be equally due to a congested gastric mucosa or reduced gastrointestinal motility of portal hypertension or central effects of unidentified toxins. Malabsorption of long-chain fats, including those with polyunsaturated fatty acids (PUFAs), is dependent on intra-luminal bile acid concentration. Cholestasis may result in the intra-luminal bile acid concentration falling below that required for micelles to be formed. The resulting steatorrhoea creates faecal energy loss, but also risks essential fatty acid deficiency, with possible neurodevelopmental consequences, particularly in early life. Protein malabsorption may also result from functional pancreatic insufficiency with failure of protease activation by bile acids. Malabsorption may also result from bacterial overgrowth or other unspecified effects of portal hypertension; for example, congestion of the gut may cause impaired active or passive absorption.

Thus malnourished children with liver disease have high energy expenditure for their size. Target energy intake should be estimated from what the child's current weight for age should be.

Breast milk contains more PUFAs than typical formula milks. PUFAs are long-chain fats that are dependent on intraluminal bile acids for absorption, and are essential for normal cell membranes and for myelination, particularly in infancy. **Breastfeeding is therefore important in children with CLD.**

Treatment with intensive enteral feeding and **high-dose enteral or parenteral vitamins** can improve the quality of life of children who have malnutrition from their liver disease. In the absence of specialist feeds, a modular feed may be prepared using protein powder, carbohydrate polymer, MCT oil and long-chain fat oil, preferably with essential fatty acids from walnut oil or another similar source, to provide 4% of fat. Up to 4 grams/kg/day of protein, and 100–140 kcal/kg/day of energy, of which two-thirds is from carbohydrate and one third is from lipid as MCT, is an ideal target range.

Commercial liver formulas are extremely expensive, and their effect on the outcome of the liver disease is unproven. In the absence of the supplements described above, proprietary baby formula can be enriched with locally available oils and starches to give 140 kcal/kg/day, with half of the total formula energy as lipid and half as starch. Remember that if commercial formula is given at an increased concentration to increase protein intake, the electrolyte intake will increase proportionally, with a risk of sodium overload and fluid retention.

## 5.8 Endocrine disorders

### 5.8.A Diabetes

#### BOX 5.8.A.1 Minimum standards

- ABC resuscitation skills and equipment.
- Oxygen.
- IV 0.9% saline or Plasma-Lyte 148.
- Insulin.
- Potassium.
- Mannitol or 3% saline.
- ECG monitoring.

#### Diabetic ketoacidosis

Diabetic ketoacidosis (DKA) is the commonest endocrine emergency that may occur in individuals with previously diagnosed diabetes, but should be suspected in any child with:

- dehydration (diarrhoea is not the only cause)
- abdominal pain
- ketone smell on the breath
- acidosis
- acidotic breathing
- unexplained coma.

**A child with DKA may die from inhalational pneumonia, hypokalaemia, severe metabolic acidosis or cerebral oedema.** Cerebral oedema is unpredictable, occurs more frequently in younger children and those newly diagnosed with diabetes, and has a mortality of around 80%.

**These guidelines are intended for the management of children who are more than 3% dehydrated and/or vomiting and/or drowsy and/or clinically acidotic.**

**Children who are 3% dehydrated or less and not clinically unwell usually tolerate oral rehydration and subcutaneous insulin.**

Every unit should have a written policy for the care of children with DKA. The following guidance is adapted from that provided by the British Society for Paediatric Endocrinology and Diabetes (BSPED) ([www.bsped.org.uk/clinical/docs/DKAGuideline.pdf](http://www.bsped.org.uk/clinical/docs/DKAGuideline.pdf)).

#### Emergency management of children who are over 3% dehydrated and clinically unwell General resuscitation: A, B, C

- **Airway:** ensure that the airway is patent, and if the child is comatose consider inserting an oropharyngeal airway. If they are comatose or suffering from recurrent vomiting, insert a nasogastric tube, aspirate and leave on open drainage.
- **Breathing:** give 100% oxygen. Give bag-and-mask ventilation if the child is apnoeic or hypoventilating.
- **Circulation:** insert an IV cannula and take blood samples (see below). Only if the child is shocked (tachycardia

with poor capillary filling or hypotension) give 10 mL/kg 0.9% saline or Plasma-Lyte 148 solution as quickly as possible, and repeat as necessary up to a maximum of 30 mL/kg. Note that normal (0.9%) saline causes a hyperchloraemic acidosis because of its excess of the chloride anion. In patients who are acidotic because of diabetes, Plasma-Lyte 148 may be preferable, as it does not contain such a high concentration of chloride ions.

#### Confirm the diagnosis

- History: polydipsia, polyuria.
- Clinical signs: acidotic respiration, dehydration, drowsiness, abdominal pain/vomiting.
- Biochemical investigations: high blood glucose levels on finger-prick or venous blood test, presence of ketones or glucose in the urine.

#### Investigations

- **Weight the child.** If this is not possible because of their clinical condition, use the most recent clinic weight as a guideline, or an estimated weight from centile charts.
- Blood glucose concentration.
- Urea and electrolytes (if plasma bicarbonate is not available, measure **arterial blood gas**).
- Packed cell volume (PCV) and full blood count.
- Blood culture.
- Urine microscopy, culture and sensitivity.
- Set up a cardiac monitor to observe T waves (hypokalaemia causes flat T waves and may cause cardiac dysrhythmias; hyperkalaemia causes peaked T waves).
- Other investigations (e.g. chest X-ray, CSF, throat swab, etc.) if indicated if the child is febrile, as there may be an underlying infection.

#### Assessment

Assess and record the following in the child's notes, so that comparisons can be made by others later:

- Degree of dehydration:
  - < 3%: dehydration is only just clinically detectable.
  - 3–5%: dry mucous membranes, reduced skin turgor.
  - 5–8%: as above with sunken eyes, poor capillary return.
  - > 8%: with shock – severely ill with poor perfusion, thready rapid pulse, reduced blood pressure.
- Conscious level:
  - Assess the AVPU score (**A**lert, responds to **V**oice, responds to **P**ain, **U**nresponsive).
  - Institute hourly neurological observations. If less than **A**lert on admission, or there is any subsequent deterioration, record the Glasgow Coma Scale score (see Section 7.3.C) and transfer the child to a

high-dependency-care unit (if available). Consider instituting cerebral oedema management.

- Full examination, looking in particular for evidence of the following:
  - **Cerebral oedema: irritability, slow pulse, high blood pressure** and papilloedema. Examine the fundi: papilloedema is a late sign.
  - Infection: look for a focus. **DKA can cause a leucocytosis but not a fever.**
  - Ileus.
- Observations to be carried out (ensure that full instructions are given to the nursing staff):
  - Strict fluid balance and urine testing of every sample for glucose.
  - Hourly capillary blood glucose measurements.
  - Twice daily weights.
  - Initially hourly or more frequent neurological observations.
- **Report immediately to the medical staff (even at night) symptoms of headache or any change in either conscious level or behaviour.**
  - Report any changes in the ECG trace, especially T-wave changes.

### Management

By this stage, the circulating volume should have been restored if shock was initially present. If not, give a further 10 mL/kg of 0.9% saline or Plasma-Lyte 148 over 30 minutes. Avoid overzealous fluid replacement, as this may be a risk factor for cerebral oedema.

### Estimating fluid requirements

The amount of fluid that the child needs over a 24-hour period must be calculated. It is the sum of:

**estimated fluid deficit + maintenance requirements  
+ ongoing losses.**

#### Deficit

**In DKA the deficit must be replaced more slowly than in gastroenteritis, over 48 hours rather than 24 hours. Even in very severe dehydration, use no more than 10% dehydration as the maximum in your calculations. Document the fluid balance carefully.**

Determine the degree of dehydration, and **never estimate more than 10% dehydration in this situation.**

Weigh the child, or else estimate their weight from their age as follows:

$$\text{weight (kg)} = 2 \times [\text{age (years)} + 4].$$

Use the following formula: **percentage dehydration × weight (kg) × 10 = deficit (in mL).**

For example, a child whose weight is estimated to be 10 kg is 10% dehydrated.

Their estimated fluid loss is  $10 \times 10 \times 10 = 1000\text{ mL}$  (40 mL/hour if replaced over 24 hours **or** 20 mL/hour **if replaced over 48 hours, which is safer in DKA.**

### Maintenance

**TABLE 5.8.A.1** Estimated maintenance fluid requirements based on child's body weight

Body weight	Volume of fluid needed per day	Volume of fluid needed per hour
First 10 kg of body weight	100 mL/kg	4 mL/kg
Second 10 kg of body weight	50 mL/kg	2 mL/kg
Subsequent kg	20 mL/kg	1 mL/kg

### Ongoing losses

For each diarrhoea stool	< 2 years old: give 50–100 mL > 2 years old: give 100–200 mL
For each vomit	2 mL/kg oral rehydration solution (ORS): give small frequent volumes (e.g. 5 mL/minute in a child) via a spoon, syringe or cup
For nasogastric tube aspirates	Replace volume for volume with either ORS or 0.9% saline or Plasma-Lyte 148 containing 5% or 10% glucose

### Type of fluid

Initially use 0.9% saline or Plasma-Lyte 148. Once the blood glucose concentration has fallen to 14 mmol/litre, change the fluid to 0.9% saline or Plasma-Lyte 148 containing, in addition, 5% glucose and 20 mmol KCl per 500-mL bag.

**Expect the sodium concentration to rise initially as the glucose level falls and water is removed from the circulation.**

**Cerebral oedema may be related to a plasma sodium concentration that falls or does not show the expected rise as glucose levels fall.**

### Electrolytes

#### Bicarbonate

Bicarbonate is rarely, if ever, necessary. Continuing acidosis usually indicates insufficient resuscitation. Bicarbonate should only be considered in children who are profoundly acidotic (pH < 7.0) and shocked with circulatory failure. Its only purpose is to improve cardiac contractility in severe shock. The maximum volume of 8.4% sodium bicarbonate for half-correction of acidosis is calculated according to the following formula, and given over 60 minutes:

Volume (mL) of 8.4% sodium bicarbonate =  $1/3 \times \text{weight (kg)} \times \text{base deficit (mmol/litre)}$  divided by 2.

If no **blood gas measurement** is available, do not give bicarbonate unless the child is in **profound shock**.

#### Potassium

- Commence potassium immediately unless anuria is suspected, or there are peaked T waves on the ECG, or the serum potassium concentration is higher than 7.0 mmol/litre.
- Potassium is mainly an intracellular ion, and there is always massive depletion of total body potassium, although initial plasma levels may be low, normal or even high. Potassium levels in blood will fall once insulin is commenced.
- Add 20 mmol KCl to every 500 mL unit of IV fluid given.
- Check urea and electrolytes 2 hours after resuscitation

is commenced and then at least 4-hourly thereafter, and alter potassium replacements accordingly (more potassium is sometimes needed).

- Use a cardiac monitor to observe frequently for T-wave changes, and alert nursing staff to any changes that might be seen, and advise them when to call for medical help.
- **If potassium-containing fluids are not available, start insulin (see below) after 1–2 hours of rehydration, and arrange transport to a unit that can provide this (if available).**

### Insulin

Once fluids are running, calculation of the insulin infusion rate may be undertaken at leisure, as the blood glucose levels will already be falling. Continuous low-dose IV infusion is the preferred method.

However, **if a syringe pump is not available or not safe to use** after at least 1 hour of rehydration treatment give subcutaneous boluses of short-acting insulin 1- to 2-hourly at 0.1 unit/kg/dose. Give half the dose if the blood glucose level is falling too fast.

There is no need for an initial bolus, and some evidence that insulin should not be given during the first hour of IV fluid treatment.

If an infusion system is available and safe to use, make up a solution of 1 unit/mL of human soluble insulin (e.g. Actrapid) by adding 50 units (0.5 mL) of insulin to 49.5 mL of 0.9% saline in a syringe pump. Attach this using a Y-connector to the IV fluids that are already running. Do not add insulin directly to the fluid bags. The solution should then run at 0.1 unit/kg/hour (0.1 mL/kg/hour).

Once the blood glucose level is down to 14 mmol/litre, change to 5% glucose in 0.9% saline (add 50 mL of 50% glucose to a 500 mL bag of saline) and potassium as above. Do not reduce the insulin infusion until the pH is > 7.3 and the glucose concentration is < 14 mmol/litre, when it may safely be reduced to 0.05 mL/kg/hour.

If the blood glucose level falls below 7 mmol/litre, consider adding extra glucose to the infusion.

If the blood glucose level rises out of control, re-evaluate the patient (check whether there is sepsis or some other condition). Then:

- 1 Check that the insulin syringe pump is connected and working.
- 2 Make up a fresh solution of insulin, preferably using a new source of insulin in case the original one is denatured, and consider starting the whole protocol again.

Frequent sips of oral rehydrating fluid or nasogastric fluid up to 5 mL/kg/hour may be used as a substitute in the immediate initial period while arranging transport. Once the blood glucose level is < 14 mmol/litre, more glucose may be required (e.g. fruit juice if tolerated).

**Remember that you must have glucose ready to treat hypoglycaemia (5 mL/kg of 10% dextrose).**

### Continuing management

#### Output

- Urinary catheterisation should be avoided, but may be useful in a critically ill child with impaired consciousness. With or without catheterisation, documentation of fluid balance, if necessary by weighing nappies, is of paramount importance.

- Measure accurately and test all urine samples for glucose and ketones.
- Record all fluid input (even oral fluids).
- If a massive diuresis continues, fluid input may need to be increased.
- If large volumes of gastric aspirate continue, replace them IV with 0.45% saline plus 10 mmol/litre KCl.

### Laboratory results

Check biochemistry, blood pH and laboratory blood glucose levels 2 hours after the start of resuscitation, and at least 4-hourly thereafter.

Review the fluid composition and rate according to each set of electrolyte results. If acidosis is not correcting, resuscitation may have been inadequate, in which case consider giving more 0.9% saline or Plasma-Lyte 148. Consider sepsis as a cause of persistent acidosis. Consider antibiotic treatment.

### Insulin management

Continue to give IV fluids until the child is drinking well and able to tolerate food. Do not expect ketones to have disappeared completely before changing to subcutaneous insulin. **Discontinue the insulin infusion 60 minutes after the first subcutaneous injection in order to avoid rebound hyperglycaemia.**

## Cerebral oedema in DKA

### Signs and symptoms of cerebral oedema

These include the following:

- headache
- irritability
- seizures
- increasing blood pressure and slowing pulse
- confusion
- reduced conscious level
- small pupils
- possible respiratory impairment.

### Management

- Exclude hypoglycaemia as a cause of neurological symptoms.
- Give mannitol 500–1000 mg/kg immediately (2.5–5 mL/kg 20% mannitol over 15 minutes). Alternatively, give 3% saline 5 mL/kg over 5–10 minutes. Give this as soon as cerebral oedema is suspected.
- **Restrict IV fluids to two-thirds maintenance, and replace the deficit over 72 hours rather than 48 hours.**
- **Keep Na<sup>+</sup> levels > 135 mmol/litre. Keep the head in the midline and 30 degrees elevated.**
- **Avoid fever > 38.0°C.**
- Repeated doses of mannitol or strong saline (at the dose stated above, every 2–4 hours) should be used to control intracranial pressure.

### Care of the newly diagnosed diabetic child

After treatment of DKA in the newly presenting but well diabetic child, the process of education and treatment should commence. It is not feasible to stabilise the child's control or to teach all aspects of diabetic care while they are an inpatient, so ideally (if resources permit) this should take place at home, although some authors advocate a prolonged initial admission for this process.

Ensure that the parents and the child (if he or she is able to do so) understand or can perform the following:

- insulin administration
- urine testing for ketones
- blood testing
- dietary measures
- other general issues.

### **Insulin**

Draw up the specified dose of insulin correctly. As a rough guide, a new patient will need approximately 0.5 unit/kg/day.

The frequency and choice of insulin depends entirely on local resources. This may mean twice daily medium-acting insulin alone (60% in the morning, 40% in the evening), or medium-acting insulin mixed together with short-acting soluble insulin (usually in a 30% short/70% long ratio). If newer analogue fast-acting insulins are available, these may be given before every meal in an initial dose of 1 unit for every 20 grams of carbohydrate eaten, with a longer-acting insulin (40% of the total daily dose) given before bedtime.

It is very rarely possible to achieve adequate control with a single daily dose of insulin except in very small children. However, once-daily medium-acting or pre-mixed insulin should be seen as a minimum fallback position if availability of insulin is a problem. Likewise, although it is common practice to use human or genetically modified insulins, pork or beef insulin may be substituted if necessary.

Further modification of the dose will take place as an outpatient, as more insulin will be needed after the initial period and with growth and puberty.

### **Urine testing**

Test the urine for sugar using stick tests. Clinitest tablets for reducing substances are too cumbersome for routine use, but may be used as a substitute if they are the only option. Suggest stick testing about twice daily at home. Emphasise the value of testing the first morning urine to estimate overnight control.

Test the urine for ketones using Ketostix or tablets. This only needs to be routinely done if the urine contains 3% glucose or more, and in times of intercurrent illness when the persistence of ketonuria should prompt the seeking of medical attention for incipient DKA.

The importance of accurate recording of the results in a control book, if possible, should be emphasised, to aid decision making at follow-up.

### **Blood testing**

If resources allow, all parents should be able to test the blood glucose level, at least in an emergency, and ideally also for routine monitoring of control. The parent or carer (and also the child, if appropriate) should be taught the following:

- how to use a lancet (or automatic finger-pricking device) to draw blood from the side (**not the pulp**) of the finger
- how to ensure that an adequate sample is placed on the strip
- how to read the strip visually (a meter may be used if resources allow)
- if this method of monitoring control is chosen, the importance of providing test results at staggered times through the day (ideally one or two tests per day) should be explained; **the need for accurate recording of the**

**values in a diary should be emphasised (ascertain the parents' literacy and numeracy levels)**

- the instantaneous nature of the result obtained and the detection of hypoglycaemia with blood testing should be highlighted, and compared with urine testing.

### **Diet**

The parents or carers and the child should **ideally meet a specialist diabetic dietitian** and discuss the concept of carbohydrate balance and how the diet is spread through the day. The diet must be adequate for growth and nutrition, and should contain around 50% of energy as complex carbohydrate. It is not advisable to allow 'free' fatty foods, as they may accentuate later macrovascular complications.

Explain the importance of fairly close adherence to the advised diet, and that the diet may need to be revised from time to time as the child grows and their pattern of activity changes.

The parents or carers and the child should understand the influence of food intake on blood sugar levels. Diabetic carbohydrate 10-gram 'portions' are often used with analogue short-acting insulin boluses before meals (if available), but need considerable expertise to be taught effectively.

Sweet unrefined sugars should ideally only be taken before exercise or as occasional treats, although ideally the insulin dose should be varied to take this into account.

### **General care**

- **It is essential that the parents or carers and the child (if he or she is old enough) understand how inadequate glycaemic control may predispose to micro- and macrovascular complications in the longer term. These are not uncommon findings in teenagers in Africa, due to their appalling glycaemic control in earlier childhood.**
- **It is also important that the parents or carers ensure that a supply of insulin is always available, as the commonest cause of DKA is lack of insulin at home in resource-limited environments.**
- The parents or carers and child (if appropriate) should understand how exercise, diet and insulin interact to influence blood sugar levels.
- The symptoms of hypoglycaemia should be explained. It is important that the parents or carers understand the possible signs of an attack and what can be done to terminate the 'hypo'. They should know how to use rapid-acting sweet sugary gel, non-'diet'/'lite' sugary drinks or tablets during the early stages of the attack. Ideally, a 1-mg glucagon pack (if available) should be given to each family prior to discharge, and the parents should be shown how to prepare and give the pre-packed injection in an emergency to terminate a severe hypoglycaemic attack with unconsciousness or fits. If a 'hypo' is treated, a more complex carbohydrate snack should be given to prevent immediate recurrence.
- The family should be given the address of any local support groups for individuals with diabetes and their families (if such groups exist). If possible, give the parents and child a folder containing relevant booklets on diabetes.
- The family should ideally have access to medical advice and treatment 24 hours a day if they are worried about their child's immediate health, or can be seen at the next outpatient clinic for less urgent problems.

**Ideal checklist for use at discharge**

- Dextrose gel: 1 box of plastic tubes or 50 grams of dextrose tablets.
- Disposable syringes and needles, ideally 0.3-mL low-volume syringes with as small a needle as can be located (down to 31-gauge are available).
- Insulin.
- GlucaGen Novo 1 mg pack.
- Glucose testing blood sticks, finger-pricking device, plus lancets or urine sticks.
- Control book and pen.
- Ketostix.
- Sharps disposal bin.
- Appointment at next diabetic clinic.

**Outpatient care**

The patient should be reviewed at regular intervals (as frequently as resources allow). Ideally, at least once a year the child should have the following reviewed:

- their knowledge of diabetes and emergency management
- growth
- blood pressure

- state of injection sites
- foot examination and discussion of foot care
- fundoscopy (at diagnosis, for cataracts; after 5 years of diabetes or in teenagers, for retinopathy)
- microalbumin/creatinine ratio in the first morning urine sample for detection of renal complications (after 5 years of diabetes or in teenagers)
- **glycosylated haemoglobin** for monitoring long-term control (ideal control is a level of < 55 mmol/mol).
- **thyroid disorders and coeliac disease are both more likely to occur in children with diabetes. Although, ideally, antithyroid antibodies and anti-gliadin antibodies could be checked** at the time of diagnosis of diabetes, and every 4 years thereafter, they are expensive tests and in resource-limited environments it is better to undertake a careful clinical assessment for additional thyroid or coeliac disease at annual outpatient appointments.

Transfer to adult services should take place in a planned manner, ideally at a joint handover clinic.

**5.8.B The child with hypoglycaemia****BOX 5.8.B.1 Minimum standards**

- Oral glucose solutions.
- IV 10% and 50% glucose.

**Introduction**

Hypoglycaemia is an important cause of morbidity and mortality that needs to be recognised, as the complications are potentially preventable.

**Definition**

Hypoglycaemia is now widely defined as a blood glucose concentration of less than 2.5 mmol/litre (45 mg/dL) at any age. The measurement should ideally be made in a laboratory with appropriate quality control. Testing with reagent strips is less accurate, particularly within the critical range.

**Presentation and aetiology**

Hypoglycaemia may present at any age from birth into adulthood. Symptoms are varied and rarely specific, particularly in infants. In neonates, fits and apnoeic attacks may be important clues. In infants and children the most important presentation, because of the risk of complications, is also fits and encephalopathy (see Table 5.8.B.1). The common causes are listed below.

In infants and children in well-resourced countries, ketotic hypoglycaemia, endocrine disorders and metabolic disorders usually predominate. By contrast, in resource-limited countries, malnutrition and infections such as malaria (and its treatment) are more common.

**Treatment****Glucose dosage**

There is insufficient scientific data to be definite about the

quantity of glucose to give parenterally to a hypoglycaemic child. 5 mL of 10% glucose was the standard dose for a time but there is evidence that this much glucose can raise the plasma glucose to a level high enough to produce an insulin surge which then results in another hypoglycaemic episode. Of course, in a diabetic child who has become hypoglycaemic because of insufficient calories or too much insulin, this will not occur, so in these circumstances 5 mL of 10% glucose is safe.

- When testing for hypoglycaemia is not possible, treat any critically ill child presenting with suspicious symptoms such as fits, with encephalopathy, or with a condition known to be associated with hypoglycaemia, such as severe malnutrition or malaria.
- If the child is conscious and able to eat and drink, give them food or sugary fluids or glucose orally (0.5–1.0 gram/kg).
- Otherwise, give 2–5 mL/kg 10% glucose IV over 3 minutes. **Never use stronger glucose solutions IV.** Continue with 0.1 mL/kg/minute 10% glucose to maintain the blood sugar concentration in the range 5–8 mmol/litre.
- If hypoadrenalism/pituitarism is suspected, give hydrocortisone as described in Section 5.8.C.
- In hypoglycaemic children with diabetes or suspected hyperinsulinaemia, if IV access is not possible and glucagon is available, give IM 100 micrograms/kg (maximum of 1 mg as a single dose).

**Longer-term management**

- Provide appropriate endocrine management (see Section 5.8.C).
- Avoid periods of fasting. Give glucose orally when at risk during intercurrent infections, or IV if the child is comatose or vomiting, and during anaesthesia.

## Diagnosis of the cause of hypoglycaemia

If the blood sugar level is less than 2.5 mmol/litre, it is important to establish a cause. Transfer 1 mL of blood into a fluoride tube, if possible also 1 mL heparinised blood, and the first urine after the hypoglycaemic episode to send for metabolic analysis, in particular for ketones.

- Is there ketosis? If so, look for signs of hypopituitarism and/or growth hormone deficiency.
- If feasible, check the cortisol growth hormone level and insulin levels in blood taken at the time of hypoglycaemia.
- If the blood lactate level is raised, consider organic acidaemia or a defect of gluconeogenesis.
- If ketosis is absent, consider hyperinsulinism (high birth weight) or disorders of fatty acid oxidation.

### Prevention

As the symptoms are non-specific, measure blood glucose levels if possible in any suspected situation. If hypoglycaemia is suspected and blood glucose measurement is not possible, treat with glucose and observe the response.

**If the response is clearly related to giving glucose, assume that hypoglycaemia was present.**

In the neonate, every effort should be made to avoid those factors that will exacerbate hypoglycaemia, including delayed feeding and hypothermia (see Section 3.4).

**TABLE 5.8.B.1 Common symptoms and signs of hypoglycaemia**

In childhood	In neonates
Convulsions	Convulsions
Reduced conscious level	Reduced conscious level
Anxiety	Jitteriness, tremor
Sweating, pallor	Cyanotic episodes
Palpitations	Apnoeic episodes
Headache	
Behaviour abnormalities	
Visual disturbances	
Slurred speech	
Ataxia	
Hunger	

### Some causes of hypoglycaemia

#### Neonates

- Birth asphyxia.
- Small for gestational age.
- Preterm birth.
- Sepsis.
- Malnutrition.
- Hypothermia.
- Infant of diabetic mother.
- Liver disease, endocrine and metabolic disorders (see below).

#### Infants and children

##### Endocrine disorders

- Diabetic on treatment.
- Persistent hyperinsulinaemic hypoglycaemia of infancy (formerly nesidioblastosis) and other congenital and inherited hyperinsulinaemic syndromes.
- Islet-cell tumours.

- Hypopituitarism.
- Growth hormone deficiency.
- Adrenal insufficiency (any cause).

##### Metabolic disorders

- Disorders of glycogen metabolism, gluconeogenesis or fatty acid oxidation, organic acidaemias, etc.
- Ketotic hypoglycaemia ('accelerated starvation').
- Liver disease: any severe acute liver disease.
- Malnutrition.
- Infections: malaria, especially when treated with quinine.
- Any severe illness.

##### Poisoning

- Alcohol.
- Salicylates.
- Insulin.

##### Drugs

- Oral hypoglycaemic agents.

### How to give glucose in suspected hypoglycaemia

If the patient is conscious, give sugary drinks or foods such as jam, candy or honey.

If the patient is unconscious:

- 1 Insert an IV or IO line and draw blood for emergency laboratory investigations.
- 2 Check blood glucose levels with a glucose monitoring stick. If low (< 2.5 mmol/litre (45 mg/dL) in a well-nourished child or < 3 mmol/litre (54 mg/dL) in a severely malnourished child) or if blood glucose cannot be measured because no stick test is available, treat as for hypoglycaemia anyway.
- 3 Give 2–5 mL/kg of 10% glucose solution rapidly by IV or IO injection or 2.5 mL/kg of 10% glucose in the neonate.
- 4 Recheck the blood glucose level after 20 minutes. If it is still low, repeat 2–5 mL/kg of 10% glucose solution. Continue if necessary with an infusion of a glucose containing fluid such as 5 mL/kg/hour of 10% glucose in 0.45% saline until the child is capable of drinking. Monitor the blood glucose until stable.
- 5 If venous or intra-osseous access is impossible in an unconscious patient, give sublingual sugar (see below for technique).
- 6 Feed the child as soon as they are conscious.
- 7 If it is not possible to feed the child without risk of aspiration, give:
  - milk or sugar solution via a nasogastric tube (to make sugar solution, dissolve 4 level teaspoons of sugar (20 grams) in a 200-mL cup of clean water)
  - IV fluids containing 5–10% glucose (dextrose).

**Note:** 50% glucose solution is the same as 50% dextrose solution or D50.

If only 50% glucose solution is available: dilute 1 part of 50% glucose solution to 4 parts of sterile water, or dilute 1 part of 50% glucose solution to 9 parts of 5% glucose solution. **For example, 10 mL of 50% solution with 90 mL of 5% solution gives 100 mL of an approximately 10% solution.**

**Note:** For the use of blood glucose stick tests, refer to the instructions on the box. Generally, the strip must be stored in its box, at 2–3°C, avoiding sunlight or high

humidity. A drop of blood should be placed on the strip (it is necessary to cover all of the reagent area). After 60 seconds, the blood should be washed off gently with drops of cold water and the colour compared with the key on the bottle or on the blood glucose reader. (The exact procedure will vary with different strips.)

### **Sublingual sugar (sucrose) for treatment of hypoglycaemia**

Sublingual sugar may be used as an immediate 'first-aid' measure when managing hypoglycaemia in an unconscious child in situations where IV or IO administration of glucose may be impossible or delayed.

- 1 Give ½ to 1 teaspoonful of sugar, moistened but not dissolved with 1–2 drops of water and insert under the tongue (sublingually) and between the lower jaw and the gums (in the buccal area). Children should be

monitored for early swallowing, which leads to delayed absorption, and in this case another dose of sugar should be given. If sublingual sugar is given, repeat the doses at 20-minute intervals. This is a useful technique in the community where facilities for parenteral glucose may not be available. However, note that sublingual and buccal absorption is not as effective as gastrointestinal absorption of sugar.

- 2 Recheck the blood glucose level after 20 minutes, and if the level is still low ( $< 2.5$  mmol/litre or  $< 45$  mg/dL), repeat the IV glucose (5 mL of 10% glucose/kg) or repeat the sublingual sugar.
- 3 Prevent further hypoglycaemia by feeding where possible. If IV fluids are being given, prevent hypoglycaemia by adding 10 mL or 20 mL of 50% glucose to 90 mL or 80 mL, respectively, of Ringer-lactate solution or 0.9% saline to give a 5% or 10% glucose solution, respectively.

## 5.8.C Other endocrine disorders

### Adrenal crisis

#### **BOX 5.8.C.1 Minimum standards**

- ABC resuscitation skills and equipment.
- Hydrocortisone and fludrocortisone.
- IV saline 0.9%.
- IV glucose 10%.

#### Diagnosis

An adrenal crisis is most likely to be encountered in a neonate with congenital adrenal hyperplasia (CAH) or hypopituitarism (look for virilisation in the female with CAH, and micropenis and cryptorchidism in the male with hypopituitarism). It may occur in older children with adrenal destruction secondary to autoimmune processes or tuberculosis.

Suspect adrenal crisis in a severely ill child with:

- acidosis
- hyponatraemia
- hypotension
- hyperkalaemia
- hypoglycaemia.

#### **Children receiving long-term steroid therapy**

Replacement steroids given as hydrocortisone up to 10 mg/m<sup>2</sup>/day replicate natural secretion and are free of side effects if adequately monitored.

Therapeutic doses of steroids for asthma, rheumatoid arthritis, etc. will produce adrenal suppression in a manner related to the dose and duration of treatment. Short 5-day courses of prednisolone therapy will produce measurable adrenal suppression that almost never requires action. Longer courses up to 1 month should be tapered off over a 2-week period to allow recovery of the pituitary adrenal axis.

More prolonged treatment with high-dose steroids may produce profound hypoadrenalism for months after cessation of treatment. In this case, taper the steroid dose to the equivalent of 5 mg/m<sup>2</sup>/day of prednisolone. Then convert

this to an equivalent dose of hydrocortisone given in the morning (1 mg prednisolone is equivalent to approximately 3 mg hydrocortisone). Then reduce the hydrocortisone by 2.5 mg/week until the child is on approximately 6 mg/m<sup>2</sup>/day, when it is probably safe to stop treatment after 2 weeks. **If possible, check the 9 a.m. pre-dose cortisol level and stop treatment if this exceeds 150 nmol/litre at any time.** Severe stress, infection or injury will require increased steroid cover **during the next 6 months.**

Children on physiological replacement treatment or prolonged pharmacological doses of steroids should ideally carry some warning identification for medical staff, advising against the abrupt cessation of steroids, and stating the emergency stress dose of oral (usually three times replacement dose) or parenteral treatment for operative cover or at times of illness associated with vomiting (hydrocortisone, 12.5 mg for infants, 25 mg for children, 50 mg for older children and 100 mg for adults, given as an immediate IV/IM dose and then 4- to 6-hourly IV).

#### **Management of adrenal crisis**

- Treat airway, breathing, shock and hypoglycaemia (see Section 5.8.B).
- Continue 0.9% saline to correct the deficit and for maintenance (see Section 5.8.A).
- Give hydrocortisone IV 6-hourly as follows: 12.5 mg dose for neonates and infants, 25 mg for children aged 1–5 years, 50 mg for children aged 6–12 years, and 100 mg for adolescents aged 13–18 years.
- If the diagnosis is established, continue maintenance hydrocortisone, 8–12 mg/m<sup>2</sup>/day in three divided doses (12–15 mg/m<sup>2</sup>/day for CAH) and, if salt loss is demonstrated in the context of CAH or adrenal destruction, fludrocortisone 150–250 micrograms/m<sup>2</sup>/day in one dose. Infants may also require oral sodium chloride, 1 gram/10 kg/day (60 mg = 1 mmol).

#### **Hypoglycaemia**

For a discussion of neonatal hypoglycaemia, see Section 3.4.

## Thyroid disorders

### BOX 5.8.C.2 Minimum standards

- Thyroxine.
- Carbimazole.
- Propranolol.
- Iodine supplements.

### Neonatal thyrotoxicosis

Mothers who have active thyrotoxicosis or who have become hypothyroid as a consequence of treatment of thyrotoxicosis may still pass thyroid-stimulating antibodies to the fetus during the last trimester. The neonate (or fetus) will show the following:

- hydrops in severe cases
- tachycardia with heart failure: **this may occur at up to 1 week post delivery**, especially if the mother is on anti-thyroid drugs
- thinness/light for dates
- diarrhoea
- hyperkinesia
- possibly craniosynostosis.

### Management

- If hyperthyroidism is detected antenatally, treat the mother with low-dose carbimazole, 5–15 mg/day (use the lowest dose possible for control).
- Treat the infant with:
  - propranolol, 1 mg/kg three to four times orally daily
  - carbimazole, initially 250 micrograms/kg 3 times a day
  - aqueous iodine oral solution (5% iodine plus 10% potassium iodide), 130 mg/mL of total iodine, 1 drop 0.05–0.1 mL every 8 hours until thyroid control is achieved.
- Stimulating antibodies will clear by 3 to 6 months of age, and treatment can be stopped.

### Congenital hypothyroidism

Between 1 in 2000 and 1 in 10000 babies are born with a maldescended or absent thyroid gland. There are rarer cases of dyshormonogenesis (dominant and recessive – more common as a consequence of consanguineous relationships) associated with neonatal goitre and very rare central isolated thyroid-stimulating hormone (TSH) deficiency.

Untreated early hypothyroidism results in cretinism.

**Many countries screen for this condition in the first month of life**, looking for elevated TSH (except in TSH deficiency) and/or low thyroxine or free thyroxine levels. Different screening laboratories will produce different assay results.

In general, TSH in high double figures (mU/litre) is unequivocally raised and will be confirmed by a total thyroxine concentration of less than 50 nmol/litre or a free thyroxine in single figures (pmol/litre).

In resource-limited countries, X-ray of the knee or wrist to detect delayed bone age in infants and young children is helpful for diagnosis where TSH or thyroxine assays are unavailable.

An untreated affected child will develop, in the following order:

- jaundice

- constipation
- hoarse cry
- umbilical hernia
- coarse features
- mental retardation
- poor growth.

Therefore clinical awareness is important in order to identify possible cases of hypothyroidism in babies with the common symptoms of jaundice and constipation. Prolonged jaundice should lead to investigations, including those for hypothyroidism (see Section 3.4).

### Management

Give thyroxine, 10–15 micrograms/kg once daily, titrated to maintain TSH in the normal range with normal growth and development. The adult dose is around 2–3 micrograms/kg.

### Iodine deficiency

This most commonly occurs in inland mountainous areas. The clinical features vary among different ethnic groups, with deafness, mutism, mental impairment and poor growth being common, and goitre being universal. The disorder may be prevented by adding potassium iodide to cooking salt (10 mg/kg salt) or providing it as supplemented sweets and bread. Iodide as an oily suspension can be given intramuscularly every 3 years.

### Acquired hypothyroidism

This is usually part of an autoimmune process (which may be familial), and may be associated with diabetes mellitus. It is much more common in older girls, who will usually have the following:

- goitre
- lethargy
- poor growth rate with excess weight gain
- pallor
- constipation
- hair loss/dry skin
- delayed puberty.

The diagnosis is confirmed by raised blood TSH levels and, if possible, demonstration of antithyroid peroxisomal antibodies.

### Management

Thyroxine is given to suppress TSH to the normal range and allow normal growth and pubertal development.

### Doses of thyroxine

Neonate: initially 10–15 microgram/kg once daily (maximum 50 micrograms daily) then adjusted in steps of 5 micrograms/kg every 2 weeks or as clinically indicated; usual maintenance dose 20–50 micrograms daily.

Child 1 month–2 years: initially 5 microgram/kg once daily (maximum 50 micrograms daily) then adjusted in steps of 10–25 micrograms daily every 2–4 weeks or as clinically indicated; usual maintenance dose 25–75 micrograms daily.

Child 2–12 years: initially 50 micrograms once daily then adjusted in steps of 25 micrograms daily every 2–4 weeks or as clinically indicated; usual maintenance dose 75–100 micrograms daily.

Child 12–18 years: initially 50 micrograms once daily then adjusted in steps of 25 micrograms daily every 3–4

weeks or as clinically indicated; usual maintenance dose 100–200 micrograms daily.

### Thyrotoxicosis

This is much more common in older girls, often those with a family history of thyroid disease. It should be suspected if the following are present:

- fine tremor
- weight loss
- psychiatric disturbance
- exophthalmos (rare in children)
- tachycardia with a wide pulse pressure
- loose stools
- goitre with bruit.

The diagnosis is confirmed by suppressed TSH (level is undetectable) with raised thyroxine level.

### Management

Treatment is with low-dose carbimazole. In neonates to children aged 12 years initially 250 micrograms/kg 3 times a day (maximum 30 mg/day) and adjusted as necessary until euthyroid. In children aged 12 to 18 years initially 10 mg 3 times a day adjusted as necessary. Carbimazole should be continued for at least 2 years, after which withdrawal should be attempted. If relapse occurs, the options include further medical therapy, surgery by an experienced thyroid surgeon, or radio-iodine in a specialised centre.

### Thyroid mass

#### Smooth goitre

An isolated smooth goitre with or without a bruit may occur in:

- iodine deficiency
- acute and subacute thyroiditis (viral, bacterial, lymphocytic or other), which is usually tender
- ingestion of goitrogens (e.g. cabbage, kale or other brassicas)
- familial dyshormonogenesis
- idiopathic pubertal goitre
- thyrotoxicosis (Graves' disease, thyroiditis, thyroid hormone resistance)
- Hashimoto's thyroiditis.

If thyroid function is normal, no treatment is necessary; otherwise treat as described above. In iodine-deficient areas where thyroid investigations are not available, treat with oral aqueous iodine as described above.

Nodules require investigation by fine-needle aspiration and histology.

#### Nodular goitre

Nodular goitre may occur in:

- Hashimoto's thyroiditis
- adenoma (hot, cold, euthyroid)
- lymphoma
- non-thyroidal masses (lymph nodes, branchial cleft cyst, thyroglossal cyst)
- isolated simple cyst
- carcinoma
- histiocytosis.

## Disorders of sexual development (DSD)

Uncertainty regarding a child's gender is a distressing emergency for the family.

Most of these children are well unless associated with congenital adrenal hyperplasia (CAH) and salt loss (see above) or other major congenital abnormalities.

**Avoid the urge to decide the appropriate sex of rearing of the child until the results of diagnostic tests are available.**

Support the parents during this difficult time.

- DSD may be the result of excess androgens in females (the commonest situation, usually secondary to CAH of the 21-hydroxylase deficiency variety), lack of androgens (or the receptor) in males, or (rarely) mixed gonadal DSD with the presence of ovarian and testicular tissue. Minimum investigations are chromosome analysis and plasma for 17-hydroxyprogesterone (**which is elevated in the commonest form of CAH**). **If a baby with a DSD becomes unwell with hypotension, hyponatraemia and hyperkalaemia, assume an adrenal crisis and treat as described above.**

- Further investigation requires highly specialised tests (i.e. blood, radiology and ultrasound, fibroblasts, laparoscopy or laparotomy). Treatment of non-CAH DSD is also complex, but can often be deferred to allow appropriate transfer of care to a specialist centre. In specialist centres there need to be close working relationships between the different specialists. It is not appropriate for surgeons to operate without involving endocrinologists in working up these patients, and **it is essential that the members of the multidisciplinary team work closely together in the management of these cases.**

## Congenital adrenal hyperplasia (CAH)

Congenital adrenal hyperplasia (CAH) is an autosomal-recessive condition, and therefore is more common in consanguineous relationships. Many forms exist, as several enzymes involved in the synthesis of cortisol and aldosterone may be deficient; partial cases also occur within each subtype.

Salt-losing 21-hydroxylase deficiency is by far the commonest type. Most forms result in over-masculinisation of the female (although under-masculinisation of the male can also occur in defects near the start of the biosynthetic pathway). Salt loss occurs in several forms (see above), although the second commonest deficiency (11-beta-hydroxylase) causes salt retention and hypertension.

Females usually present as DSD (see above) and males with salt loss, which usually occurs after the first week of life (see above for acute and long-term management). In non-salt-losing forms there will be incomplete early puberty (see below).

Once the diagnosis is established, treat with mildly suppressive doses of hydrocortisone, 12–15 mg/m<sup>2</sup>/day in three divided doses and, if salt loss is demonstrated, fludrocortisone, 150–250 micrograms/m<sup>2</sup>/day in one dose. Infants may also require oral sodium chloride, 1 gram/10 kg/day (60 mg = 1 mmol).

## Addison's disease and Cushing's syndrome

### Addison's disease (hypoadrenalism)

Hypoadrenalism may present as an emergency (see above) or be suspected if there is:

- unexplained lethargy
- failure to thrive
- pigmentation of scars and skin
- vitiligo or other signs of autoimmune disease
- a strong family history of hypoadrenalism or unexplained sudden death
- hyponatraemia and hyperkalaemia
- syndrome of candidiasis and hypoparathyroidism preceding the hypoadrenalism (HAM or APECED syndrome).

**If confirmed by a low 9 a.m. cortisol level (< 150 nmol/litre), treat as outlined above for adrenal crisis.**

### Cushing's syndrome (hyperadrenalism)

Cushing's syndrome is usually the result of iatrogenic corticosteroid administration (> 12 mg/m<sup>2</sup>/day hydrocortisone or the equivalent; see above). Over-secretion of adrenal steroids is rare. Signs of corticosteroid excess include the following:

- poor (zero) growth rate
- red cheeks
- striae
- glucose intolerance
- excess weight gain (central)
- muscle weakness
- hypertension.

Adrenal carcinoma or adenoma may produce Cushing's syndrome. There is often accompanying virilisation and an abdominal mass. The child is usually young, in contrast to the older child with Cushing's disease secondary to an ACTH-secreting pituitary adenoma.

The diagnosis is supported by a **detectable midnight cortisol level (> 50 nmol/litre) or raised urinary free cortisol excretion. The 9 a.m. cortisol level fails to be reduced to undetectable levels in response to dexamethasone 0.3 mg/m<sup>2</sup> given as a single dose the previous night.**

**Treatment usually requires specialist surgery.**

### Hypogonadism and delayed puberty

- Hypogonadism may be secondary to central gonadotrophin deficiency (hypogonadotrophism: LH/FSH low) or peripheral gonadal failure (hypergonadotrophism: LH/FSH high).
- Suspect congenital central hypogonadism in a male neonate with undescended testes and micropenis (shaft length < 2.5 cm). Hypopituitarism may also be present.
- If hypogonadism remains undetected, failure of or incomplete pubertal development will occur.
- Delayed puberty is often familial, but may be induced by emotional or nutritional deprivation.
- There is delayed maturation of gonadotrophin secretion.
- Treat if the delay is severe enough to cause psychological damage.
- Give a brief course of testosterone esters (100 mg by deep IM injection (Sustanon) at 1-month intervals three times in boys) or oral oestrogen (5–10 micrograms/day

for 3 months in girls). This allows puberty to be induced and also reduces the risk of later osteoporosis.

- If the hypogonadism is likely to be permanent, continue and gradually increase testosterone to 250 mg/month or oestrogen to 25–50 micrograms/day over a 2½-year period (the latter eventually as a combined oral contraceptive medication to allow withdrawal bleeding).

**TABLE 5.8.C.1 Causes of delayed puberty**

Low LH/FSH + low testosterone/oestrogen	High LH/FSH + low testosterone/oestrogen
Chronic ill health	Gonadal trauma/infection
Constitutional/familial	Gonadal dysgenesis or Turner's syndrome (XO)
Starvation, low body mass index	Klinefelter's syndrome (XXY)
Genetic (e.g. Kallmann's syndrome, Prader–Willi syndrome)	Some cases of DSD
Prolactinoma (rare)	Autoimmune ovarian damage
Hypopituitarism, hypothyroidism	Galactosaemia
Thalassaemia	

### Precocious puberty

- In precocious puberty, early sexual maturity (at less than 8 years of age in females, or less than 10 years of age in males) is usually accompanied by a growth spurt and relatively tall stature for age.
- In central gonadotrophin activation, there is development of full puberty (i.e. breasts and pubic hair with eventual menstruation, or testicular enlargement plus pubic hair and penis development).
- In secondary cases there is excess peripheral sex steroid production/ingestion. Some aspects of puberty will be exaggerated, whereas other tissues will be normal, or may regress (e.g. large penis and pubic hair plus small hard testes in androgen excess in CAH, large breasts but no pubic hair in oestrogen-secreting tumour).
- Idiopathic central precocity is commonest in females, and may be familial.
- Male gonadotrophin activation may be a sign of a CNS tumour.
- Investigation and treatment are complex and specialised, and include suppression of gonadotrophin secretion in central precocious puberty, and surgical removal or suppression/blocking of the peripheral source of sex steroid production in peripheral causes.

### Growth hormone deficiency and short stature

Growth hormone deficiency (GHD) may be idiopathic, familial, part of hypopituitarism or isolated.

In the neonatal period, isolated GHD or hypopituitarism may cause hypoglycaemia (see Section 3.4). After excluding or treating hypoadrenalism (see above), growth hormone may be required to maintain **normoglycaemia and normal growth but such treatment requires expert input.**

Growth hormone is essential for normal growth, and GHD should be suspected in the child who is:

- short in relation to their peers and in comparison with their parents
- growing slowly
- relatively heavy for their height.

Outside the neonatal period, treatment is rarely urgent. Growth hormone is administered as a subcutaneous injection. It is expensive and difficult to store.

The causes of severe short stature include the following:

- secondary to chronic ill health or under-nutrition; these patients are often thin
- secondary to chronic emotional trauma; these patients are often thin
- endocrine (hypothyroid, hypopituitary, GHD, Cushing's syndrome); these patients are often relatively heavy
- syndromic (e.g. Turner's syndrome, etc.); these patients are usually dysmorphic, but some may have few external features, so it should be suspected in all short females outside their genetic range
- disproportionate with short limbs (bony dysplasias, rickets)
- metabolic (storage disorders, osteogenesis); these patients have longer limbs than back.

Short stature in the latter three causes is extremely difficult and expensive to treat.

### Hypopituitarism

In the neonate there will be hypoadrenalism with or without GHD leading to hypoglycaemia. Suspect hypopituitarism in any male neonate with cryptorchidism and micropenis.

Onset later in life may signal an intracranial lesion such as craniopharyngioma (which may be visible as a calcified mass on plain lateral skull X-ray or CT scan; MRI scans show a cystic cavity at the base of the brain). Symptoms outside the neonatal period include the following:

- poor growth/short stature (secondary to GHD)

- lethargy
- hypotension
- hypothermia
- hypothyroidism (see above)
- hypogonadism (see above)
- visual field defects, headache and/or raised intracranial pressure if secondary to tumour.

Treatment is outlined in the sections on individual hormone deficiencies above.

### Diabetes insipidus

Isolated diabetes insipidus is rare, but it can occur as part of hypopituitarism or secondary to infiltration of the posterior pituitary by tumour or destruction by infection. Suspect it in any case of:

- dehydration with dilute (colourless) urine
- polyuria and polydipsia not due to diabetes mellitus
- secondary daytime wetting without an obvious cause
- familial history.

It is important to request a fluid balance diary at home, and for carers to allow access to water alone between meals as the only fluid permitted. This will help to identify the many behavioural causes of polydipsia, and will avoid the need for awkward and unnecessary tests of urinary concentrating capacity.

Diagnosis is confirmed by the simultaneous presence of hyperosmolar serum (> 290 mOsm/litre) and dilute urine (< 300 mOsm/litre or specific gravity < 1005).

Treat by allowing free access to water and, if possible, replacement of antidiuretic hormone **with** a long-acting analogue, DDAVP, which can be given intramuscularly, by nasal spray or orally. The dose is titrated to keep **the specific gravity of the urine in the range 1005–1010** and/or the serum osmolarity normal. Try to allow one period of diuresis before each dose is due, to prevent dangerous hyponatraemia from over-treatment.

## 5.9

# The child or adolescent with a mental health problem

### BOX 5.9.1 Minimum standards

- Knowledge, skills and tests that exclude organic medical causes.
- Effective child protection systems.
- Fluoxetine.
- Risperidone, chlorpromazine and flupenthixol.
- Supportive family therapy.

### Introduction

Around 10–20% of all children have one or more mental or behavioural problems (World Health Report 2001). The rates are higher in urban areas and increase in adolescence. One in ten young people suffers from mental illness or symptoms

of mental distress severe enough to cause some level of impairment, yet less than one in five receives the treatment that they need.

Prematurity, poor nutritional status, low birth weight, organic brain damage and physical handicap often bring about biological stressors. A disadvantaged socio-economic status of families contributes negatively to the mental health of children. Child development suffers where there is persistent marital discord, parental psychiatric ill health and/or a history of substance abuse. Protective factors include stable care, an adaptable and engaging personality, problem-solving abilities and a supportive network of family and friends.

The aggregate disease burden of these disorders has

not been estimated, and it is complex because many of these disorders can be precursors to much more disabling disorders during later life. Mental health disorders of childhood and adolescence are very costly to society in both human and financial terms.

Psychiatric disorders that arise in adolescence are different from those in children and similar to those in adults. The vulnerability of adolescence relates to difficulty in establishing an identity, during which there may be alienation from the parents. There is also intense emotional interaction with friends, which makes adolescents especially vulnerable to the effects of peer pressure, and issues of sexuality. Emotional disorders include anxiety states, depression, hysteria and specific phobias.

Conduct disorders occur in about the same proportion, and include conditions that range from oppositional defiant behaviour to persistent patterns of aggression and rule breaking. About 20% of the teenagers may present with a mixture of disorders.

**The link between adverse family environmental factors and mental health disorders in children and adolescents is fundamental and must be explored as part of the assessment and treatment.**

### Acute psychiatric emergencies: suicide and deliberate self-harm

In well-resourced countries there has been a persistent rise in fatal suicide attempts, especially in young males. A history of substance abuse, conflict with the law and personal and mental illness are important factors. **The possibility of abuse within (most likely) or outside the family must be at the forefront of a search for why this occurred, as there may be other children 'at risk'.** The method of suicide depends on the means available. Males are more likely to use violent means than females. Overdoses of drugs or poison, hanging and immolation are common methods of suicide.

Suicide is extremely rare in pre-pubescent children, but the frequency rises sharply during the teenage period. Again a search for evidence of abuse must be undertaken.

Deliberate self-harm is a non-fatal act in which a child or young person deliberately ingests noxious substances in excess of therapeutic doses, or causes self-injury. It is best interpreted as a 'cry for help'. Again, the possibility of abuse must be considered in all cases.

#### Assessment and questions to be asked

- **Are there any indicators or clinical signs of physical or sexual abuse?**
- **Have there been any previous attempts at suicide?**
- Is there a risk of suicide or of a repeated attempt?
- Was a suicide note left?
- Was there pre-planning?
- How likely was the young person to be found?
- What was the method used?
- How lethal was the method used?
- Did the young person know how toxic the substance was?
- What quantity of the substance was taken?
- Was it impulsive in the context of a conflictual relationship?
- Was it to attract sympathy or seek attention (e.g. following a disciplinary crisis or the loss of a friend)?

- Is there a psychiatric disorder?
- What is the family and developmental history, including educational functioning?
- How well does the child solve problems and cope with difficulties?
- How effective and who are the social/parental supports, including adequacy of supervision?

**It is important to clarify to the family (preferably in the presence of the child) that information given by the child is confidential.**

#### High-risk factors

- Undiagnosed and unmanaged abuse.
- The risk of repetition is higher in the next 4 weeks after the attempt. It also increases if there is a history of previous self-harm attempts.
- Male gender.
- Lack of support, and easy access to a means of committing suicide (e.g. a firearm or drugs belonging to other family members in the home).
- Presence of depressive illness, with loss of sleep, appetite, depressed mood, agitation, and in particular continued suicidal ideas (hopelessness, inability to enjoy life, asking 'What's the point?').

#### Treatment

- Treatment of the medical consequences of self-harm is the priority (see Section 7 especially Section 7.4).
- Assessment of the child and their family should be undertaken when the child is free from the after-effects of the drug overdose/self-inflicted injury.
- It is important to take the young person's suicidal ideas seriously and not to expose them to sarcasm or ridicule in discussions. Assessment should include consideration of a mental illness and also of the family and social circumstances of the young person and the context in which the self-harm occurred.
- Nothing predicts behaviour better than past behaviour. Those with a low risk of repetition can be offered support during subsequent crises, and arrangements made to assist the child and their family in developing coping strategies. A psychologist, social worker or trained psychiatric nurse (if available) can assist the family in this way.
- **If there is abuse, the child must be protected from further harm by arranging the involvement of social services and the police (as appropriate in the setting).**
- Children at high risk of death need a major input, although inpatient facilities are generally sparse and often unavailable. Depending on resources (or lack of them) the physician needs to improvise and involve social agencies and the family (particularly the extended family if there are immediate parental problems) to provide appropriate supervision, support and treatment.
- Those with a history of substance abuse will need specific counselling.
- The presence of mental illness merits specific treatment (psychological therapies and/or medication) and intervention (see below). Issues that triggered the self-harm should be addressed if possible. Relationship difficulties should be borne in mind.

## Depressive disorders

Depression is a recurring illness characterised by episodes of dysfunction. It is common, and has a lifetime prevalence in adults of 15–20%. It has been reported in 1% of preschool children, 2% of school-age children and 5–8% of adolescents; girls are twice as likely to suffer from depression as boys. The incidence is rising, or else depression is being recognised more, with each successive generation. It is detected at a younger age and there has been a parallel increase in suicide in the paediatric age group.

Sadness, unhappiness and misery are common childhood experiences (usually in reaction to adverse family circumstances), but when sadness is extreme in intensity and duration, it may be due to a depressive illness. Depression or depressive illness always needs urgent attention.

The presentation of depression varies with the age of the child. Infants and preschool children cannot express feelings of sadness in language. In this age group, depressive symptoms must be inferred from apathy, withdrawal from caregivers, delay or regression of developmental milestones, and failure to thrive that has no organic cause.

School-aged children are cognitively able to internalise family conflict, criticism or failure to achieve. They display low self-esteem and guilt, but depression is often mainly expressed in somatic complaints (headaches, stomach aches, disturbed sleep and appetite), anxiety (school phobia, excessive separation anxiety), irritability (temper tantrums and other behavioural problems) and academic decline.

Common symptoms in adolescents resemble adulthood depression, with more anger than sadness, hostility mainly towards family, sleep and appetite often normal, drug abuse, academic decline and suicide attempts. A depressed mood (dysphoria) is accompanied by loss of emotional involvement (withdrawal), feelings of guilt and unworthiness, and an inability to cope effectively. A 'depressive disorder' refers to an observable depressed mood, tearfulness, suicidal thoughts, disturbance of sleep and appetite, and a lack of energy.

When the above symptoms persist or occur despite an absence of adverse environmental causes, and functioning is impaired, a diagnosis of depressive illness can be considered. It is worth noting that around 40% of children with conduct (behaviour) disorders have associated mood disturbances, and that children presenting with depression may have other problems, such as anxiety or substance abuse.

### Assessment

Assessment should include the child or adolescent and their family or other people who know the young person well. This may be impossible for the teenager who has no family, or for the older teenager who refuses to have their parents involved.

**At the beginning of the assessment it is helpful to clarify the bounds of confidentiality.** The parents and the child need to understand that what each of them says will not be freely shared without consent. However, it should also be made clear that there are limits to confidentiality in situations in which the law requires reporting, such as abuse, and also in situations where the child's safety is at serious risk – for example, of suicide.

Assess the degree of dysfunction and distress that the symptoms are causing the child and their family.

Assessment requires a detailed history, mental state

examination, play and observation of the child–parent interaction. A full medical examination and neuropsychological testing to rule out neurological or learning disorders and to assess the child's developmental capabilities should be undertaken. Psychological assessment tests such as a strength and difficulty questionnaire may be helpful.

### Risk factors

- A family history of depression predisposes to depression, and the children of depressed parents are three times more likely to develop depression themselves. Early onset in the parents is associated with a higher risk for the children.
- Family and social environmental risk factors include family conflicts, rejection, lack of communication, lack of expression of love, poor family support systems, abuse (physical, emotional or sexual), and parents who are excessively controlling.
- Adverse life events, such as the death of a parent or other loved one, parental divorce, exposure to suicide, relationship problems and academic failure can precipitate depression.
- Negative emotions such as low self-esteem, self-criticism, negative interpretation of life events and a feeling of lack of control can all contribute.
- The process of puberty can precipitate depression.

### Issues in management

The diagnosis of a depressive illness (as opposed to transient sadness, which is very common) should be made **only** after careful history taking and information from the family, school and (if possible) close friends. **Almost all 'depression' in children or adolescents is related to environmental factors, and a diagnosis of depressive illness should only be made when it is certain that environmental factors are not responsible.**

In addition, and in older adolescents, **bipolar disorder** may present for the first time, and a history of symptoms of hypomania should always be undertaken. If such symptoms are elicited, a daily symptom diary may be helpful. There are specific drug treatments for bipolar disorder which include mood stabilisers, and the support of an adult psychiatrist can be very helpful.

**Medical conditions that can present with depressive illness must be excluded, using appropriate investigations,** in particular vitamin or mineral deficiencies (full blood count), thyroid dysfunction (TSH levels), tuberculosis (chest X-ray) and HIV infection.

If possible, address any stressful factors in the child's environment.

### Management of sadness

The opportunity to discuss their difficulties with a sympathetic and helpful listener can itself be very useful to a depressed child or adolescent. The depressed child will tend to blame him- or herself, and there should be an attempt to enable the child to deal with issues without such negative feelings.

It is important to explore sensitively any factors in the child's life that may have led to the episode of self-harm, and to put the problems right as far as possible, while recognising that some situations cannot be changed.

Work to help the young person to understand him- or herself, identify feelings, change maladaptive patterns of

behaviour and improve relationships can be very helpful, and will provide useful skills for them later on in their life.

Consider the mental health of other members of the family, which may be having a significant effect on the child or adolescent. Helping the parents may help the child. Postnatal depression occurs in about 10% of mothers, and tends to recur with each pregnancy. Family therapy and support can also be very helpful.

Regular exercise (e.g. involvement in sport) can be very useful for some people with depression. It is also important to get enough sleep and to eat as healthy a diet as possible.

**Formal ‘talking therapies’** such as cognitive-behavioural therapy can be helpful, but they require specialist training and are not widely available, even in well-resourced countries.

### **Management of depressive illness**

**It is vital that the child or adolescent is informed that their symptoms and the effects of the symptoms on their behaviour and educational function are not due to anything they have done or are doing wrong.** The young person and their family need to learn how to distinguish between the normal range of feelings and those, including sadness, that suggest the onset or presence of the depressive disorder.

In more severe forms of depressive illness, particularly in adolescents, antidepressants can be helpful, but in general their use is best avoided.

### **Antidepressant medication**

The antidepressants of first choice for adolescents aged 12–18 years are selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, which can be effective but are expensive. They should be prescribed following baseline measurements of blood pressure and heart rate, physical examination for extrapyramidal symptoms, etc. The suggested baseline laboratory investigations are complete blood count, liver function tests, pregnancy tests for girls, and ECG. The common side effects of SSRIs are dizziness, sweating, diarrhoea, headaches, fatigue, restlessness, initial insomnia, and weight loss or gain. Uncommon side effects may include delayed micturition, blurred vision, skin rashes, etc., and should be explained to the patient and their family.

Usually fluoxetine is best tolerated if given in the morning after breakfast, but in situations in which it causes drowsiness it can be taken in the evening. Changes in symptoms do not occur for at least 3–6 weeks. Follow-up must be insisted upon while the young person is on medication.

Suicidal feelings must be explored routinely at onset and at follow-up.

**Fluoxetine:** the starting dose in children aged 12 to 18 years is 10mg daily, and the dose may be increased to 20mg daily after 1–2 weeks. There is little information about the use of fluoxetine in children under 12 years of age.

Abrupt discontinuation of SSRIs may induce withdrawal symptoms, some of which mimic a relapse of a depressive episode (e.g. tiredness, irritability and severe somatic symptoms).

Once the patient has been free of symptoms and back to normal life for at least 8 weeks, fluoxetine should be continued for 6 months, then gradually reduced and stopped over a period of 6–12 weeks. The speed of reduction should be decided with the patient, taking into consideration any symptoms of withdrawal.

**Tricyclic antidepressants have major side effects, including cardiovascular complications. They are also very dangerous in overdose. Therefore they must not be used.**

**Monoamine oxidase inhibitors (MAOIs) must not be used because of their dangers when taken with certain foods.**

### **Hysterical conversion disorder**

This is a subgroup of somatoform disorders. It refers to loss or alteration of physical functioning without organic cause. The child presents with physical symptoms which result in disability in the absence of consistent physical signs or evidence of a physical illness. The most frequent symptoms are pseudo-seizures, loss of sensation and loss of limb function. These are common in post-pubertal female adolescents. They usually arise when the adolescent is facing a predicament that they cannot resolve. This may be related to academic, family, interpersonal, sexual, abuse, religion or societal issues.

As well as a thorough history and interview, the assessment should include a full physical examination to assess symptoms that do not correlate with known neurological pathways (e.g. a gait that is inconsistent and varying). It is important to keep an open mind about the possibility of a physical problem which has not yet manifested itself, and reconsider this regularly.

Pseudo-seizures may occur in adolescents who also have epileptic seizures, and it may be difficult to distinguish between them and provide the correct treatment. A blood test taken within 20 minutes of an episode to measure serum prolactin levels (if facilities for this are available) can be useful for differentiating between pseudo-seizures (prolactin levels are normal) and epileptic seizures (prolactin levels are raised).

Once a psychiatric disorder has been diagnosed, the emphasis should move from medical investigations to amelioration of presenting symptoms and appropriate psychological intervention. The latter should incorporate ‘face-saving’ formulae to allow the young person to come to terms with the absence of physical disease, but the presence of an illness which is ‘real’ as far as the young person is concerned. Whatever the cause, the disability and the impact on the young person’s life are real, and may be more difficult to manage than a physical illness with similar symptoms. This aspect of the disorder must be carefully explained to the family as well, in case they believe that the young person is faking an illness.

### **Drugs and alcohol: use and abuse**

Drug use and availability have changed radically in the last decade or two. The substances abused depend on availability and supply. As children get older, the proportion who have ever tried drugs increases. Which drugs are illegal and which are socially acceptable vary between countries and among different groups of people in the same country, and the use of drugs by children and adolescents is influenced by this. A child’s abuse of drugs is contextual – that is, it depends on societal norms, family history, etc. Parental criminality or substance abuse increases the risk. Reliable data on drug abuse in children are scarce and not validated. However, there is increasing acceptance that the rates of drug use are increasing, particularly in inner-city areas among children who are deprived (e.g. ‘street children’).

Volatile substance abuse is common in children, but seldom persists into adulthood. Solvents are easily available (e.g. butane gas, lighter fuel, paint thinners, aerosols, etc.), and are most commonly abused through a plastic bag to maximise the effects.

Stimulants such as cocaine and amphetamines are taken in powder form, intranasally or injected. They produce elevation of mood, energy, a reduction in appetite and hallucinations.

Drugs may be used for pleasure, or to remove (however briefly) the pain of daily life. Many drug users live in very difficult conditions and/or have mental health problems in addition to their drug habit. Prostitution is often associated with drug use, trapping (mainly women) in a vicious cycle. There is also a strong association of substance abuse with conduct disorder. In conduct disorders there is a repetitive and persistent pattern of behaviour in which societal norms or rules are violated (e.g. fighting, bullying, cruelty to people and animals, destruction of property, stealing and deceit). Many drug abusers will take up crime to pay for their drugs.

### Assessment

It is important to establish the extent, frequency and severity of drug abuse or dependence. In addition, information needs to be elicited concerning behavioural patterns, social competency, educational functioning, peer relationships and psychiatric status.

Physical examination should include a check for fresh injection marks, old scars or the physical sequelae of drug use.

### Management

There are very few, if any, specialised treatment centres for children who abuse drugs. Treatment outcome will vary according to the chronicity and/or the substances abused. For example, only a limited impact is made on alcohol or marijuana abuse, whereas heroin or cocaine treatment programmes are more successful in reducing the use of these drugs.

Methadone as part of a well-controlled and structured treatment system is the most common approach to managing long-term opiate dependence. However, it is rarely available in resource-limited settings. The initial dose for children over 15 years of age is 10–20 mg daily, increasing by 10 mg/day until there are no signs of withdrawal or toxicity (the usual dose is 40–60 mg/day). Opiates can give rise to nausea and vomiting. Withdrawal symptoms include restlessness, irritability, and increased bowel activity with abdominal pain. Methadone treatment is not appropriate for those with a short history of opiate dependence.

### Schizophrenia

This is a serious mental illness characterised by abnormalities of thinking, perception and emotion, usually first diagnosed in late adolescence, although rarely the onset can be seen in childhood. Consider the diagnosis if two or more of the following symptoms are present for 1 month or longer:

- delusions: beliefs which are unshakeable
- hallucinations: 80% of affected children have auditory hallucinations; visual hallucinations are more likely to be due to an organic medical disorder such as a brain tumour or poisoning
- disorganised (incoherent) speech

- grossly disorganised or catatonic behaviour
- negative symptoms (flat affect).

The onset is usually insidious. Many children have pre-existing problems with social withdrawal, disruptive behaviour, developmental delay and language problems, and then go on to develop more florid symptoms such as hallucinations. Mood disorders may present with schizophrenic-like symptoms, and making the diagnosis may be difficult.

### Assessment

Any diagnosis is dependent on detailed history taking and examination, and schizophrenia is no exception. To evaluate the progress, it is important to define the baseline symptoms, functioning and problems in various aspects of the young person's life (i.e. education, family and social functioning).

Before a definitive diagnosis of schizophrenia is made, **organic medical conditions must be excluded** by the following tests. However, it has to be accepted that in resource-limited settings many of these tests will not be available: blood tests for haemoglobin, indices such as MCV (to rule out vitamin B<sub>12</sub> deficiency), thyroid function, liver and renal function, heavy metals such as lead, mercury and arsenic, HIV indicators, the Wassermann reaction for syphilis, urine test for toxicology, an EEG to help to rule out temporal lobe epilepsy, and a CT scan of the brain.

### Management

Children and adolescents with schizophrenia present a challenge as they are seriously ill, and often their social and educational progress is seriously disrupted. Treatment is difficult, and all management should be under the supervision of a psychiatrist (if available). Treatments aim to reduce the frequency of relapses and disability.

It is important to work closely with the family. Negative symptoms such as blunting of emotions, impoverished thinking and lack of motivation are particularly distressing to relatives. Furthermore, highly expressed emotions and negative feelings increase the risk of relapse. The family will need support and help to manage their child's symptoms. The techniques for reducing highly expressed emotions require specialist training.

Pharmacological treatment to control symptoms is the important initial management. Psycho-educational, social, cognitive and family intervention programmes are important in long-term management. Oral neuroleptics provide the patient with a sense of control. Any adverse effects will quickly become apparent, but the medication must be administered daily and the patient may not always be compliant. Depot neuroleptics provide a way of enhancing compliance.

**Atypical antipsychotic drugs** are now the treatment of choice (if available), as they have less extrapyramidal side effects. Risperidone can be given to children over 12 years of age, starting at 2 mg per day and increasing by 1 mg per week to a maximum daily dose of 8 mg. Side effects include postural hypotension, weight gain, hyperglycaemia and mild extrapyramidal signs.

**Standard antipsychotic drugs** are more likely to be available in resource-limited settings. Standard antipsychotic treatment for acute schizophrenic symptoms is usually initiated with chlorpromazine. For children aged

12–18 years, start with oral treatment with 25 mg three times a day or 75 mg at night, and then gradually increase the doses until there is control of symptoms, usually achieved with a maximum dose of 100–300 mg daily. Premature changes in drug choice should be avoided, as the response time may be 30 days or more.

Poor response may be due to an inadequate dose or poor compliance.

Depot medication is suitable for long-term treatment (flupenthixol by deep IM injection into the outer buttock or lateral thigh with a test dose of 20 mg, then after 7 days 20–40 mg repeated 3- to 4-weekly according to the response. The usual maintenance dose is 50 mg every 4 weeks to 300 mg every 2 weeks,

Side effects include extrapyramidal signs (Parkinsonism, dystonia, restlessness and tardive dyskinesia), hypotension and less commonly neuroleptic malignant syndrome (hyperthermia, fluctuating consciousness, muscle rigidity and autonomic dysfunction).

## Post-traumatic stress disorder (see also Section 1.23)

### Introduction

Nearly all children and adolescents who have experienced catastrophic situations will initially display symptoms of psychological distress, including intrusive flashbacks of the stress event, nightmares, withdrawal and inability to concentrate, among others. **Most children and adolescents will regain normal functioning once their basic survival needs are met, safety and security have been restored, and developmental opportunities have been regained, within the social, family and community context.**

Post-traumatic stress disorder (PTSD) is a relatively new diagnostic category first officially created by DSM-III in 1980. Around 25–35% of those exposed to traumatic events develop PTSD. Individual differences in response to trauma depend on the following:

- stressor severity and degree of exposure to the stressor
- exposure to previous traumatic events
- the child's perception of the event
- the child's appraisal of the threat to their survival, and the degree of human accountability
- for younger children, the response and functioning of adults, particularly close family, around them can be important.

Anxiety disorders, abnormal grief reaction, somatic complaints and impairment in educational functioning can all occur.

### Diagnostic criteria

The child has experienced an event that is outside the range of normal experience and that is life-threatening to them or to those close to them. There is persistent re-experiencing of the traumatic event – that is, distressing recollections, dreams or flashbacks.

There is avoidance of the stimuli associated with the trauma, and a range of signs of physiological arousal occur, such as difficulty in sleeping, irritability or poor concentration.

In younger children, repetitive play related to the trauma may be present. They may have frightening dreams that have no obvious content, and may regress in their development.

### Assessment

It must first be established that the child has experienced a traumatic event that preceded the onset of the symptoms. The traumatic event may not necessarily lead to development of PTSD. Instead, the child may develop acute stress disorder or sadness.

When assessing the child, the interviewer will need to take account of the child's maturation, and their verbal facility and functioning. Details of the traumatic event, the child's perception of the event, and their response immediately and later, should be evaluated.

The differential diagnoses include obsessive-compulsive disorder, schizophrenia and anxiety disorder. Flashbacks may need to be distinguished from intrusive and unwanted thoughts that are unrelated to the traumatic event, which occur in obsessive-compulsive disorder.

### Management of trauma-affected children (see also Section 1.23)

If possible, reuniting the child with their parents or other close relatives and restoring normal comforting routines is helpful.

Some children will require more specialised interventions to address their suffering and help to restore their flow of development. Immediately after traumatic events, activities and opportunities that allow children to talk about or otherwise express painful experiences and feelings (e.g. by physical and artistic expression) are most beneficial if facilitated by people whom the children know and trust, and have continued contact with.

The goals of psychological treatment are reduction of symptoms, development of coping skills, and helping the individual to gain a sense of well-being and control. Education and gradually increasing goal setting help the child to relax, solve problems and gradually achieve mastery over fearful thoughts. The help of a clinically trained psychologist or psychiatrist may be needed to plan the treatment.

Trauma counselling should never be provided unless an appropriate and sustained follow-up mechanism is guaranteed.

The psychosocial well-being of adults, particularly parents and caregivers, has a direct impact on that of children, and should therefore be addressed through concurrent parent-focused psychosocial interventions. The participation of children, and adults, in decisions that affect their lives has a positive effect on their mental health, empowers them, and helps them to regain control over their own lives.

### Panic attacks

These are common in children and adolescents, and can mimic physical illnesses. Hyperventilation, sometimes with tetany, is a key feature, as well as the fear of 'going crazy' or dying. The best way of controlling such attacks is to explain the physiological features of panic to the child and their family, and to teach proper breathing techniques (namely to breathe slowly at a rate normal for the child's age).

### Preventive intervention

The promotion of mental health through a healthy lifestyle brought about by health education and life skills training has the potential to equip a young person for their journey through life. There is material available in the public domain on life skills training (e.g. on the WHO/UNICEF websites)

which has been used in many resource-limited and middle-income countries.

### **Autism and autistic spectrum disorders**

This is a group of disorders with similar features, although an individual child may not display all of them, and the severity may vary. Autism becomes evident before 3 years of age, but children with other conditions that form part of the autistic spectrum may present later (e.g. at school age).

Autistic behaviour may occur as an isolated problem, or it may be a component of a number of childhood developmental disorders. It is important to consider these when assessing a child, in case intervention may help. Sensory deficits, particularly deafness, which may be hard to identify in a young child, are especially important in this respect. Children with hydrocephalus, metabolic disorders (e.g. phenylketonuria), hypothyroidism, fetal alcohol syndrome, tuberous sclerosis, neurofibromatosis, Down's syndrome and other chromosomal disorders may exhibit features of autism.

Autistic children characteristically have difficulties with the following:

- social interaction and reciprocity
- language development and communication skills
- imagination and play
- rigid thinking
- restrictive and repetitive stereotypical patterns of behaviour, activities and interests.

#### **Social interaction**

Autistic children may make little or no eye contact. They may not be able to share experiences or to understand the feelings of others, or recognise clues to their feelings from their behaviour (e.g. that people who are crying are sad).

#### **Language and communication**

Young children with autism may not point to get attention or to show another person something. They may never develop any useful language, or they may have unusual speech with abnormal intonation, jumbled words, incomprehensible sounds, or repetition of the same words again and again (echolalia).

#### **Cognitive function**

Children with autism may have global cognitive impairment or general impairment but considerable skill in some areas (e.g. numbers, art).

#### **Rigid thinking and ritualistic behaviour**

Autistic children often have very structured repetitive play (e.g. organising objects in a certain pattern). They may persist much longer than usual in putting things in their mouths, or they may hold on to objects, moving and feeling them in their hands, for long periods. Routine is very important, and they are often very upset by any disruption, which may lead to outbursts of temper.

#### **Management**

There is no cure as yet for autism. Management focuses on encouraging the child to learn as much as possible and to develop behaviour that helps him or her to live happily within the family and community.

Support for the family in caring for these children, who

can be very challenging, is essential. Education for the family and community about the difficulties of autistic children, so that their behaviour is not misinterpreted as naughtiness, or caregivers criticised inappropriately, is also very important. Healthcare professionals and teachers experienced in the care of children with autism can give a great deal of assistance to families.

Vigilance for other problems, especially with hearing or vision, which if undiagnosed will add to the child's difficulties, should be maintained.

For some children with autism who have severe aggressive behaviour and only under expert supervision consider risperidone:

- **Child over 5 years and 15–20 kg:** 250 micrograms daily increased if necessary after at least 4 days to 500 micrograms daily; thereafter increased by 250 micrograms daily at 2-week intervals to maximum of 1 mg daily
- **Child over 5 years and over 20 kg:** 500 micrograms daily increased if necessary after at least 4 days to 1 mg daily; thereafter increased by 500 micrograms daily at 2-week intervals; max. daily dose 2.5 mg if under 45 kg; maximum daily dose 3 mg if over 45 kg.

Review effectiveness and side effects after 3–4 weeks; stop if no response at 6 weeks.

### **Asperger's syndrome**

Asperger's syndrome has some features in common with autism, in that affected individuals also have difficulties with social interaction, especially in understanding the usual patterns of social behaviour of their community. They often develop very deep and detailed knowledge about subjects that interest them, and become experts who can contribute to society, but they may also become isolated if others do not share or understand their interests.

Asperger's syndrome is usually identified later than autism, often when children are at school, and are recognised as different from their peers. They may be bullied and very lonely, as they long to have friends and 'fit in', but do not have the social skills to enable them to do so.

Like autism, there is no cure for Asperger's, but teaching from as early an age as possible about appropriate behaviour can help these children. Education for their families and communities, so that they understand that the child has a condition which makes it hard for him or her to pick up social clues, and is not just being difficult, along with appreciation of any special talents, is essential. If it is acceptable to the child or adolescent, written information to give to people to explain what they find hard may be useful.

### **Attention deficit hyperactivity disorder (ADHD)**

Children with ADHD characteristically have difficulties with the following:

- inattention
- hyperactivity
- impulsivity.

These features must be present before the age of 6–7 years, evident in more than one situation (e.g. at home and at school), and interfere with the child's social or educational functioning.

These characteristics may persist into adult life, resulting in inattentive and disorganised or impulsive risk-taking behaviour.

### **Inattention**

Children with ADHD cannot concentrate for very long, especially on tasks they have been given which have no immediate reward (e.g. schoolwork).

### **Hyperactivity**

These children are always on the move. Young children with ADHD may run, jump, climb, make a lot of noise and never settle to anything. School-age children and adolescents have difficulty sitting still, and may be constantly tapping their feet, wriggling and fidgeting.

### **Impulsivity**

Children with ADHD do not think before they act. They may have accidents or get into trouble for recklessness.

### **Other problems**

Children with ADHD can be exhausting. They are often in trouble because they are so active and may have poor relationships with other children and adults, and low self-esteem. They may sleep badly, struggling to get to sleep or waking frequently, and be poor eaters because they cannot sit still for long enough to finish a meal.

### **Causes**

There is no known cause of ADHD. Some of the contributory factors include the following:

- genetic: parents or siblings affected
- living conditions: ADHD is more common in children from disadvantaged backgrounds
- depression in the child's mother
- these factors may all interact.

In addition to occurring alone, the features of ADHD may be seen in young people with neurological conditions such as head injuries, fetal alcohol syndrome, encephalitis and meningitis, epilepsy, hypothyroidism and some syndromes, such as fragile X syndrome, Williams' syndrome and tuberous sclerosis.

### **Comorbidities**

Children with ADHD often have additional problems, such as mild cognitive impairment, delayed language development, poor coordination, reading difficulties and mood disorders.

### **Assessment**

- Developmental history, especially any delay and when noted.
- Pregnancy and birth, including any exposure to drugs or alcohol.
- Family history of similar problems, maternal depression and social circumstances.
- Educational progress: both intelligent children and children with specific learning difficulties who are bored can be disruptive.
- The parents' expectations of the child and their response to his or her behaviour.
- Medical history and examination for neurological problems, including any medication being taken by the child that might affect his or her behaviour.

- Careful observation of the child in several settings, including home and school.

### **Management**

There is no cure for ADHD, but careful management can help these children and their families a great deal.

- Look for any health problems that might be contributing to the condition and could be treated (e.g. large tonsils and adenoids preventing undisturbed sleep).
- Explain to the child and their family that they have a disorder that affects their behaviour, and that they are not just a naughty child.
- The most useful management is behavioural.
- Drugs may be helpful in severe cases.

### **Behavioural management**

Children with ADHD do best where there are as few distractions as possible around them, and where there are clear rules about the conduct that is expected, with praise or reproof given immediately if merited. When doing tasks such as schoolwork, they are best on their own or in a small group, sitting near to the person in charge. They often have low self-esteem. Giving praise when they do well, with frequent small rewards, is very helpful.

### **Drugs**

The most widely used drugs for ADHD are stimulants such as methylphenidate (Ritalin), which can be given to children aged over 6 years in a dose of 5 mg once or twice daily, increasing by 2.5–5 mg weekly up to a maximum daily dose of 60 mg. If methylphenidate has not made any difference after 3 weeks at full dose it should be stopped. Slow-release preparations are also available and can be given less frequently. If effect wears off in the evening (with rebound hyperactivity) a dose at bedtime may be appropriate (establish need with trial bedtime dose). Careful supervision is needed, and ideally children who require these drugs should be treated by a professional experienced in their use.

## 5.10 Nutritional disorders

### 5.10.A Vitamin or mineral deficiencies

#### BOX 5.10.A.1 Minimum standards

- Adequate diet.
- Vitamins A, B, C, D and K.
- Folic acid.
- Zinc.
- Iodine.

#### Vitamin A deficiency (VAD)

##### Significance

- Vitamin A deficiency is the single most important cause of childhood blindness in resource-limited countries.
- It makes a significant contribution to morbidity and mortality from common childhood infections, even at subclinical levels of deficiency.
- A Cochrane review indicates that regular vitamin A supplementation reduces mortality by 24%.

##### Prevalence

- Vitamin A deficiency is endemic in at least 60 countries worldwide, especially in Africa, South and South-East Asia, some areas of South America and the Western Pacific.
- Around 250 million preschool children are at risk.
- It causes 250 000–500 000 cases of blindness per year.

**Good food sources** are red palm oil, mango, pawpaw, dark green leafy vegetables, unskimmed milk, eggs and liver.

##### Aetiological factors

- Persistent inadequate intake of vitamin A exacerbated by insufficient consumption of dietary fat, leading to ineffective absorption.
- Frequent infections, especially measles, gastroenteritis and respiratory infections, resulting in decreased food intake, malabsorption, increased urinary loss, and increased utilisation of vitamin A by the body resulting in depletion of liver stores. The decrease in vitamin A levels in the body in turn predisposes children to infection, and so a vicious cycle is set up.
- Vitamin A deficiency is common in the context of poverty, social under-development, hostile living environments, water shortage and food scarcity, and individual factors such as lack of breastfeeding, inappropriate weaning practices and increased physiological needs during periods of rapid growth.

##### Clinical effects

- Night blindness (decreased ability to generate rhodopsin in the retinal rod photoreceptors essential for vision in dim light).

- Compromised integrity of epithelial surfaces due to loss of mucus-producing goblet cells, leading to 'dry eye' (conjunctival xerosis), Bitot's spots, corneal xerosis, corneal ulceration, and irreversible damage to the eye (keratomalacia).
- Depressed immunity (both innate and adaptive immunity), which results in increased susceptibility, duration and severity of common infections (e.g. acute respiratory infection, diarrhoea, measles).
- Poor growth, apathy and slow development.

TABLE 5.10.A.1 Signs of vitamin A deficiency in the eyes

Sign	Description
Night blindness	Inability to see in dim light (e.g. at dawn or dusk). Often occurs in the later part of pregnancy
Conjunctival xerosis	The conjunctiva looks dry and slightly rough instead of smooth and shiny
Bitot's spots	White foamy patches on the conjunctiva. Not always present
<i>Active corneal lesions:</i>	
At this stage the condition can worsen within a few hours and complete or partial blindness can result	
Corneal xerosis	The cornea looks dry and cloudy
Ulcers on the cornea	Often on the edge of the cornea
Keratomalacia	The cornea is cloudy and soft like jelly. Rare

##### Assessment of vitamin A status

There are no simple tests for vitamin A deficiency, but it is likely to affect communities where vitamin-A-rich food is scarce and infection and/or malnutrition rates are high.

- Vitamin A deficiency becomes a public health problem when the following are prevalent in the child population:
  - night blindness (> 1%)
  - Bitot's spots (> 0.5%)
  - corneal xerosis with or without ulceration (> 0.01%)
  - corneal scarring (> 0.05%).

##### Prevention

- Encourage the use of local foods rich in vitamin A.
  - Provide dietary education about vitamin-A-rich foods (e.g. dark green leafy vegetables, carrots, mango, papaya, eggs, orange fruits, liver, red palm oil, fatty fish).
  - Treat the siblings and mother. Mothers are especially vulnerable to vitamin A deficiency, and should be supplemented in the first month of lactation.

- Give regular supplementation every 4 to 6 months as described in Table 5.10.A.2.
- Prevent recurrent infections by recommending the use of impregnated nets, deworming, using clean water and breastfeeding.

**TABLE 5.10.A.2 Vitamin A supplements to prevent vitamin A deficiency**

Target group	Immunisation contact	Vitamin A dose
Infants under 6 months who are not breast fed or breast fed infants whose mothers have not received vitamin A supplements.		50 000 IU
Infants aged 6–11 months	Measles vaccine contact	100 000 IU
Children aged 12–59 months	Booster doses Special campaigns Delayed primary immunisation doses	200 000 IU every 4 to 6 months

Regular vitamin A supplementation is advised for all children in resource-limited countries. It has been shown to reduce all causes of mortality, and especially mortality from diarrhoea.

If a child has malnutrition, severe diarrhoea or measles, give one high-dose vitamin A capsule, according to Table 5.10.A.3, unless they have received a dose in the previous month.

### Treatment

If there are any eye signs, give vitamin A as indicated in Table 5.10.A.3.

**TABLE 5.10.A.3 Doses of vitamin A for treatment of clinical deficiency**

Age	Day 1	Day 2	Two weeks later
< 6 months	50 000 IU	50 000 IU	50 000 IU
6–12 months	100 000 IU	100 000 IU	100 000 IU
> 12 months	200 000 IU	200 000 IU	200 000 IU

If there are ulcers or the eyes look soft or cloudy, instil atropine 0.1%, three times a day for 3–5 days, and a topical antibiotic. Cover the affected eye with a saline-soaked bandage.

Deep IM injection of vitamin A (retinyl palmitate) 50 000 IU for children under 2 years of age, and 100 000 IU for those over 2 years, should be given if severe stomatitis, persistent vomiting or malabsorption are present.

### Vitamin B<sub>1</sub> deficiency: beriberi

- This may occur in areas of severe nutritional deprivation where little more than polished rice is consumed. It is uncommon in Africa, as the staple is maize or wheat, which contains vitamin B<sub>1</sub>.

- It affects adults, children and breastfed infants of thiamine-deficient mothers.
- It is often mistaken for oedematous malnutrition (kwashi-orkor), nephritis, cerebral malaria, encephalopathy or septicaemia.
- It causes wet (cardiac) or dry (neurological) beriberi:
  - cardiac failure with breathlessness, oedema and tachycardia
  - peripheral neuritis, with tingling and burning of feet, and reduced tendon reflexes
  - acute encephalopathy and coma.
- An aphonic form is characterised by a noiseless cry due to laryngeal nerve paralysis.

### Beriberi is rapidly fatal.

- The initial dose is 50–100 mg thiamine hydrochloride. IM or orally. This is particularly effective in heart failure (facilities for treating anaphylaxis must be available).
- Continue with 10 mg/day for children under 2 years of age, 25 mg/day for those aged 2–12 years, and 50 mg/day for those over 12 years for 3–4 days.
- Patients with beriberi often have other B vitamin deficiencies.
- Good food sources of vitamin B<sub>1</sub> are pork, whole grain cereals, legumes, nuts and liver.

### Nicotinic acid (niacin) deficiency: pellagra

Nicotinic acid is synthesised from the essential amino acid tryptophan, and pellagra is found where the diet is deficient in either nicotinic acid or tryptophan. It is common where maize is the staple diet, as in many parts of Africa. Maize is deficient in tryptophan, and the nicotinic acid is bound and unavailable.

### Clinical features

- Dermatitis of parts of the skin exposed to sunlight, namely the neck (Casal's necklace), face and hands, usually seen in children over 5 years.
- Diarrhoea and malabsorption.
- Encephalopathy, which is rare in children.

### Treatment

- Nicotinic acid:
  - 10 mg three times daily for 7 days in children under 2 years of age
  - 25 mg three times daily for 7 days in children over 2 years. In severe cases give 100 mg IV.
- Treat other B vitamin deficiencies at the same time (thiamin and riboflavin).
- Improve the diet with protein and green vegetables, peanuts, wholegrain cereals, meat, fish, chicken and liver.

### Vitamin C deficiency: scurvy

This usually presents at the age of 4–10 months. Cow's milk is low in vitamin C.

- Vitamin C is needed for collagen formation (in bones, cartilage, teeth and capillary walls).
- It is important for the healing of wounds.
- It increases iron absorption.
- It is found in citrus fruits, vegetables and breast milk.

Very little vitamin C is present in cow's milk, especially if it is heated.

- Vitamin C deficiency is found in severe malnutrition and in children fed on very poor diets in institutions.

### Clinical features

- Spontaneous haemorrhages, especially from gums, and defective bone, cartilage and dentine formation.
- Local tenderness and swelling of the legs (due to subperiosteal haemorrhages), which may present as irritability when the child is picked up or moved.
- Pseudo-paralysis of the limbs.
- Haemorrhagic and spongy changes in the gums.
- Petechiae and ecchymoses around the eyes.
- Microscopic haematuria may be present.
- The anterior ends of the ribs swell.
- Mild anaemia.
- Increased risk of fractures.
- Poor healing of fractures and wounds.
- Characteristic X-ray appearance: loss of trabeculae in long bones gives a ground-glass appearance, dense lines of calcification in the epiphysis next to the epiphyseal plate and calcification of subperiosteal haemorrhages.

### Treatment

- **By mouth**
  - Child 1 month–4 years 125–250 mg daily in 1–2 divided doses
  - Child 4–12 years 250–500 mg daily in 1–2 divided doses
  - Child 12–18 years 500 mg–1 g daily in 1–2 divided doses.
- A subsequent improvement in diet is needed, with plenty of fresh fruit and vegetables.

### Vitamin D<sub>3</sub> deficiency: rickets

Vitamin D deficiency causes the following:

- rickets (failure of mineralisation of growing bone)
- hypocalcaemic tetany in infancy
- osteomalacia in adults.

Nutritional rickets is most prevalent in North Africa, the Middle East and Pakistan. Asian and Afro-Caribbean children are also at risk in the UK and other countries where there is limited sunshine. Vitamin D deficiency is unusual in African children over 18 months, as at this age they can walk and therefore go out into the sunshine. Older children in Africa with rickets must be investigated for causes of rickets other than vitamin D deficiency, such as dietary calcium deficiency or inherited forms of hypophosphataemic rickets.

### Biochemistry

- Vitamin D increases Ca<sup>2+</sup> absorption from the gut, reabsorption of Ca<sup>2+</sup> from the kidney, and a phosphate diuresis.
- Vitamin D deficiency reduces Ca<sup>2+</sup> and increases parathyroid hormone (which increases phosphate loss by the kidney), resulting in low Ca<sup>2+</sup> and low phosphate levels. Subsequently there is a rise in alkaline phosphatase and then the X-ray features of rickets occur.

### Aetiology

- Prolonged breastfeeding, especially if the mother is vitamin D deficient.
- Lack of vitamin-D-containing foods such as oily fish, eggs, butter and margarine.
- Lack of sunlight exposure (UV light) (black- and brown-skinned children living indoors or in countries where there is little sunlight are particularly at risk).
- An infant's diet contains only small amounts of vitamin D, so fortification of foods and vitamin D supplementation is recommended.
- If a child presents with rickets and has normal exposure to sunlight, consider a hypocalcaemic diet (reported in South Africa and Nigeria). Cereals can bind calcium and prevent its absorption.
- Rarely, there is a metabolic disorder such as familial hypophosphataemic rickets. Where consanguinity is common, renal tubular disorders can produce this.
- Vitamin D deficiency also occurs in chronic renal and liver failure.

### Clinical features

- 1,25-Dihydroxyvitamin D crosses the placenta, and the neonate generally has sufficient levels for the first few months of life.
- Disturbance of the normal growth of the epiphyseal plate leads to the formation of inadequately calcified new bone at the diaphysis edge of the plate (so-called osteoid tissue). The proliferating zone on the epiphyseal side of the plate enlarges excessively, producing a swelling of the plate. Osteoid tissue may also form subperiosteally. There is also demineralisation of the skeleton. The following features result from these abnormalities:
  - epiphyseal swelling (especially distal radii at the wrists, and also the ankles and knees)
  - craniotabes (soft areas of the skull bones, especially of the occiput, which when pressed gently are easily depressed)
  - rickety rosary (enlarged costochondral junctions)
  - delayed fontanelle closure
  - curvature of the shafts of the tibia and femur (may occur in severe cases)
  - bossing of the frontal and parietal skull bones due to osteoid formation
  - pigeon chest (pectus carinatum)
  - Harrison's sulci
  - deformities of the thoracic and lumbar spine can produce kyphoscoliosis and lumbar lordosis
  - pelvic bone deformities in female children can lead to subsequent birthing difficulties due to damage to the inlet and outlet of the birth canal
  - delayed dentition
  - delayed gross motor development with generalised muscle weakness and hypotonia
  - growth retardation
  - occasionally, especially in infants, symptoms of hypocalcaemia.

### Diagnosis

- Very elevated plasma alkaline phosphatase activity.
- Usually normal, but possibly slightly low, plasma calcium levels.
- Very low plasma phosphate levels.

- Lowered plasma levels of 25-hydroxyvitamin D<sub>3</sub>, but often this cannot be tested for.
- The best sites to radiologically assess for rickets are those where there is rapid bone growth, namely the wrists and knees.
  - Typical X-ray appearance: cupping and fraying of the distal ends of the long bones, such as the ulna and radius.
  - There is widening of the metaphyseal plate due to osteoid formation.
  - The periosteum may be raised.
  - There may be abnormal curvature of bones and generalised under-calcification.

### Prevention measures

- Exposure to sunlight and foods such as egg yolk, milk and fortified margarine.
- Vitamin D<sub>2</sub> (ergocalciferol) supplementation, 400–600 IU daily.

### Treatment

- Vitamin D<sub>3</sub> (colecalciferol) or vitamin D<sub>2</sub> (ergocalciferol) by mouth daily for 4 weeks: child aged 1–6 months 3000 IU, 6 months–12 years 6000 IU and 12–18 years 10 000 IU.
- If hypocalcaemia is present, calcium supplements may be added in the early stages of treatment.

### Vitamin K deficiency

- Vitamin K is a cofactor for the hepatic synthesis of clotting factors (prothrombin, and factors VII, IX and X).
- Sources are green leafy vegetables, meat, liver, cheese, and synthesis by gut flora.
- Deficiency may occur as a result of the lack of bile salts and the malabsorption of fats after the use of broad-spectrum antibiotics, or in the breastfed newborn whose gut is not yet colonised with bacteria and therefore does not produce vitamin K.
- Treat bleeding due to vitamin K deficiency with 250–300 microgram/kg (max 10 mg) IV; neonates 1 mg. Repeat doses every 8 hours if needed.
- Prevent haemorrhagic disease of the newborn by giving 1 mg vitamin K to all newborn infants either orally or IM (preterm 400 microgram/kg maximum dose 1 mg).

### Folic acid deficiency

- The most important issue here is that women who are deficient in folic acid at the time of conception and in early pregnancy are at increased risk of having a baby with a neural tube defect (spina bifida or anencephaly).
- Relative deficiency occurs in haemolytic anaemias and in preterm infants (see Section 3.3 and Section 5.11.C).
- Deficiency occurs in malabsorption syndromes such as coeliac disease and blind loop syndromes.
- Anticonvulsants such as phenytoin may interfere with the metabolism of folic acid.
- Consequences of folic acid deficiency include the following:
  - fetal abnormalities
  - megaloblastic anaemia, neutropenia and thrombocytopenia.
- Sources of folic acid include green leafy vegetables, oranges and other fruit, legumes, nuts, liver and yeast.

### Treatment

- All women who are anticipating pregnancy should be taking an additional 400 micrograms of folic acid per day before and throughout pregnancy.
- To treat deficiency, give infants 500 micrograms/kg once daily and children over 1 year of age 5 mg once daily.
- Treat for up to 4 months and exclude concomitant vitamin B<sub>12</sub> deficiency, which if untreated could result in neuropathy.
- For haemolytic anaemia, treat with 2.5–5 mg orally once a day for children aged 1 month to 12 years, and 10 mg once a day for those over 12 years of age.
- Neonates 50 micrograms once daily or 500 micrograms once weekly.
- Give preterm infants 100–200 micrograms orally per day.

### Iodine deficiency

Iodine deficiency in pregnancy causes maternal hypothyroidism and cretinism in the newborn.

- It is one of the commonest causes of disability worldwide.
- Clinical features of cretinism range from mild neuromuscular incoordination and cognitive deficit to severe mental retardation, spasticity and deafness, and severe stunting of growth.
- Iodine deficiency is endemic in mountainous regions far from the sea (e.g. the Andes, the Himalayas, Central Africa, Papua New Guinea) and areas where iodine is eluted from the soil by repeated flooding (e.g. Bangladesh).
- The prognosis is poor even after early recognition and treatment with thyroid hormone.
- Prevention is by salt iodination or a single oral dose of iodine in pregnancy.

### Zinc deficiency

- Zinc is an essential trace element required for maintaining cells, bone growth and immune function (it scavenges for free radicals).
- Deficiency often occurs in children living in resource-limited settings, and arises from either insufficient intake of zinc-containing foods or insufficient absorption.
- Foods high in zinc are of animal origin, such as meats, fish and dairy products.
- Dietary fibre and phytates found in cereals and legumes bind zinc and reduce its absorption.
- Zinc deficiency is difficult to diagnose, as serum zinc levels do not reflect total body zinc levels.
- Zinc deficiency is associated with stunting of growth, impaired immunity and increased risk and severity of diarrhoea and respiratory infections.
- Zinc deficiency is a feature of the rare disease acrodermatitis enteropathica, in which children present with peri-oral and peri-anal rashes.

**Therapeutic zinc supplementation is now recommended as an adjunct to oral rehydration therapy for treatment of diarrhoea. Routinely giving 10 mg per day to children under 6 months of age and 20 mg per day to those over 6 months of age for 10–14 days can reduce diarrhoea duration and severity and the likelihood of subsequent infections for 2 to 3 months.**

Zinc supplements of 2 mg/kg/day should be an essential component of the mineral mix used in the management of severe malnutrition.

### Useful website

World Health Organization (1997) *Vitamin A Supplements: a guide to their use in the treatment and prevention of vitamin A deficiency and xerophthalmia*, 2nd edn. <http://whqlibdoc.who.int/publications/1997/9241545062.pdf>

## 5.10.B Severe malnutrition

### BOX 5.10.B.1 Minimum standards

- Scales (accurate to 5 gram), metre length board, MUAC tapes, care charts.
- ReSoMal.
- Vitamin and mineral mixtures.
- Antibiotics.
- IV 10% glucose.
- Anthelmintic drugs.
- F-75 and F-100 feeds.
- Barrier skin cream.
- Sources of heat (blankets, hat, warm room, clothes).

### Introduction

Severe acute malnutrition (SAM) is characterised by oedema or wasting, often with anorexia and infection. The main immediate causes of death are infections, septic shock, hypoglycaemia, electrolyte imbalance, dehydration, hypothermia, cardiac failure and severe anaemia. Every physiological and metabolic function is impaired, so the children affected are extremely fragile, similar to the premature neonate.

In 2009 the WHO and UNICEF defined SAM for children aged 6–60 months as follows:

- 1 using new weight for length/height charts (see procedures) a cut-off of below minus 3 standard deviations
- 2 **and** the mid upper arm circumference (MUAC) less than 115 mm.

Two clinical pictures are seen, with much overlap between them.

- Marasmus (wasting) affects all ages, but young infants are particularly at risk. It is usually due to insufficient intake of growth nutrients after breastfeeding stops. It can also be due to chronic illness. The baby is extremely thin, with loss of subcutaneous fat, resulting in skin wrinkles and folds. Weight for length or height is less than 70% of the median (see Section 9), or the MUAC is less than 115 mm.
- Kwashiorkor (oedematous malnutrition) usually occurs in children aged 2–4 years. It is an acute illness that suddenly appears over a few days. It is thought to be due to a deficit in the antioxidant nutrients. It presents with sodium retention and oedema of various degrees (from pedal to generalised), and skin lesions that are like severe sunburn in a fair-skinned person. There is fatty liver, with low circulating levels of all hepatic export proteins. The hair may be de-pigmented (this has no relation to the prognosis, and should be ignored clinically), and the hair pulls out very easily and painlessly (which **is** related to the prognosis).

In severe malnutrition, biochemical abnormalities include the following:

- low urea
- severe hypoproteinaemia
- hypokalaemia and hypophosphataemia
- hypomagnesaemia
- hypoglycaemia (see below)
- anaemia (frequently present).

### Principles of treatment

Early identification and treatment is important, and children are often missed on the general admission wards or in outpatients because they are not measured. Screening using MUAC is helpful for identifying children if length measurement is not easily performed, or weight for height is not charted.

Treatment is much more successful if standard treatment protocols are followed than if clinical judgements are made on individual patients. This is because the illness itself changes the clinical presentation, signs and symptoms of common complications.

### Inpatient versus outpatient community management of acute malnutrition (CMAM)

Traditionally, care has been provided for all children in inpatient hospital units, ideally in a defined malnutrition ward. However, carers are less likely to be prepared to attend these until the child is unwell, so patients tend to present late. They also want the child to be discharged as soon as they are clinically stable, so often leave before nutritional deficits have been restored and the child has recovered. This predisposes to higher post-discharge mortality, which is rarely identified by the inpatient programme.

There has been a change to management of the malnourished child who is not unwell, through CMAM programmes. This is sometimes referred to as community-based therapeutic care (CTC). These programmes separate children into those with complications or severe oedema (complicated malnutrition), and those with uncomplicated malnutrition. Children with uncomplicated malnutrition have a reasonable appetite, and on formal testing are able to eat a portion of ready-to-use therapeutic food (RUTF). Children with fever, poor appetite, diarrhoea or dehydration, or who are not fully alert or have generalised oedema are identified and referred to inpatient care (a stabilisation centre), where initial management is delivered.

If a CMAM programme is operating in your area, children with complicated malnutrition will be sent to the hospital, and you may be able to direct those with uncomplicated malnutrition to the CMAM programme after hospital

admission for an illness, or if they present with complicated malnutrition, once they are stabilised and on phase II feeds (see later).

This subsection will deal with the care of children managed in an inpatient hospital unit.

## Inpatient management

The inpatient treatment of severe malnutrition is divided into two phases, which are separated by a transition phase.

### Phase I (initial treatment)

**Specific objectives:** return of normal homeostasis and treatment of complications.

- The immediate treatment of life-threatening complications: hypoglycaemia, hypothermia, heart failure, septic shock, infections and infestations, severe dehydration and very severe anaemia.
- The prevention of hypoglycaemia and hypothermia.
- Nutritional treatment based on a maintenance diet (total 100 kcal/kg/day), divided into frequent meals (eight meals per 24 hours).

**Transition phase:** the diet is gradually increased over 4–5 days.

### Phase II (rehabilitation or catch-up growth)

**Specific objectives:** promotion of rapid weight gain (10–20 g/kg/day) and preparation for discharge.

- A nutritional treatment based on a high energy intake (160–200 kcal/kg/day) divided into six meals a day.
- Emotional and physical stimulation.

The treatment in phase II can be given as ready-to-use therapeutic food (RUTF) in the community, or through an Outpatient Therapeutic Programme (OTP), either administered through a hospital clinic, or preferably in community-based clinics. If RUTF or an equivalent (such as a high-energy biscuit) is not available, children continue on F-100 until nutritional cure is achieved. This is usually defined as achieving 85% of median weight for height.

### Ongoing nutritional support

After discharge from this therapeutic programme, it is good practice to link the child to a supplementary feeding programme, which gives a food ration to the family for up to 4 months following discharge. This is a means of ensuring food security for the vulnerable child. Programmes with this safety-net provision often discharge children at 80% of median weight for height.

### Admission criteria

- Weight for height less than 70% of the median.
- Oedema (exclude nephritic syndrome and other clinical conditions).
- MUAC of less than 110 mm if the child is over 65 cm in length.

### Assessment of nutritional status and recovery

For practical procedures relating to nutrition measurement, see Section 9.

### Discharge criteria

These depend upon the quality of the follow-up services. If adequate follow-up services and a Supplementary Food Programme (SFP) are available, the discharge criteria are as follows:

- weight for height of more than 80% of the median for 3 days (85% if there is no SFP)
- **and** no oedema for 10 days
- **and** no medical complications.

### Medical and nutritional history and examination

The pro-forma history and examination sheet (see Appendix, Section 9) should be filled in by the admitting physician or an experienced nurse.

#### Key points in the history

- Recent intake of foods and fluids.
- Usual diet before current illness.
- Whether breastfeeding or not.
- Duration and frequency of diarrhoea and vomiting.
- Type of diarrhoea (watery/bloody).
- Appetite.
- Family circumstances.
- Previous attempts at treatment, local drugs and/or traditional medicines given.
- History of chronic cough or contact with TB.
- History of contact with measles.
- Potential HIV infection (including mother's status and whether parents are alive).

#### Key points on examination

- Oedema.
- Dehydration (this is very difficult to diagnose, and impossible in the oedematous child).
- Shock (often gives the appearance of dehydration in a child with oedema).
- Severe palmar pallor.
- Eye signs for vitamin A deficiency (dry eyes, Bitot's spots, corneal ulceration, keratomalacia) (see Section 5.10.A).
- Signs of local infection (ear, throat, skin, pneumonia).
- Signs of HIV (adenopathy, oral candida, chronic ear discharge) (see Section 6.2.D).
- Fever.
- Hypothermia (oral temperature < 35.5°C, axillary temperature < 35°C).
- Mouth ulcers, *Candida* or other oral problems.
- Skin changes of kwashiorkor (hypo- or hyperpigmentation, desquamation, ulceration, exudative lesions resembling burns, often with secondary infections such as *Candida*).

**Children with vitamin A deficiency are likely to be photophobic and will keep their eyes tightly closed. Examine their eyes carefully to prevent corneal rupture.**

### Laboratory tests

Laboratory tests are not needed to guide or monitor treatment. Electrolytes and haemoglobin are difficult to interpret and can easily be misleading. If haemoglobin is measured this should be done on admission only, and a transfusion should be given at this time if essential. The patient should not be given a blood transfusion after the first 48 hours

following admission. The haemoglobin level nearly always falls after admission due to haemodilution with expansion of the circulation during mobilisation of oedema and export of sodium from inside the cells in marasmus. At this time, with expansion of the circulation, there is such a grave danger of precipitating heart failure that a transfusion should rarely be given, even for very severe anaemia.

In endemic areas, a malaria smear or rapid test is useful if malaria treatment is not given as part of the routine management of all severely malnourished children.

In regions where HIV is prevalent, HIV testing (serology using two tests in children over 1 year of age, or serology and PCR for children under 1 year) is informative for ongoing care, initiating co-trimoxazole prophylaxis, and determining eligibility for antiretroviral (ARV) therapy. The

mother of a seropositive child is invariably HIV infected, and mothers of seropositive children should be offered an HIV test. Services vary, but would normally include counselling prior to voluntary HIV testing. Where testing is routinely offered, uptake is usually high. CD4 counts are not usually required for the initial management of severe acute malnutrition, as this follows the standard protocols, but may be relevant when considering initiating ARV therapy (see Section 6.2.D).

### Details of treatment

In Phase I (initial phase) the aim is to restore nutritional imbalances and metabolic function and treat complications. Phase II (catch-up growth) is a period of rapid weight gain. There is a 'transition phase' between these phases.

**TABLE 5.10.B.1 Phases of malnutrition treatment**

Phases of treatment		
Phase 1 (1–7 days)	Transition phase (3–4 days)	Phase 2 (usually 14–21 days)
Treat dehydration		Correct nutrient deficiencies
Treat hypoglycaemia		
Treat hypothermia		
Treat infection	Treat helminths	
Do not give iron	Do not give iron	Correct iron deficiency
Correct electrolyte problems		
Diet is maintenance intake	Diet is moderate intake	Diet is high intake
Stimulate the child	Stimulate the child	Stimulate the child
		Provide physical activities
		Prepare for discharge

- There are **routine measures** that are systematically implemented for all malnourished children, and additional routine treatments that are often included.
- **Specific treatments:** these include emergency management of life-threatening complications and of specific diseases.
- **General points:** on admission, severely malnourished children should be separated from those with infections and kept in a warm room (25–30°C) without draughts. Washing should be minimal and when possible with warm water, and the child immediately dried. The mother should be encouraged to stay with her child.

### Intravenous infusion and blood transfusion

Intravenous infusions are to be avoided whenever possible in all severely malnourished children. The risk of precipitating heart failure is very high because of their atrophic heart muscle and high intracellular sodium and electrolyte imbalance.

- The only indication for IV infusion in severely malnourished children is unconsciousness due to circulatory collapse or shock. This is a condition which is difficult to diagnose.
- The only indication for blood transfusion is when anaemia is present on admission and is life-threatening.
- Cannulas should not have IV fluids running after the prescribed treatment has been given. If flushed for IV treatment, they should be removed when not required.

Nasogastric tube feeding is recommended in cases of:

- anorexia with an intake of less than 70 kcal/kg (70% of phase I feed prescribed)
- severe dehydration with inability to drink
- inability to drink and eat because of weakness or clouded consciousness
- painful or severe mouth lesions (herpes, cancrum oris)
- repeated, very frequent vomiting.

Try to not tube-feed for more than 3–4 days. Always explain the reason to the mother.

Try to breastfeed or feed by mouth every time, and top up by nasogastric tube.

### Dehydration with severe malnutrition

Dehydration from diarrhoea is common in severely wasted children (with marasmus) on admission. The treatment of dehydration is not the same as in the non-malnourished child (with the exception of cholera).

This section does not apply to mild diarrhoea occurring during transition from one phase to another, which is a common event.

### Signs of dehydration in malnutrition

The normal signs used to assess dehydration are all unreliable in severe malnutrition.

Assume that all children with acute watery diarrhoea have some dehydration.

The interpretation of the signs relies on the history. The specific signs are as follows:

- history and observation of frequent **watery** diarrhoea
- history of recent sinking of the eyes; the eyes appear 'staring'
- history of not passing urine for 12 hours
- history and observation of thirst.

Reduced skin turgor and sunken eyes (that are long-standing symptoms) are features of malnutrition itself. It is not possible to adequately determine the degree of dehydration in the severely malnourished child.

The appearance of dehydration in children without watery diarrhoea or in those with oedema can be caused by a toxic shock with dilatation of the blood vessels. These patients should not be treated as if they have dehydration, but as cases of septic shock (see later).

**Note that** low blood volume can occur with oedema.

### Oral treatment of dehydration in malnutrition

Standard WHO oral rehydration solutions (ORS) have too high a sodium content and too low a potassium content for children with severe malnutrition.

ReSoMal (rehydration solution for malnutrition; see below) is a special solution for this situation.

**TABLE 5.10.B.2** Composition comparison of ReSoMal, standard WHO ORS and reduced-osmolarity WHO ORS

Composition	ReSoMal (mmol/litre)	Standard ORS (mmol/litre)	Reduced-osmolarity ORS (mmol/litre)
Glucose	125	111	75
Sodium	45	90	75
Potassium	40	20	20
Chloride	70	80	65
Citrate	7	10	10
Magnesium	3	–	–
Zinc	0.3	–	–
Copper	0.045	–	–
Osmolarity (mOsm/litre)	300	311	245

### Children with watery diarrhoea in an adequate clinical state

At admission, give one dose of ReSoMal orally or by nasogastric tube and start to feed the child with the phase I diet. Feed smaller amounts more frequently if they are vomiting. Further ReSoMal can be given after each stool or vomit.

- Give a 50-mL dose for children less than 2 years or less than 85 cm in length.
- Give 100mL for children over 2 years or over 85 cm in length.

### Children with watery diarrhoea in a poor clinical state

Start rehydration with ReSoMal immediately. Give 10mL/kg/hour for the first 2 hours, and then 5mL/kg/hour until rehydration is complete.

This rate is slower than for normally nourished and dehydrated children.

### Completed rehydration

The rehydration is completed when the child is alert, no longer thirsty, and has passed urine. There should be less sunken eyes and fontanelle and improved skin turgor. (**Note that loss of sunken eyes in a severely wasted patient or the worsening of oedema can be a sign of over-hydration.**)

The diet should now be given.

### Monitoring

ReSoMal at 70mL/kg weight per day is usually enough to restore hydration. However, be careful, as **rehydration can quickly lead to fluid overloading, causing cardiac failure or sudden death.** Malnourished children do not excrete excess sodium well. The clinical state of the child should be reassessed every 30 minutes during the first 2 hours, and then every hour. The best way to monitor the child is by regularly measuring their weight; this gives 'fluid balance' directly and accurately, without having to measure any stool or vomit. The ReSoMal should be stopped immediately if:

- the body weight increases by 10% or more
- the respiratory rate or pulse rate increase
- the jugular vein becomes engorged
- oedema appears or the eyelids become puffy
- the liver enlarges by more than 2 cm (mark its position on the skin with marker pen at the onset of rehydration).

**Note:** It is common for malnourished children to pass many small unformed stools. This must not be confused with profuse watery stools, and does not require fluid replacement.

### Feeding and rehydration

- Breastfeeding should continue during rehydration.
- Phase I diet should start immediately when the child is alert.
- If the child has had severe dehydration, feeding should start as soon as the child is alert and the severe dehydration has been treated (2–3 hours).

### Rehydration solutions

If no commercial ReSoMal is available, a solution can be made. (**Note that this is double the quantity of water normally used, i.e. 2 litres, so the solution is effectively half strength.**)

To 2 litres of boiled filtered water add:

- 1 sachet of ORS (3.5 grams sodium chloride, 2.9 grams trisodium citrate dihydrate, 1.5 grams potassium chloride, 20 grams glucose)
- 50 grams of sugar
- 40mL of combined mineral mix\* (or commercial CMV if available).

\* See below for the recipe for the electrolyte/mineral solution. If this cannot be made up, use 45mL of potassium chloride solution (100 grams of KCl in 1 litre of water) instead.

### Formula for concentrated electrolyte/mineral solution

This is used in the preparation of starter and catch-up feeding formulas and ReSoMal. Sachets containing pre-mixed electrolytes and minerals are produced by some manufacturers. If these are not available or affordable, prepare the solution (2500 mL) using the ingredients shown in Table 5.10.B.3.

**TABLE 5.10.B.3 Electrolyte and mineral mixture**

Constituent	Grams	Concentration/20 mL
Potassium chloride (KCl)	224	24 mmol
Tripotassium citrate	81	2 mmol
Magnesium chloride	76	3 mmol
Zinc acetate	8.2	300 micromol
Copper sulphate	1.4	45 micromol

Water: make up to 2500 mL.

If available, also add selenium (0.028 grams of sodium selenate) and iodine (0.012 grams of potassium iodide) per 2500 mL.

- Dissolve the ingredients in cooled boiled water.
- Store the solution in sterilised bottles in the fridge to slow down deterioration. Discard if it turns cloudy.
- Make fresh solution each month.
- Add 20 mL of the concentrated electrolyte/mineral solution to each 1000 mL of milk feed.

If it is not possible to prepare this electrolyte/mineral solution, and pre-mixed sachets are not available, give potassium, magnesium and zinc separately. Make a 10% stock solution of potassium chloride (100 grams in 1 litre of water) and a 1.5% solution of zinc acetate (15 grams in 1 litre of water).

### Emergency IV treatment of severe dehydration with shock in severe malnutrition

IV infusion should be administered only in the case of circulatory collapse severe enough to reduce consciousness.

#### Alert children should never be given an infusion.

The main signs are as follows:

- cold hands and feet with increased capillary refill time > 3 seconds
- weak or absent radial pulse
- diminished consciousness.

Severe dehydration and septic shock are difficult to differentiate in children with severe malnutrition. They both present with signs of hypovolaemic shock. The following points help to differentiate them:

- Eyelid retraction associated with a history of diarrhoea is a sign of severe dehydration. The child with septic shock has eyelids that droop.
- If the child is unconscious (or asleep) without having the eyelids together (a sign of excess adrenaline), either dehydration or hypoglycaemia is present.
- Superficial veins are always constricted in severe dehydration, but may be dilated in septic shock.

### Treatment protocol for life-threatening dehydration with shock in severe malnutrition

Immediate treatment should be given as follows:

- 1 Give 15 mL/kg IV over 1 hour. The recommended solution is Ringer-lactate or Hartmann's solution, each with 5% glucose.
- 2 At the same time, insert a nasogastric tube and give ReSoMal at 10 mL/kg per hour.

- 3 Monitor carefully for signs of over-hydration, reassessing respiratory rate and heart rate every 15 minutes.

- **If after 1 hour the child is improving but still severely dehydrated**, continue nasogastric ReSoMal 10 mL/kg/hour for up to 5 hours.
- If after 1 hour the child has not improved (i.e. radial pulse is still weak), assume that they have septic shock and treat it accordingly (see below for treatment of septic shock). Since hypoalbuminaemia is likely also to be present, 4.5% albumin 5–15 mL/kg IV over 1 hour may also be helpful in intractable shock but this approach requires urgent research.

### Electrolyte problems in SAM

All severely malnourished children have deficiencies of potassium and magnesium that may take 2 weeks or more to correct. Oedema is partly a result of these deficiencies.

**Do not treat oedema with a diuretic.** Excess body sodium exists even though the plasma sodium levels may be low. **Giving high sodium loads could kill the child.**

#### Treatment

- Give extra potassium (3–4 mmol/kg daily).
- Give extra magnesium (0.4–0.6 mmol/kg daily).
- The extra potassium and magnesium are present in commercial F-75 and F-100 feeds, but if making from ingredients locally should be added to the feeds during their preparation. See Table 5.10.B.3 for a recipe for a combined electrolyte/mineral solution. Add 20 mL of this solution to 2.5 litres of feed to supply the extra potassium and magnesium required.
- Prepare food without adding salt.

### Infections in SAM: treatment and prevention

All malnourished children must be assumed to have an infection. Because of the lack of an inflammatory response, clinical signs of infection may be entirely absent in a malnourished child with severe systemic infection. If untreated, this may cause mortality, morbidity and poor weight gain.

**All children with severe acute malnutrition should routinely be given broad-spectrum antibiotics.**

#### Protocol for treatment Specific infections

Children with specific infections should receive the appropriate antibiotic according to local guidelines.

#### No specific infection and no suspected septic shock

The principle is to have a first-line treatment and a second-line treatment.

- **First-line treatment** is routinely given on admission to all severely malnourished children **without** complications such as septic shock, hypothermia, hypoglycaemia or a specific infection (skin, eyes). This is usually oral amoxicillin or co-trimoxazole.
- **Second-line treatment** is given after 48 hours to children who do not respond to the first-line treatment, and to all children with complications. This usually includes a parenteral antibiotic, although absorption of oral ciprofloxacin and chloramphenicol is excellent, so these can

be used orally once the child is stabilised. Some units routinely give metronidazole 7.5 mg/kg orally 8-hourly for 7 days in addition to the above.

The choice of the antibiotics used in first-line and second-line treatment is based on local guidelines, which are ideally informed by local resistance patterns. Factors such as route of administration, availability and cost of the drugs are all relevant. It should be a broad-spectrum antimicrobial agent, such as gentamicin 7.5 mg/kg IV once daily for 7 days, **in combination** with either ampicillin (50 mg/kg 6-hourly for 2 days IV) then oral amoxicillin (15 mg/kg/dose 8-hourly for 5 days) **or** ciprofloxacin (10 mg/kg 12-hourly IV or orally for 7 days). If the child fails to improve after 48 hours, add chloramphenicol 25 mg/kg 8-hourly (IV or oral) or ceftriaxone 100 mg/kg daily IV (or IM if this is not possible). These doses are correct for children over 1 year of age, but all doses should be checked against local guidelines, and for infants.

### **Septic shock: recognition**

Septic shock is a very common cause of deaths in these patients. The signs are as follows:

- clouding of consciousness
- rapid respiratory rate:
  - 50 breaths/minute for children aged 2–12 months
  - 40 breaths/minute for children aged 12 months to 5 years
- rapid pulse rate
- cold hands and feet with visible subcutaneous veins and prolonged capillary refill time > 3 seconds
- signs of dehydration but without a history of watery diarrhoea
- hypothermia or hypoglycaemia
- poor or absent bowel sounds
- an abdominal splash when the child is shaken.

It can be very difficult to distinguish between severe dehydration and septic shock.

### **Suspected septic shock: treatment**

- A broad-spectrum IV antibiotic treatment (ceftriaxone) is started immediately.
- Warm the child to prevent or treat hypothermia (see hypothermia below).
- Feeding and fluid maintenance should be undertaken by nasogastric tube or orally.
- Close monitoring of the vital signs (pulse, respiration and conscious level) is essential.

### **Circulatory collapse**

- Give high-flow oxygen through a face mask with reservoir.
- Give IV infusion as described in the case of circulatory collapse due to severe dehydration. However, as soon as the radial pulse becomes strong and the child regains consciousness, discontinue the infusion and start the diet orally or by nasogastric tube.

### **Hypothermia: prevention and treatment**

Malnourished children have a low metabolic rate. The thermoneutral temperature is 28–32°C. At 24°C they can become hypothermic. Those with infection or extensive skin lesions are at particular risk. A hypothermic malnourished child should always be assumed to have septicaemia.

### **Signs**

The signs of hypothermia are a core temperature (oral) < 35.5°C (with a low-reading thermometer). If the axillary temperature is < 35°C or does not register, assume hypothermia.

### **Routine prevention**

- Cover all children with clothes and blankets. They should wear a warm hat (most heat is lost from the head).
- Ensure that the mother sleeps alongside her child. **Do not leave a child alone in bed at night.**
- Keep the ward doors and windows closed to avoid draughts.
- Avoid wet nappies, clothes or bedding.
- Do not wash very ill children. Others can be washed quickly, ideally with warm water, and dried immediately.
- Make sure that the child is fed, so that metabolic heat can be produced. Ensure that feeds occur during the night.
- **Avoid medical examinations which leave the child feeling cold.**

### **Emergency treatment of hypothermia**

- Immediately place the child on the mother's bare chest or abdomen (skin to skin) and cover both of them. Give the mother a hot drink to increase her skin blood flow.
- If no adult is available, clothe the child thoroughly (including the head) and put them near a lamp or radiant heater.
- Immediately treat for hypoglycaemia (see below) and then start normal feeds.
- Give second-line antibiotics.
- Monitor the temperature every 60 minutes until it is normal (> 36.5°C).

### **Hypoglycaemia: prevention and treatment**

Severely malnourished children easily develop hypoglycaemia. This is associated with serious infection. If available, test blood glucose levels (< 2.5 mmol/litre), or if they are not measurable assume that hypoglycaemia is present.

### **Signs**

The main signs of hypoglycaemia are as follows:

- lethargy, limpness, loss of consciousness or convulsions
- drowsiness/unconsciousness with the eyelids partly open, or retraction of the eyelids
- low body temperature
- convulsions.

**Sweating and pallor do not usually occur in this situation.**

### **Routine prevention**

- Give frequent small feeds, day and night.
- Feeding should start while the child is being admitted.
- Treat any infections.

### **Emergency treatment**

If hypoglycaemia is suspected:

- **If the child can drink:** give therapeutic milk or 50 mL of glucose 10%, or 50 mL of drinking water plus 10 grams of sugar (one teaspoon of sugar in 3.5 tablespoons of clean water). Follow this with the first feed as soon as possible. If achievable, divide the first feed into four and

give half-hourly. If not, give whole feeds every 2 hours during the day and night for at least the first day.

- **If the child is unconscious or has convulsions:** give 5 mL/kg body weight of glucose 10% IV or by the intra-osseous (IO) route, or if neither of these routes is possible give 5 mL/kg of glucose 10% or sugar solution as described above by nasogastric tube.

Continue frequent feeding to avoid a recurrence.

Give second-line antibiotics.

If there are convulsions other causes must be excluded, including cerebral malaria, meningitis, encephalitis, thiamine deficiency and hypernatraemic/hyponatraemic dehydration (especially in hot dry climates).

If blood glucose levels are available and are low, repeat the finger or heel prick after 60 minutes.

## Congestive heart failure

This is a common and dangerous complication that usually occurs several days after admission. The heart muscle is atrophic (effectively there is a cardiomyopathy). During early recovery from severe malnutrition, sodium can be mobilised from the tissues before the kidney recovers sufficiently to excrete the excess. All blood transfusions must be done as soon as possible (in the first 2 days after admission), and should be rarely indicated.

Heart failure is usually caused by inappropriate treatment, including the following:

- misdiagnosis of dehydration with consequent inappropriate 'rehydration'
- very severe anaemia
- overload due to blood transfusion
- a high-sodium diet, using conventional oral rehydration solution, or excess ReSoMal
- inappropriate treatment that involves 're-feeding diarrhoea' with rehydration solutions.

## Signs

Excess weight gain is the most reliable sign, and daily weights should be taken for all malnourished children. Differentiate pneumonia and heart failure by weighing the child. If their weight has increased, particularly if by more than 5%, consider heart failure. If they have lost weight, consider pneumonia.

**First sign:** fast breathing:

- 50 breaths/minute for children aged 2–12 months
- 40 breaths/minute for children aged 12 months to 5 years.

**Later signs:**

- lung crepitations
- respiratory distress
- rapid pulse rate
- engorgement of the jugular vein
- cold hands and feet
- cyanosis or hypoxaemia diagnosed by pulse oximetry if available ( $\text{SaO}_2 < 94\%$  in air at sea level)
- liver enlarged by  $> 2$  cm from baseline.

## Emergency treatment of congestive cardiac failure

- Give high-flow oxygen.
- Stop all oral intake and IV fluid.

- The treatment of heart failure takes precedence over feeding of the child.
- No fluid at all should be given until the cardiac function improves, even if it takes 24–48 hours.
- Give a diuretic IV, usually furosemide (1 mg/kg). This is the only situation in which diuretics should be used: **diuretics should never be given to reduce oedema in malnourished children.**

## Measles: prevention and treatment

Measles is especially dangerous in severe malnutrition.

### Routine prevention

All children over 6 months of age who are admitted with malnutrition should be vaccinated against measles. This is often done weekly, but if measles is being transmitted locally, it should be done on admission. A second dose of vaccine in a previously immunised child is not harmful. A second dose should be given once recovered or at the normal time, where the prior vaccination state is uncertain or the child was not vaccinated before admission.

### Treatment of measles

If a case of measles is admitted:

- Isolate the individual and any suspected cases.
- Review the vaccination status of all patients in the ward, and ensure that all are immunised.
- Give two doses of vitamin A separated by 1 day.
- Treat for measles (see Section 6.2.E) as well as for malnutrition.

## Micronutrient deficiencies

All children with acute malnutrition will have these deficiencies. Commercial F-100 and RUTFs contains all of the required micronutrients in the correct amounts.

If not using these, give a daily multivitamin supplement, and add a mineral mix to the feeds. This should contain potassium, zinc, copper, magnesium and ideally selenium. Premixed sachets are available, or a solution can be made. It is important to **avoid** adding iron to milk-based feeds during the first 2 weeks, and until the child is gaining weight (RUTFs contain iron within the food, and this is safe to use for stable children and in CMAM programmes). After 2 weeks, iron is added to the F-100 feeds. In goitrous regions, potassium iodide should be added to the mineral mixture (12 mg/2500 mL), or else the child should be given Lugol's iodine, 5–10 drops per day.

## Vitamin A: prevention and treatment

### Routine preventive treatment

Oral vitamin A is particularly important for the severely malnourished child, and one dose should be given routinely to each child admitted with malnutrition.

**TABLE 5.10.B.4 Vitamin A dosage: preventive treatment**

Weight	Dose at admission
< 6 kg	50 000 IU once
6–10 kg	100 000 IU once
> 10 kg	200 000 IU once

### Treatment of xerophthalmia

If a child shows signs of vitamin A deficiency (xerophthalmia) or has measles, three doses of vitamin A treatment should be given.

**TABLE 5.10.B.5 Vitamin A dosage in xerophthalmia**

Weight	Dose on day 1	Dose on day 2	Dose on day 3
< 6 kg	50 000 IU	50 000 IU	50 000 IU
6–10 kg	100 000 IU	100 000 IU	100 000 IU
> 10 kg	200 000 IU	200 000 IU	200 000 IU

If the eyes show signs of inflammation or ulceration, give the following additional care to the affected eye(s) to prevent corneal rupture and extrusion of the lens:

- Instil chloramphenicol or tetracycline eye drops, 2- to 3-hourly as required for 7–10 days.
- Instil atropine eye drops, one drop three times daily for 3–5 days.
- Cover with sterile saline-soaked eye pads.
- Bandage the eye(s).

Note that **children with vitamin A deficiency are likely to be photophobic and have their eyes closed. It is important to examine their eyes very gently to prevent corneal rupture.**

### Treatment of anaemia

The majority of malnourished children have anaemia. This is due to the many deficiencies they have (iron, folic acid, riboflavin, pyridoxine, ascorbic acid, vitamin E, copper) and their inability to metabolise iron. **Iron should not be given until 2 weeks after the start of treatment.**

#### Routine treatment

##### Folic acid

Give 5 mg of folic acid on the day of admission, then 1 mg/day thereafter (in F-100 already).

##### Iron

**Iron should never be given during Phase I or during the transition phase.** In malnourished patients, iron is not properly metabolised and is therefore dangerous. The free iron enhances the production of free radicals that can damage cell walls. Excess free iron encourages systemic infection.

**Oral iron supplementation should start 14 days after admission.** This is best added to the F-100 milk diet at a dose of one crushed tablet of ferrous sulphate (200 mg) to 2 litres of therapeutic milk. Alternatively, it can be given as ferrous sulphate 3 mg/kg/day orally, which should be continued until anaemia has resolved clinically, or ideally on blood test. It is present in adequate amount in RUTF.

### Emergency treatment of very severe anaemia

Blood transfusion in malnourished children is potentially dangerous because it can precipitate heart failure. There are only two indications for considering blood transfusion, namely:

- the child with a haemoglobin concentration of < 4 grams/100 mL, especially if in shock

- the child with signs of heart failure due to anaemia (at immediate risk of death).

Give 10 mL/kg body weight of packed cells (or whole blood) slowly by partial **exchange** transfusion. Ideally, and if this can be achieved, use a carefully and continuously observed cannula in an artery or central vein. It is also possible in a vein in the antecubital fossa. First 2.5 mL/kg of anaemic blood is removed and then when 5 mL/kg of appropriately screened and cross-matched blood has been transfused, 2.5 mL/kg is again taken and the cycle is repeated. The child is closely monitored for signs of congestive heart failure.

If partial exchange is not possible and heart failure is present, give 10 mL/kg, ideally as packed cells, otherwise as whole blood. Transfuse over 4 hours and give IV furosemide 1 mg/kg at the start of the transfusion. Monitor carefully for worsening heart failure.

### Intestinal parasites

#### Routine treatment

Routine deworming treatment is given to all children over 1 year of age, but only in phase II or the transition phase.

For children over 1 year of age, give mebendazole 100 mg (1 tablet) twice daily for 3 days. Some countries use albendazole 200 mg (for children aged 12–24 months) or 400 mg (for those over 24 months of age) once.

### Dermatosis of kwashiorkor

Shedding of the skin in scales or sheets, desquamation, exfoliation, cracking of the skin surface, and ulceration of the genital or perianal areas are all common.

There can be widespread weeping skin lesions that resemble burns.

Zinc deficiency is usual in this situation, and oral zinc supplements improve the skin (give 2 mg/kg/day of elemental zinc).

#### Treatment

- Leave the exposed area open to dry during the day.
- Apply barrier cream (zinc and castor oil ointment) or petroleum jelly or tulle gras to the raw areas, and gentian violet or nystatin cream to the skin sores twice a day.
- These children should be on broad-spectrum antibiotics.
- Do not use plastic pants or disposable nappies for these children.

### Continuing diarrhoea

See also Section 5.12.B.

Diarrhoea should subside during the first week of treatment. In the rehabilitation phase, loose or poorly formed stools are normal and do not need treatment provided that weight is increasing.

#### Treatment

##### Giardiasis

Giardiasis and mucosal damage are common causes of continuing diarrhoea. Where possible, examine the stools by microscopy.

If cysts or trophozoites of *Giardia lamblia* are found, give metronidazole (7.5 mg/kg 8-hourly for 7 days). If not

detected but clinically *Giardia* is possible, give metronidazole anyway.

### Lactose intolerance

Diarrhoea is only rarely due to lactose intolerance. Only treat for lactose intolerance if the continuing diarrhoea is preventing general improvement. Starter F-75 is a low-lactose feed. In exceptional cases:

- Substitute milk feeds with yoghurt or a lactose-free infant formula.
- Reintroduce milk feeds gradually in the rehabilitation phase.

### Osmotic diarrhoea

This may be suspected if the diarrhoea worsens substantially with hyperosmolar F-75, and ceases when the sugar content and osmolality are reduced. In these cases:

- Use a lower osmolar cereal-based starter F-75 (for the recipe, see Table 5.10.B.7) or, if available, use a commercially prepared isotonic starter F-75.
- Introduce catch-up F-100 gradually.

## Malaria: treatment and prevention

In endemic areas, all malnourished children should have a rapid malaria smear or rapid test on admission. Where this is not possible, all malnourished children should receive antimalarial treatment according to local guidelines for the area. The parasitaemia is usually much lower than in normal children. In initially smear-negative children, there can be a recrudescence during nutritional replacement treatment, so consider malaria in children who develop fever.

Children and mothers should sleep under impregnated nets in the wards.

## Tuberculosis

In patients treated for malnutrition, tuberculosis (TB) can be a cause of failure to gain weight. In malnourished children, the diagnosis of tuberculosis is particularly difficult and misdiagnosis is common.

### How to diagnose pulmonary TB

The signs of TB in malnourished children are often not specific (e.g. anorexia, failure to thrive). Asymmetric chest signs or asymmetric lymph nodes are usually TB. Pneumonia in malnourished children affects both lungs, and HIV gives symmetrical lymphadenopathy.

Consider TB as a possible diagnosis in children who fail to gain weight during admission.

Sputum is rarely available. The Mantoux test can be negative in malnutrition. Undertake a chest X-ray if possible. A family history is often helpful. BCG offers protection against TB, but does not protect completely against infection.

### Treatment (see Section 6.1.N)

**Children with TB should not be isolated**, for the following reasons:

- Young children are not a source of transmission (as it is rarely a cavitating disease).
- Treatment quickly eliminates the risk of transmission.
- An isolated child is stigmatised and neglected in resource-limited settings.

Usually paediatric TB is acquired from a sputum-positive adult, so the TB infected carer is a much higher infection risk to the ward. Take note of the carer on the ward with cough, as they should have a chest X-ray.

## Malnutrition and AIDS

Basically, the initial stabilisation phase and nutritional treatment of HIV-infected patients is the same as for any other severely malnourished patient (see Section 6.2.D). They follow the same dietary and initial medical treatments. Many HIV-positive patients will respond well to the nutritional treatment and gain weight.

However, in units where HIV is prevalent, and particularly where there are programmes that offer additional nutritional support, co-trimoxazole, ARV treatment, PMTCT, and counselling on future pregnancies, there are excellent reasons why a carer would choose to have their child identified during admission as infected with HIV. Moreover, where this is routinely offered, such a policy is not found to be stigmatising.

The presentation of HIV-infected children is similar to that of the uninfected, so cannot be easily identified clinically, although there are some conditions that are more common. HIV-infected children are less likely to present with kwashiorkor than with marasmus. They are more likely to have oral candida, discharging ears, lymphadenopathy, chronic cough, persistent diarrhoea and dermatosis. They may have a family member with HIV, or be orphaned. They may present in infancy, while still breastfeeding, which is an uncommon time for presentation with severe acute malnutrition otherwise.

HIV testing should follow counselling, and be voluntary. It is usually done using two rapid ELISA serological tests. In infants under 1 year of age, serology reflects maternal status rather than infection in the infant. To diagnose infection in infants, a PCR test is required. All children identified as infected with HIV (or where PCR is not available as having indeterminate status) should be commenced on prophylactic co-trimoxazole. This has been shown to reduce long-term mortality.

In an HIV-infected infant, or one possibly infected with HIV and presenting with malnutrition, it is not sensible to stop breastfeeding during admission, as this will deprive the infant of an important source of nutrition. For children who are PCR negative, but exposed to HIV, the decision is less clear, although it will depend on the mother's likely viral load (check whether she is on ARV treatment), the food security of the family, the mother's ability to provide an alternate breast milk substitute, and her choice. There will usually be guidelines depending on local factors.

If the HIV-infected child is not responding well to malnutrition treatment, this may be because of unidentified infection. Non-typhoidal salmonella (NTS) is more common, as are organisms resistant to commonly used antibiotics. TB is a recognised co-infection, although it may be difficult to identify. Some children do not start gaining weight until ARV drugs are started.

It is not known when it is best to initiate ARV therapy in severe acute malnutrition, although it is generally accepted that children should be on phase II feeds. Some children do not meet the criteria for treatment clinically if they respond well to nutritional support with rapid weight gain. CD4 testing is helpful for determining who would benefit, as not

all HIV-infected children have severe immunodeficiency, because HIV can be related to malnutrition through food insecurity as well as illness. However, long-term follow-up of infected malnourished children has identified them as being at high risk of mortality, suggesting that earlier ARV treatment might be of greater help in reducing this.

On discharge it is important to ensure that the child is linked into HIV and nutrition support programmes which the family can access, that carers are aware of the ongoing needs of the child, and that the wider family is offered HIV testing.

## Dietary treatment of severe malnutrition

### Dietary treatment in Phase I

#### Objectives

The aim of this phase is progressive restoration of the electrolyte, metabolic and physiological balance by the frequent feeding of special formula milk.

#### Principles

Severely malnourished children are usually anorexic, and have thin bowel walls, damaged metabolism, and too much sodium in their bodies. Initially they require a low-salt and low-protein diet and are unable to tolerate large amounts of food because their **capacity is reduced**. Therefore initially a diet high in carbohydrate with low levels of sodium and iron and very modest protein content is given. This diet leads to restoration of metabolic and physiological function, but is insufficient for weight gain.

- Feeding should start quickly after admission.
- It should be divided into many small meals to stay within the absorptive and metabolic capacity of the child and to prevent hypoglycaemia and hypothermia.
- The child should be encouraged to eat, but not be forced to do so. Feeding a malnourished child requires time and patience. Use a cup, bowl, spoon or syringe to feed very weak children. If the child takes less than 70% of the prescribed diet, they should be fed by a nasogastric tube.
- Always continue breastfeeding, and encourage the mother to breastfeed. After the breastfeed give the scheduled amounts of starter formula first (see below).

The following guidelines are also useful:

- Give frequent small feeds of low osmolarity and low lactose content.
- Night feeds are essential.
- Give oral or nasogastric feeds (never parenteral preparations).
- Give 100 kcal/kg/day.
- Protein: give 1–1.5 grams/kg/day.
- Liquid: give 130 mL/kg/day to all children, whether or not oedema is present.

**TABLE 5.10.B.6 A recommended schedule**

Days	Frequency	Volume/kg/ feed	Volume/kg/ day
1–2	2-hourly	11 mL	130 mL
3–5	3-hourly	16 mL	130 mL
6 onwards	4-hourly	22 mL	130 mL

**TABLE 5.10.B.7 Volumes of F-75 per feed**

Child's weight (kg)	2-hourly (mL/feed)	3-hourly (mL/feed)	4-hourly (mL/feed)
2.0	20	30	45
2.2	25	35	50
2.4	25	40	55
2.6	30	45	55
2.8	30	45	60
3.0	35	50	65
3.2	35	55	70
3.4	35	55	75
3.6	40	60	80
3.8	40	60	85
4.0	45	65	90
4.2	45	70	90
4.4	50	70	95
4.6	50	75	100
4.8	55	80	105
5.0	55	80	110
5.2	55	85	115
5.4	60	90	120
5.6	60	90	125
5.8	65	95	130
6.0	65	100	130
6.2	70	100	135
6.4	70	105	140
6.6	75	110	145
6.8	75	110	150
7.0	75	115	155
7.2	80	120	160
7.4	80	120	160
7.6	85	125	165
7.8	85	130	170
8.0	90	130	175
8.2	90	135	180
8.4	90	140	185
8.6	95	140	190
8.8	95	145	195
9.0	100	145	200
9.2	100	150	200
9.4	105	155	205
9.6	105	155	210
9.8	110	160	215
10.0	110	160	220

Mix the milk, sugar, oil and electrolyte/mineral solution to a paste, and then slowly add the warm boiled water. Make up to 1000 mL. If available, use an electric blender or hand whisk.

#### What food to give

The special milk for phase I is called F-75. If it is not available, F-100 should be diluted to the same calorie strength as F-75 and given in its place. Alternatively, it can be made from ingredients using the recipe in Table 5.10.B.7 above.

**TABLE 5.10.B.8** Homemade recipes for re-feeding formulas F-75 and F-100

	F-75 <sup>ab</sup> (starter)	F-75 <sup>c</sup> (starter: cereal-based)	F-100 <sup>d</sup> (catch-up)
Dried skimmed milk (grams)	25	25	80
Sugar (grams)	100	70	50
Cereal flour (grams)	–	35	–
Vegetable oil (grams)	27	27	60
Electrolyte/mineral solution (mL)	20	20	20
Water: make up to (mL)	1000	1000	1000
<i>Contents per 100 mL</i>			
Energy (kcal)	75	75	100
Protein (grams)	0.9	1.1	2.9
Lactose (grams)	1.3	1.3	4.2
Potassium (mmol)	4.0	4.2	6.3
Sodium (mmol)	0.6	0.6	1.9
Magnesium (mmol)	0.43	0.46	0.73
Zinc (mg)	2.0	2.0	2.3
Copper (mg)	0.25	0.25	0.25
% energy from protein	5	6	12
% energy from fat	32	32	53
Osmolality (mOsm/litre)	413	334	419

<sup>a</sup> A comparable starter formula can be made from 35 grams of whole dried milk, 100 grams of sugar, 20 grams of oil, 20 mL of electrolyte/mineral solution, and water to make 1000 mL. If using fresh cow's milk, take 300 mL of milk, 100 grams of sugar, 20 mL of oil, 20 mL of electrolyte/mineral solution, and water to make 1000 mL.

<sup>b</sup> Isotonic versions of F-75 (280 mOsmol/litre) are available commercially, in which maltodextrins replace some of the sugar, and in which all of the extra nutrients (potassium, magnesium and micronutrients) are incorporated. These are of lower osmolality and therefore less likely to cause osmotic diarrhoea.

<sup>c</sup> Cook for 4 minutes. This may be helpful for children with dysentery or persistent diarrhoea.

<sup>d</sup> A comparable catch-up formula can be made from 110 grams of whole dried milk, 50 grams of sugar, 30 grams of oil, 20 mL of electrolyte/mineral solution, and water to make 1000 mL. If using fresh cow's milk, take 880 mL of milk, 75 grams of sugar, 20 mL of oil, 20 mL of electrolyte/mineral solution, and water to make 1000 mL.

F-75 contains:

- 75 kcal/100 mL
- 0.9 grams of protein/100 mL (around 5% of kcal provided by protein)
- 2 grams of fat/100 mL (around 32% of kcal provided by fat)
- 13 grams of carbohydrate/100 mL (around 62% of kcal provided by carbohydrates).

#### **What quantity of food to give**

Give 100 kcal/kg/day. The daily number of kcal should be divided by the number of meals given during the day (usually eight meals per day).

F-75: 133 mL = 100 kcal.

#### **Example**

A child of 6 kg should receive a diet of 100 kcal/kg/day. The child will be given eight meals of F-75.

Number of kcal/day: 100 kcal × 6 kg = 600 kcal.  
Quantity of F-75 per day: 800 mL (798 exactly). Quantity per meal: 800/8 = 100 mL.

Do not exceed 100 kcal/kg/day in this initial phase. Diarrhoea should gradually decrease and oedematous children should **lose weight** as the oedema disappears. If diarrhoea continues, see above.

#### **Dietary treatment in the transition phase (for 48 hours)**

##### **What food to give**

In the transition phase, full-strength F-100 is given in the same volume that was calculated for F-75 in phase I. There is no other change made in the transition phase.

F-100 contains:

- 100 kcal/100 mL
- around 2.6 grams of protein/100 mL (10% of kcal provided by protein)
- around 5.6 grams of fat/100 mL (50% of kcal provided by fat)
- around 9.8 grams of carbohydrate (40% of kcal provided by carbohydrate).

There are two forms of F-100.

#### **Commercial F-100**

This therapeutic milk is prepared in a sachet. All that the nurse has to do is open the packet and dilute the contents in 2 litres of potable (boiled) water. The commercial F-100 has a lower osmolality to reduce 're-feeding' diarrhoea in the severely malnourished children.

**Home-made F-100**

This can be made from ingredients using the recipe shown in Table 5.10.B.8 above.

**Dietary treatment in phase II****Objectives**

The aim is catch-up growth of the child with rapid weight gain (10–20g/kg/day). Usually the appetite has returned.

**Principles**

The child has re-established their physiological balance and should get enough food to gain weight as quickly as possible. They are given a high-energy diet with normal protein content.

- The intake is increased in quantity (to about 200 kcal/kg/day).
- Reduce meal frequency from eight to six meals per day.
- There should be no limit on the quantity of food given. The child is allowed to eat as much as they want, but must never be forced to eat.
- Breastfeeding continues. Breast milk must always be offered **before** the high-energy food is given.
- Aim for weight gain of more than 10 grams/kg/day.
- Remain alert for heart failure.

**What food to give**

The basic diet is composed of F-100 meals. However, when the child is gaining weight quickly, other foods can be introduced – for example:

- enriched porridges (1 mL contains 1 kcal/gram) as one to two meals a day
- enriched biscuits (useful for overnight feeding if phase II is conducted in a day-care centre) or RUTF (see below)
- local meal: composed of the usual food eaten in the area; this should be enriched in the pot with the addition of oil and CMV and sometimes DSM.

**Quantity of food to give**

Dispense and offer 200 kcal/kg of F-100 per kg of body weight per day.

**Example of calculation**

A child who weighs 9 kg should receive  $200 \text{ kcal} \times 9 = 1800$  kcal per day. The child will receive six meals per day, and each meal should provide  $1800 \text{ kcal}/6 = 300$  kcal.

The diet is composed of six meals of F-100. The enriched porridge or family meal is given **in addition** if the child wishes to take it.

- F-100 (1 mL of F-100 = 1 kcal): the child should receive 300 mL of F-100 per meal.

Older children and adolescents, when they are gaining weight rapidly, often do not want the milk and demand 'solid food'. This usually slows the rate of recovery. The solid food should always be enriched.

When developing local recipes the weight gain should be compared with that of children taking F-100 alone. If the weight gain is similar, the recipe for the porridge is adequate.

**Ready-to-use therapeutic foods (RUTFs)**

RUTFs have been developed to provide the same nutritional content as F-100, but in a peanut-butter-type paste that is not susceptible to pathogens growing in it, due to its low water content. These are usually based on a mix of

groundnuts, vegetable oil, dry skimmed milk, sugar and micronutrient mix. If this is available, children can be introduced to this when on phase II feeds, and if they have a good appetite, could be followed up after 1–2 weeks in an outpatient- or community-based malnutrition programme. This is referred to as an Outpatient Therapeutic Programme (OTP), CMAM or CTC (see Further Reading at the end of this subsection).

**Individual child monitoring****Phase I**

A daily medical and nutritional round of all the children in phase I should be done. The children should be carefully monitored every day for:

- oedema
- weight
- appetite: how the child is eating and the quantity eaten
- clinical state: consciousness, diarrhoea, vomiting, skin, etc.
- behaviour: apathetic, alert, crying, etc.
- temperature
- liver size, heart rate and heart sounds.

This information should be recorded every day on an individual chart.

**When to pass to the transition phase**

Children usually remain in phase I for 1–7 days. The child can pass to the transition phase when:

- they regain appetite
- they are lively and interested
- serious medical complications are under control
- oedema is decreasing (although it may be still present).

If after 5–7 days the child is not ready for the transition phase, they should be completely re-examined and investigated.

After 2 days in the transition phase without experiencing any problem, the child is ready to move to phase II. Oedema should be significantly improved, and the child must be stable, before progressing to phase II.

**Phase II**

The monitoring in phase II includes the following:

- a daily round by the nurse, who checks the general state of the child, including whether there is oedema, nausea or vomiting, and how the child is eating
- a physician round undertaken weekly if the child is stable
- measurement of the child's weight twice a week if they are well
- measurement of their height monthly or in each OTP clinic review.

This information should be recorded on the individual chart.

**If a child develops a complication in phase II, such as re-feeding diarrhoea or vomiting that requires passage of a nasogastric tube, rehydration solutions, transfusion, etc., they should be returned to phase I and subsequently the transition phase again. The above treatments must never be given to children while in phase II and taking very large amounts of F-100 diet.**

**When the child can be discharged**

Children remain in phase II until they meet the criteria for recovery. The average total length of stay is around 4 weeks

in traditional inpatient care, and longer if very severe complicated malnutrition, HIV, TB, or underlying disease or disability is present.

Figure 5.10.B.1 shows an example of a typical growth recovery chart.

When the child has reached their target weight and is in a good clinical state, they will be either referred to a supplementary feeding programme or sent directly home with arrangements made for follow-up. Children with long-term illness should be transferred to an appropriate community service.

### Failure to gain weight

If the child fails to gain weight they should be investigated. Weight gain is defined as poor if it is less than 5 grams/kg/day, moderate if it is 5–10 grams/kg/day, and good if it exceeds 10 grams/kg/day. The following are the most common reasons for failure to gain weight:

- Food prescription or food preparation (kitchen) is incorrect and the child has not received the right quantity of the right food.
- The child does not eat the amount of food prescribed (e.g. because they dislike the food, or the food is being eaten by other people).
- Suspect hidden acute infections (e.g. urinary tract infection, acute respiratory infection, otitis media, mouth candidiasis, giardiasis).
- There are chronic hidden infections (tuberculosis, HIV).
- Re-examine, do stool and urine microscopy, and take a chest X-ray.
- Look for poor feeding techniques, and check that night feeds are occurring.

FIGURE 5.10.B.1 Weight catch-up chart for a boy weighing 5.8 kg on admission to hospital.

### Emotional and physical stimulation

The severely malnourished child is nearly always psychosocially deprived. The illness itself makes the child unresponsive, and so they do not cry or complain. Because mothers use a cry as the signal to give attention, these

children do not receive the attention they need to stimulate them. The neglect is not wilful on the part of the mother, but rather it is a failure of the two-way communication between the mother and her child.

Because they do not cry or complain, these children are often also neglected by nurses and staff. This greatly compounds the problems associated with being in a strange environment. It is essential to stimulate these children, particularly the unresponsive ones. The ward should be made as much like home as possible and children should sleep alongside their mothers.

- **In phase I** it is essential that the mother (or other carer) is present, feeds the child, comforts them, holds them, plays with them, and talks and sings to them.
- **In phase II** it is important to stimulate the child to move, and to play with other children. A play area should always be present. Staff should be identified who have a responsibility for providing (local) toys and encouraging play.

### The daily organisation of the activities

To organise the treatment of malnourished children, a schedule of activities (e.g. care, distribution of meals) must be established. An example is given below.

TABLE 5.10.B.9 Daily organisation of activities

Time (24-hour clock)	Children in phase I and transition phase	Children in phase II (day care)
02.00	Milk distribution	
05.00	Milk distribution	
07.00	Team changeover (day shift)	
07.30	Temperatures	Arrival of children
08.00	Milk distribution and drugs	Milk distribution and drugs
09.00	Weight, oedema assessment	Weight, oedema assessment
09.30	Mother's meal	Medical round
10.00	Medical round	Milk distribution
11.00	Milk distribution	Mother's meal
12.00		Milk distribution and drugs
13.00	Dressings	Dressings
14.00	Milk distribution and drugs	
15.00		Porridge distribution
16.00	Mother's meal	Mother's meal
17.00	Milk distribution	Milk distribution
18.00	Medical round	Departure home with porridge and enriched biscuits for the night
19.00	Team changeover (night shift)	
20.00	Milk distribution and drugs	
21.00	Close windows, wrap child	
23.00	Milk distribution	

### Inappropriate practices

- Too much sodium, energy and protein given during phase I of treatment.
- No distinction made between phases I and II.
- Failure to monitor food intake.
- Lack of feeding at night.
- Lack of blankets and hats.
- No daily schedule organised.
- Diuretic given to treat oedema.
- Anaemia treated from time of admission with iron supplements.
- Intravenous fluids given for indications other than circulatory collapse.
- Use of high-sodium diet and standard oral rehydration solution.
- Routine antibiotics not given.
- No vitamin A given.
- No measles vaccine given.

### Problems with the management of severe malnutrition

A high level of care is needed. The treatment of a severely malnourished child requires intensive protocol-based care, like that for a premature neonate, with close monitoring, some complex medical care (severe or chronic infections), a diet well enriched in nutrients (F-100, etc.), and an emotionally stimulating, rich and physically warm environment.

**The resources are almost always limited.** The limited financial resources lead to difficulty in obtaining therapeutic milks and other fortified food, drugs and materials.

However, if staff follow the protocols advocated by the WHO, and described above, outcomes can improve. Staff need to be confident that they can follow the guidelines approved for their unit, and if they are unable to do so, be able to address these deficits in care provision. Nursing staff are often better at following the guidelines than doctors, who may try to individualise treatment as they would for other children. The recording charts, weight charts and pro forma are tools that greatly help in the management of these children.

Analysis has shown that the main reasons for death are inappropriate medical interventions, such as fluid overload from ORS, blood transfusion, and the use of

diuretics in oedema. Another reason is failure to adhere to the guidelines, due to either a lack of resources, or a lack of understanding of the differences in the care needs of this group of children. A significant and often unrecognised cause of death and relapse is inadequate discharge planning, or premature discharge.

However, perhaps the greatest problem is posed by the limited human resources on the malnutrition ward, with an insufficient number of skilled personnel, and constant movement of staff as soon as they are trained. The greatest resource that a unit can have is a motivated, trained and experienced staff, who have the basic resources to deliver the care described in this subsection.

## 5.11 Haematological disorders

### 5.11.A Anaemia

#### BOX 5.11.A.1 Minimum standards

- Haemoglobin estimation facility.
- Blood transfusion.
- Drugs:
  - Haematinic agents: iron, folic acid.
  - Antihelminthic drugs: mebendazole, albendazole, pyrantel.
  - Antimalarial drugs.

#### Introduction

##### Definition of anaemia

Table 5.11.A.1 gives the World Health Organization (WHO) definition of haemoglobin concentrations below which anaemia is present at sea level.

TABLE 5.11.A.1 Lower limit of normal haemoglobin concentrations

Age of child	Haemoglobin concentration (grams/dL)	Haematocrit (%)
6 months to 4 years	11	33
5–11 years	11.5	34
12–14 years	12	36

##### The problem of anaemia

- It is widespread in disadvantaged countries.
- It is common in young children under 5 years of age.
- More than one cause of anaemia is usually found in each anaemic child.
- Genetic causes of anaemia are common.
- It has significant deleterious effects on growth, health and development.

##### Main causes of childhood anaemia in resource-limited settings

- Low birth weight:
  - results in low iron and folate stores (0–2 years age group).
- Dietary:
  - diets tend to be low in iron
  - delayed weaning
  - poor maternal iron intake in breastfed infants
  - weaning on to non-fortified cow's milk.
- Infections:
  - malaria (haemolysis)
  - hookworm (*Ancylostoma duodenale* and *Necator americanus*) (see Section 6.3.C)
  - whipworm (*Trichuris* species)
  - congenital infection (CMV, rubella)
  - HIV.

- Genetic:
  - haemoglobinopathies (HbSS, thalassaemias)
  - glucose-6-phosphate dehydrogenase deficiency.
- Malignancy:
  - leukaemia
  - other types of malignancy.

#### The child with iron-deficiency anaemia

##### Clinical features of anaemia

- Often asymptomatic until haemoglobin concentration is < 8 grams/dL.
- Breathless on exertion when haemoglobin concentration is < 6 grams/dL.
- Pallor:
  - nail beds (the best site)
  - palmar creases
  - mucous membranes.
- Suboptimal growth, delayed puberty.
- Congestive heart failure.

##### Investigations

The tests in **bold** listed below should **always be done before a transfusion** (to exclude causes other than iron deficiency):

- **Haemoglobin concentration** (cyanmethaemoglobin method or **HemoCue B**).
- Haematocrit or PCV (microcentrifuge).
- **Blood film:**
  - **malarial parasites**
  - red blood cells: hypochromia, microcytosis, anisocytosis target cells (iron deficiency, thalassaemia)
  - sickle cells
  - macrocytes (folate, vitamin B<sub>12</sub> deficiency)
  - white blood cells: hypersegmented neutrophils (folate, vitamin B<sub>12</sub> deficiency).
- Mean corpuscular volume (MCV) and reticulocyte count as the two principal criteria for the initial classification of anaemia.
- **Haemoglobin electrophoresis:** sickle cell, thalassaemia.
- Stool test: parasitic ova, blood.

##### Management of anaemia

- Establish the diagnosis, cause and severity of iron-deficiency anaemia.
- Treat malaria (oral route) (see malaria guidelines in Section 6.3.A.d).
- Give empirical antihelminthic therapy in endemic areas (see Section 6.3.C).
- Give haematinics:

- folic acid: up to 5 years of age, 2.5 mg once daily; above 5 years, 5 mg once daily
- iron (see Table 5.11.A.2).

### Iron medication

**TABLE 5.11.A.2** Dosage of iron medications for iron-deficiency anaemia in childhood

Age or weight (6 mg/kg elemental iron)	Ferrous sulphate 200 mg (60 mg/kg elemental iron)	Ferrous fumarate 60 mg per 5 mL (12 mg elemental iron/mL)
2–4 months (4–6 kg)	–	2 mL
4–12 months (6–10 kg)	–	2.5 mL
1–3 years (10–14 kg)	½ tablet	4 mL
3–5 years (14–19 kg)	½ tablet	5.5 mL
> 5 years (> 19 kg)	1 tablet	–

- Preterm infants should start prophylactic iron (5 mg/day) from 4–6 weeks of age until mixed feeding is established.
- Treatment with iron injections may increase mortality (meningitis) and morbidity (respiratory infections, malaria) in infants.

### Antihelmintic drugs (see Section 6.3.C)

- Albendazole (the drug of choice if available):
  - 400 mg as a single dose (200 mg if child is less than 2 years of age).
- Mebendazole (most effective against hookworm and whipworm):
  - For children over 1 year of age, 250 mg as a single dose (or 500 mg if the child is over 2 years). May be repeated after 2 or 3 weeks.

### Blood transfusion (see also Section 1.7)

Only undertake this if it is essential.

- Warm the blood first under the mother's clothing, in contact with the skin, especially if it is to be given to an infant.
- Do not use blood that has been stored for more than 35 days at 2–6°C or out of the fridge for more than 2 hours, or that is visibly spoiled (plasma must not be pink, and red cells must not be purple or black), or from a bag that is open or leaking.
- Check that the blood is the correct group and that the patient's name and number are identical on both label and form.
- Use a needle/catheter that is 22 gauge or larger, to prevent clotting.
- If there are signs of heart failure, give 1 mg/kg of furosemide IV at the start of transfusion unless hypovolaemic shock is also present.
- Record the baseline temperature and pulse rate.
- Each transfused unit must be completely used within 4 hours of removal from the fridge.
- Ideally, in infants or those with heart failure, control the flow with an in-line burette.
- Record observations every 30 minutes, looking for heart failure (shortness of breath) and transfusion reactions (fever and malaise).

- Record the quantities given.

### Indications for transfusion

- Severe anaemia (haemoglobin concentration < 4 grams/dL).
- Impending or overt cardiac failure if the haemoglobin concentration is < 6 grams/dL.
- Hyperparasitaemia in malaria if the haemoglobin concentration is < 6 grams/dL.
- Children in congestive cardiac failure due to severe anaemia (consider partial exchange).
- Acute severe blood loss with shock that is unresponsive to 40 mL/kg of volume resuscitation given in 10 mL/kg aliquots, or where massive haemorrhage is continuing.

### Volume of transfusion

- Use packed red cells where possible.
- Give whole blood: 20 mL/kg or:
  - required volume (mL) = weight (kg) × 4 × desired rise in haemoglobin (grams/dL) **or**
- Packed red cells: 10–15 mL/kg **or**
  - required volume (mL) = weight (kg) × 3 × desired rise in haemoglobin (grams/dL).
- In all cases, rate = 5–10 mL/kg/hour (usually over 3–4 hours unless shocked).
- Consider giving furosemide 1 mg/kg IV immediately in advance of transfusion to avoid precipitating cardiac failure (unless there is hypovolaemic shock) in cases of very severe anaemia.

### Treatment of severely anaemic child with septic shock

The first priority will still be to call for help, and manage the airway, followed by breathing and then the circulation.

Call for help.

### Airway

Assess the airway by the simple technique of asking the child 'Are you all right?'

Any vocalisation, such as a reply or crying, indicates an open airway and some ventilation. In the absence of a response, formally open the airway with a head tilt/chin lift or a jaw thrust manoeuvre (see Section 1.12), and assess the breathing by looking, listening and feeling for its presence.

### Breathing

All children with suspected shock must receive high-flow oxygen.

If possible, this should be given through a mask with a reservoir to achieve the higher concentrations. In the absence of spontaneous breathing, give assisted ventilation with a bag-mask (see Section 1.13).

### Circulation

Intravenous access with a short wide-bore venous cannula, or placement of an intra-osseous line (see Section 8.4.B), is vital. Severely anaemic children cannot tolerate rapid boluses of fluid as they are likely to be in heart failure and may also be malnourished. The fluid they need most is blood. When transfusing severely anaemic children we usually give packed cells, but in suspected septic shock, fresh whole blood has the following advantages:

- It increases oxygen-carrying capacity.
- Plasma content improves circulating volume better than crystalloids.
- Clotting factors and platelets are beneficial in septic shock.

While awaiting the blood, which should be transfused at 20 mL/kg, give 10 mL/kg of Hartmann's solution or Ringer-lactate solution, and then reassess the child. If fresh whole blood is not available, give stored blood, but it should be packed, or if the child is in heart failure, consider partial exchange transfusion. Give antibiotics IV. A third-generation cephalosporin or a combination of gentamicin and a penicillin would be advisable. Flucloxacillin should be added if *Staphylococcus* is suspected (e.g. if there are boils or a known abscess). In suspected intra-abdominal sepsis, metronidazole should be added to cover anaerobic organisms.

### Transfusion reactions

See Section 1.7.

### Prevention of iron-deficiency anaemia

- Improve iron intake in infants:
  - breastfeeding for at least 6 months
  - give breastfeeding mothers iron
  - include vitamin-C-rich foods (citrus fruit juices) and/or meat, fish, beans and leafy vegetables by 6 months with cereals
  - low-birth-weight babies should receive oral iron 2 mg/kg daily from the age of 4 weeks, for 6 months.
- Prevent infections:
  - diarrhoea (breast milk)
  - measles (vaccination)
  - prevention and prompt treatment of malaria
  - routine deworming of children under 5 years every 3–6 months
  - malaria prophylaxis in sickle-cell patients.

## 5.11.B Sickle-cell disease

### BOX 5.11.B.1 Minimum standards

- Facility for haemoglobin estimation and electrophoresis.
- Analgesia: paracetamol, NSAIDs, opiates.
- Blood transfusion.
- Oxygen.
- Penicillin prophylaxis.
- Pneumococcal (PCV and Pneumovax), hepatitis B and *Haemophilus influenzae* vaccines.
- Oral rehydration solution (ORS).
- Antimalarial drugs.
- Iron chelation: desferrioxamine, deferasirox or deferiprone.

### Introduction

#### Genetic basis

Sickle-cell disease is a recessively inherited disorder of haemoglobin synthesis. It occurs due to a point mutation at position 6 on chromosome 11 resulting in the substitution of valine for glutamic acid on the beta-globin chain. Those affected inherit two copies of the altered beta-globin gene and are therefore homozygous for HbS (HbSS). Alternatively, a single HbS may be inherited with another beta-chain mutation such as beta thalassaemia (HbSB+ or HBSB<sup>0</sup>) or HbC (HbSC).

A child who inherits two of the same trait genes, one from each parent, will be born with the disease. However, a child of two carriers has only a 25% chance of receiving two trait genes and developing the disease, and a 50% chance of being a carrier. Most carriers lead completely normal healthy lives.

The HbS mutation is common. It is estimated that up to 5% of the world population are healthy carriers of sickle gene, and this can rise to 25% in West Africans. Although the HbS mutation is most common in Africa, it occurs widely across many groups. It is estimated that each year 300 000 children are born with homozygous sickle-cell disease worldwide.

### Prognosis

In well-resourced countries, the life expectancy of individuals with sickle-cell disease has been continuously improving, and historic data suggest that it is now well beyond the fifth decade of life, with the overwhelming majority of children surviving into adulthood. The pattern of the disease and its complications is also changing in well-resourced countries, with a shift from being a fatal paediatric illness to a chronic disease associated with episodic painful crises and progressive deterioration and organ damage in later life.

However, in resource-limited countries, sickle-cell disease is still associated with a very high mortality and morbidity, particularly during childhood. Sickle-cell disease remains a major cause of mortality in children under 5 years of age, with estimates as high as 50–90% in some rural areas of Africa. The major causes of death are infection, especially malaria and invasive pneumococcal infection, and severe profound anaemia. For those who live with the condition, sickle-cell disease is the cause of a great burden of suffering for those affected and their families.

### Pathogenesis

The clinical manifestations of sickle-cell disease are due to vaso-occlusion and chronic haemolysis, often in response to triggers such as illness, hypoxia or dehydration.

The presence of abnormal HbS leads to the production of a haemoglobin tetramer ( $\alpha_2\beta_2$ ) that is poorly soluble when deoxygenated, and polymerises readily into a rope-like fibre within the red blood cell. This leads to red cell distortion into the classic sickle shape, a reduction in red cell deformability, and red cell destruction through haemolysis, with consequent shortening of the red cell lifespan, and anaemia.

Vaso-occlusive episodes occur when blood vessels become clogged with sickle cells, causing pain, tissue oxygen deprivation and organ damage alongside altered cell adhesion and abnormal erythrocyte–endothelium

interaction. In addition to vaso-occlusion, there is a chronic intravascular haemolysis leading to a compensated anaemia with functional nitric oxide (NO) dysregulation with chronic vascular endothelial damage. This means that polymerisation alone does not account for the pathophysiology of sickle-cell disease. Changes in red cell membrane structure and function, disordered cell volume control, and increased adherence to vascular endothelium also play an important role.

### Clinical presentations

In children, the most common presentation of sickle-cell disease is with an acute crisis, usually as a painful episode. More recently, as more countries adopt a newborn screening programme, children may be diagnosed with sickle-cell disease before their first crisis.

Presentation includes the following:

- newborn screening
- a painful vaso-occlusive crisis
- infection and overwhelming sepsis
- severe anaemia
- acute chest syndrome (ACS)
- stroke.

### Newborn screening programmes

The goal of any newborn screening programme for sickle-cell disease is to identify affected children as early as possible and thus reduce the morbidity and mortality of sickle-cell disease, especially from bacterial infections, through the early introduction of antibiotic prophylaxis. In well-resourced countries, the preferred option is the universal screening programme rather than selective screening of high-risk infants only.

### Methodology of newborn screening

The methodology of screening can vary, but in principle involves the collection of a dried neonatal blood spot sample for transport and testing by haemoglobin electrophoresis, thin-layer isoelectric focusing, or HPLC. A second confirmatory test may be taken 1–2 weeks later for repeat testing by isoelectric focusing, HPLC, PCR techniques or DNA analysis by a reference laboratory. The tests used must have the capability to distinguish between HbF, HbS, HbA and HbC. As several of the sickle-cell disease syndromes can have similar results on electrophoresis or isoelectric focusing, examining the peripheral blood smear remains useful.

- Haemoglobin electrophoresis is the standard method for separating HbS from other haemoglobin variants.
- Thin-layer isoelectric focusing is a more complicated technique, which can distinguish some haemoglobins not seen on standard electrophoresis, as the bands are more sharply seen.
- High-performance liquid chromatography (HPLC) is a very precise and fully automated technique for identification and quantification of haemoglobins.
- Sickle solubility test. A positive sickle solubility test will detect the presence of HbS but will not identify whether the person is a carrier or has sickle-cell disease.

### Results and patterns in the newborn period

Finding	Pattern	Interpretation
HbF and HbA	FA	Normal baby
HbF, HbA and HbS	FAS	Sickle-cell trait
HbF, HbS and HbA	FSA	Sickle-cell beta <sup>+</sup> thalassaemia
HbF and HbA	FS	Sickle-cell disease (HbSS or HbS beta <sup>0</sup> thalassaemia)

In countries with limited resources, the combination of haemoglobin electrophoresis and a sickle solubility test will confirm the diagnosis of sickle-cell disease for most older children once the beta-chain production is fully developed beyond the newborn period.

### Diagnosis

- Haemoglobin electrophoresis demonstrates the absence of HbA and either HbS (SS) or HbS and another haemoglobin such as HbC (SC).
- A positive sickle solubility test denotes the presence of sickle haemoglobin, but does not indicate whether the person is a carrier (Hb AS) or Hb SS.
- A full blood count shows severe (SS) to mild anaemia (SC).
- Examination of the peripheral blood shows sickled erythrocytes.

### General principles of the management of an acute sickle crisis

Most children do not develop symptomatic disease in the first few months of life until adult haemoglobin production is established. The principles of managing any acute crisis are based on searching for, and actively treating, any precipitants (see Table 5.11.B.1). Any child presenting with an acute crisis should be considered at risk of sudden and life-threatening deterioration, and clinicians are advised to have an anticipatory approach.

Crisis precipitants include the following:

- infection
- dehydration
- extremes of temperature.

TABLE 5.11.B.1 Precipitants of sickle crises

Problem/precipitant	Approach
Fever and/or evidence of infection Child should be considered functionally asplenic and immunocompromised	Treatment dose of appropriate antibiotics Use of appropriate antimalarial drugs Use of antipyretic drugs
Dehydration	Rehydration
Extremes of temperature and cold	Warmth and rest

Clinicians should be alert to signs suggesting the possibility of a sudden acute deterioration during a crisis. The following **trigger list may be helpful for identifying children at increased risk of sudden or rapid deterioration:**

- uncontrolled pain despite strong opiate analgesia
- increasing pallor, breathlessness or exhaustion
- marked fever (> 38°C)
- significant tachycardia, tachypnoea or hypotension

**TABLE 5.11.B.2 Management of an uncomplicated acute painful episode**

Treatment	Comment
Antibiotics and antimalarial drugs (see later)	Any fever should prompt the search for infection and active treatment. Oral antibiotic dosages should be administered at higher dose as per the immunocompromised child
Hydration	Dehydration occurs readily in children with sickle-cell disease, due to impairment of renal concentrating power. Fluids should be given at 150% maintenance (orally or IV)
Analgesia	Assess pain using an age-appropriate visual analogue scale (VAS) (see below). Use the VAS to assess response to analgesia with the goal of minimal pain allowing successful mobilisation. Manage pain with prompt administration of the most appropriate choice and dose from the analgesic ladder. Take into account previous drugs and dosages given at home. Children in severe pain may need early use of opiates orally or IV. <b>Do not use pethidine</b>
Severe anaemia	Consider transfusion if the haemoglobin concentration is very low (e.g. < 5 grams/dL) or has fallen by > 2 grams/dL from a known baseline level, or the child is clearly clinically compromised
Oxygen	Provide oxygen if the saturations in air are below 95%. Falling saturations in air or a rising oxygen requirement should prompt re-evaluation and the search for an emerging complication of the crisis

- chest pain with or without signs of consolidation
- desaturation in air or a rising oxygen requirement to maintain saturations above 94%
- abdominal pain with or without distension
- severe diarrhoea and vomiting
- sudden profound pallor with or without jaundice
- parents reporting an enlarged spleen
- any abnormal neurological signs, including painless loss of function, headache and fitting.

**The acute painful sickle episode**

- This is also referred to as a painful or vaso-occlusive crisis, and is the most common presentation of sickle-cell disease in childhood, resulting from blockage of small vessels. The mainstay of treatment is effective and prompt pain control (see Section 1.15), alongside management of any precipitants.
- Approximately 40% of children with sickle-cell disease will have an episode of ‘hand-foot syndrome’ or dactylitis during early childhood, and this number rises to 50% of children under 2 years old who go on to develop symptomatic disease. Typically children present with vaso-occlusion and infarction of the metacarpals or metatarsals, which is evident as an overlying soft tissue reaction with swelling, redness and marked tenderness affecting either one or all of the hands and feet.
- By later childhood the most common sites of bony sickle-related pain include the long bones, thighs, hips, spine, ribs, shoulders and upper humerus, as well as the bones of the cranium, joints and muscles.

**FIGURE 5.11.B.1** Visual analogue scale.

**Hydration and fluids in sickle-cell disease**

Dehydration occurs readily in children with sickle-cell disease, due to impairment of renal concentrating power.

**FIGURE 5.11.B.2** Faces scale.

Diarrhoea and vomiting are thus of particular concern. Rehydration calculations are therefore based on the assumption that children with sickle-cell disease have a higher fluid requirement than unaffected children.

Fluids can be delivered by the oral, nasogastric or IV route (or a combination of these) and titrated against clinical response. Generally it is safe to start with hyperhydration (150% of normal), although this may be reduced to normal hydration in children who are less unwell.

**TABLE 5.11.B.3** Fluids in sickle-cell crises

Body weight (kg)	Fluids (mL/kg/day)
First 10 kg	150
11–20 kg	75
Subsequent kg over 20	30

**Infection**

Infection is a common precipitating factor in painful or other types of sickle crises. All children with sickle-cell disease (regardless of type) should be considered to be immunocompromised.

**Bacteria**

Patients with sickle-cell disease are immunodeficient due to functional asplenia.

Functional asplenia occurs irrespective of spleen size in sickle-cell disease well before the age of 1 year in the majority of sufferers. Clinicians should therefore consider all patients to have increased susceptibility to infection,

TABLE 5.11.B.4 Antibiotic choices in sickle-cell crises

Drug	Rationale and comment
Augmentin	Good activity against <i>Pneumococcus</i> <i>Haemophilus</i> resistance is low Suitable for use with clarithromycin for pneumonia Does not mask <i>Salmonella</i> osteomyelitis
Clarithromycin	Good activity against <i>Haemophilus</i> Pneumococcal resistance is low Suitable for use with augmentin for pneumonia Does not mask <i>Salmonella</i> osteomyelitis
Cefuroxime	Suitable for severe pneumonia with or without clarithromycin Masks <i>Salmonella</i> osteomyelitis
Ceftriaxone and other third-generation cephalosporins	For suspected sepsis First-line treatment for suspected osteomyelitis (with clindamycin) Second-line treatment for <i>Yersinia</i> if there is glucose-6-phosphate dehydrogenase (G6PD) deficiency
Ciprofloxacin	For use in patients on desferrioxamine with suspected <i>Yersinia</i> infection <b>Stop iron chelation if suspected</b>

particularly with the encapsulated organisms listed below, all of which can cause life-threatening sepsis:

- *Pneumococcus*
- *Salmonella* species
- *Haemophilus*.

Any suspected bacterial infection should be managed with prompt institution of IV antibiotics to cover these organisms. Suggested choices are listed in Table 5.11.B.4 (note that these may vary according to region and local sensitivities).

Persistent localised bone pain, swelling or fever should raise suspicion of osteomyelitis, which may require surgical treatment, and 6 weeks of antibiotic therapy

### Specific infections

#### Osteomyelitis

This infection can be very difficult to distinguish from vaso-occlusive bone pain, which is commonly associated with localised swelling and joint effusions. Osteomyelitis should be considered in any child with persistent and localised pain who is systemically unwell.

The diagnosis of osteomyelitis in sickle-cell disease is more likely in the presence of:

- swinging pyrexia (fevers may not be persistent)
- severe systemic upset
- unusual swelling or pain
- positive blood cultures.

Few if any investigations are absolutely conclusive in making the diagnosis. Treatment is complex and may involve surgical intervention (rare) and a prolonged course of IV antibiotics (6 weeks). The oral route can be used to complete a course of antibiotics once the child is systemically well (i.e. fevers have settled) and any tests such as CRP have returned to normal. Antibiotic choices are broad, but may include the following:

- first line: IV ceftriaxone and clindamycin (consider flucloxacillin if no clindamycin available).
- second line: IV clindamycin.
- alternatives: meropenem, imipenem or ciprofloxacin.

#### Malaria

Studies confirm that sickle-cell trait (HbAS) is protective against severe complicated malaria, including cerebral malaria and severe anaemia related to malaria in children.

By contrast, malarial infection in homozygous sickle-cell disease (HbSS) can be rapidly fatal, and requires prompt recognition and urgent treatment. Although children with sickle-cell disease are not at greater risk of complicated malaria infection, once infected they have a higher mortality, especially related to severe anaemia. In addition to drug treatment, transfusion may be required.

Prevention should be emphasised (see Section 6.3.A.d).

#### Meningitis

Bacterial meningitis is more common in children with sickle-cell disease than in unaffected children, especially in the youngest age groups. The most frequent infecting organism is pneumococcus. Clinicians should maintain a high index of suspicion for this complication and treat it empirically.

#### Gastroenteritis/diarrhoea

Severe diarrhoea may precipitate sickling and crisis, including stroke. Hydration must therefore be maintained vigorously using ORS or IV fluid where necessary. Education relating to hand hygiene, clean water and prompt treatment should be given.

Children who are systemically unwell with a diarrhoeal illness may also be at higher risk of sepsis related to Gram-negative infection, and may require IV antibiotic treatment in addition to vigorous rehydration under such circumstances.

Children with diarrhoea who are also on the iron chelation medication desferrioxamine are at high risk of *Yersinia* or *Klebsiella* infection, and require prompt treatment with ciprofloxacin, alongside discontinuation of the desferrioxamine until they recover.

#### Viral infection

Children with sickle-cell disease are at particular risk of profound anaemia secondary to parvovirus B19 infection, which may trigger an aplastic crisis.

Children with sickle-cell disease should also be protected from blood-borne viral infection, specifically HIV and hepatitis B infection. Routine immunisation against HBV must be undertaken in view of the probability that a child with sickle-cell disease may at some stage be a recipient of blood products or be started on a long-term transfusion programme.

### Severe anaemia in sickle-cell disease

Children with sickle-cell disease are known to have a compensated anaemia, but are also at risk of events that may precipitate a sudden and potentially fatal drop in their haemoglobin levels. The main conditions to consider are as follows:

- acute sequestration events
- aplastic crisis
- infection with malaria.

#### Acute sequestration events

Sequestration events are characterised by pooling of red cells in an organ, most commonly the spleen, lungs and liver, and are associated with a sudden and potentially life-threatening fall in haemoglobin level, with shock and collapse alongside rapid (and often painful) expansion of the organ affected.

Sequestration events are often precipitated by infection or sepsis that requires vigorous antibiotic treatment. There is a high mortality. Any child who appears to be deteriorating during an acute painful crisis should be re-examined to exclude undiagnosed sequestration.

Treatment includes administration of antibiotics to manage any precipitating infection, and blood transfusion in children with cardiovascular compromise, or who have a haemoglobin level of < 5 grams/dL, or where there has been a sharp fall in haemoglobin level by > 2 grams/dL.

Urgent blood transfusion in children with sickle-cell disease is not uncommon, but does carry some risks. Clinicians should be cautious about over-transfusing beyond a target of 8 grams/dL (usually a maximum of 20 mL/kg) or at a higher rate than 5 mL/kg/hour, due to the risks of hyperviscosity associated with a sudden increase in haematocrit.

#### Aplastic crisis

Transient red cell aplasia caused by parvovirus B19 (with an associated reticulocytopenia) can lead to a sudden severe worsening of the patient's anaemia. Ask about any recent viral prodromal illness, but classical erythema infectiosum ('slapped cheek syndrome') is uncommon. Second infections with parvovirus are extremely rare, as immunity to parvovirus is lifelong. Review other family members with sickle-cell disease, because they too may be infected with parvovirus.

The differential diagnosis of a sudden fall in haemoglobin level includes sequestration crisis, and therefore abdominal palpation is mandatory in any acutely anaemic child to exclude this diagnosis.

Treatment includes use of blood transfusion in children who are cardiovascularly compromised, if the haemoglobin level is < 5 grams/dL, or if there has been a sharp fall in haemoglobin level by > 2 grams/dL.

See above for the risks of urgent blood transfusion.

### Acute chest syndrome (ACS)

This is a major cause of morbidity and mortality in sickle-cell disease. It is strictly defined by evidence of new pulmonary infiltrates involving at least one complete lung segment consistent with the presence of alveolar consolidation, but excluding atelectasis. Clinically, patients have chest pain, a temperature of more than 38.5°C, tachypnoea, wheezing, or cough usually associated with arterial desaturation.

It is important to recognise that patients can be in the process of developing ACS and be severely ill before these strict criteria are met. Signs of lung consolidation, usually bilateral, generally start at the bases, but may be unilateral and impossible to distinguish from infection.

Chest X-ray signs may lag or be misleading. Early treatment may prevent further deterioration, so **prompt action on clinical suspicion is essential**.

Acute sickle chest syndrome is likely to be multifactorial in origin, with infection, thrombosis of pulmonary arteries and fat embolism all resulting in potentially similar clinical patterns. The diagnosis of this potentially life-threatening crisis must therefore be considered if there is a combination of desaturation in air, tachypnoea, pain and a high fever.

#### Management of ACS

- Anticipatory clinical approach.
- Effective analgesia to prevent basal atelectasis.
- Careful observations, including regular pulse oximetry.
- Chest X-ray:
  - upper lobe consolidation without basal changes suggests pneumonia rather than ACS.
- Start dual IV antibiotics: treat pneumonia aggressively as it is often clinically indistinguishable.
- High-flow oxygen.
- Hyperhydration.
- Arterial gases in air if the oxygen requirement is rising.
- CPAP (if available) and saturations falling to the low 90s in air.
- Exchange transfusion (if available) if PaO<sub>2</sub> in air is < 8 kPa or the child is deteriorating.
- May require ventilation.
- There is no role for diuretics.

### Neurological involvement in sickle-cell disease

Sickle-cell disease is associated with several central nervous system complications and events, as outlined below. The most significant event is stroke, mainly infarction. The treatment approach is outlined in the next section.

#### Neurological complications of sickle-cell disease

- Infection: meningitis and malaria.
- Stroke: ischaemic stroke, subarachnoid haemorrhage and transient ischaemic attacks (TIAs).
- Silent infarcts.
- Convulsions.
- Neurocognitive decline: reduction in IQ, attention deficits.

#### Stroke in sickle-cell disease

Stroke is a potentially devastating complication of sickle-cell disease, most commonly occurring in (but not limited to) individuals with homozygous disease (HbSS). The

most common event is infarctive stroke, but haemorrhagic stroke can also occur with increasing frequency as children progress towards adulthood. Stroke can occur in any age group, but is most common in children under 10 years.

Predictive factors for stroke include a history of transient ischaemic attacks, a recent episode of acute chest syndrome, hypertension, or a low haemoglobin F percentage and/or low baseline haemoglobin levels. Any child with sickle-cell disease can have a stroke (even if they are apparently not 'high risk').

Precipitating factors for stroke include a recent history of fever, infection, dehydration and acute chest syndrome. However, some children will have a stroke without any identifiable precipitating event or risk factor.

Symptoms and signs of stroke can be broad, and range from the 'classic' presentation of a focal neurological deficit such as a hemiplegia (painless loss of function) to behavioural changes, severe headache, altered consciousness, convulsions or coma.

Historic data from the USA suggest that 11% of children with sickle-cell disease have a stroke episode by the age of 20 years. More recent data from well-resourced countries speculate that this figure is coming down with the advent of transcranial Doppler (TCD) screening to identify children at high risk of stroke and the aggressive use of regular long-term blood transfusion programmes as a primary prevention strategy.

Stroke is a major cause of mortality and morbidity in sickle-cell disease. On the long-term transfusion programme the risk of stroke falls to approximately 10%.

### **Treatment of acute stroke**

Prompt treatment of an ischaemic stroke can potentially arrest a stroke in evolution. Children with a suspected stroke require:

- rehydration with fluids
- antibiotic treatment of any suspected infection, including malaria or meningitis
- treatment of any convulsions (see Section 5.16.D and E)
- exchange transfusion to reduce the circulating sickle cell percentage as rapidly as possible to less than 25%; this procedure is usually performed in a staged manner over 24–48 hours
- there is no role for aspirin in stroke related to sickle-cell disease.

In the absence of accessible exchange transfusion, it may be reasonable to consider a cautious top-up blood transfusion to maximise oxygen-carrying capacity and reduce the HbS percentage through a dilutional effect. Extreme care must be taken to avoid over-transfusion and the risk associated with increasing blood viscosity thus further contributing to the stroke. In either situation, the haematocrit should not exceed 0.4.

Most children make a good motor recovery from an initial stroke, but may be left with intellectual defects. If untreated, most of these children will suffer a second cerebrovascular accident, usually within 2–3 years of the first episode, as a result of which many of them will die and most will be seriously impaired. Transient ischaemic attacks may presage a more major event.

### **Secondary prevention of stroke**

Because of the risk of a subsequent stroke, all children

should be considered for the long-term transfusion programme to reduce their recurrence risk (although the risk is never fully eradicated). Most children require a top-up transfusion every 4 weeks for life, and this is a heavy burden for patients and their families.

The treatment goals of secondary prevention of stroke using the transfusion programme are as follows:

- to reduce and then maintain the pre-transfusion HbS% at below 30%
- to maintain the pre-transfusion haemoglobin level in the range 9–9.5 grams/dL
- in order to achieve these goals, the post-transfusion target is usually set no higher than 12.5 grams/dL
- to monitor and treat iron overload.

### **Note that there is no role for co-administration of desferrioxamine during transfusions.**

Risks of the long-term transfusion programme include the following:

- transmission of bloodborne viral infection
- allo-immunisation to foreign red cell antigens
- iron overload.

In more well-resourced settings, some children may be able to receive alternatives to long-term top-up transfusions as outlined above. These alternatives include the use of manual or automated **exchange transfusions** to maintain a low HbS% without incurring iron overload states. These children may be able to go for longer periods between blood transfusions, although the risk of exposure to blood does not change.

Unfortunately, recent trials have indicated that there is little role for drugs such as hydroxyurea as an effective alternative to transfusion in the primary or secondary prevention of stroke.

### **Transcranial Doppler (TCD) and primary prevention of stroke**

The use of annual TCD monitoring in more well-resourced countries is having a significant impact on the reduction of the incidence of stroke events in children with no prior apparent risk of stroke, and is now a routine screening tool in sickle-cell disease care.

Children are identified as at high risk of stroke if the recorded velocities on TCD persistently exceed 200 cm/second. The stroke risk can be significantly reduced from 40% in high-risk patients through the use of the long-term transfusion programme as outlined above. Unfortunately, once started, there is little evidence as to whether transfusions could ever be discontinued, as the data suggest that once transfusions are stopped the original stroke risk rapidly returns.

In areas where access to TCD machines and trained technicians may be limited, use of TCD may not be possible, particularly when weighing up the risks and benefits of the long-term transfusion programme.

## **Prevention programmes**

### **Iron overload and transfusions**

Children who are exposed to multiple and regular blood transfusions are likely to develop iron overload. The most widely available iron-chelating agent is desferrioxamine (Desferal), which is administered as a subcutaneous dose

around 20–30 mg/kg over slow subcutaneous infusion (8–12 hours) for 5–7 nights per week. Many children

become non-compliant with this regimen, and newer medications are available as outlined below.

**TABLE 5.11.B.5 Drug treatments to reduce iron loading (iron chelation)**

Drug	Advantages	Disadvantages
Desferrioxamine	Well-understood safety profile through long-term use Cheap	Relatively poor iron chelation properties Poor patient compliance Risk of <i>Yersinia</i> infection
Deferiprone	Oral administration Effective chelation agent	Requires close monitoring due to risk of sudden unexpected neutropenia and risk of overwhelming infection
Deferasirox (Exjade)	Oral once-daily administration Well tolerated Highly effective iron chelation	Expensive Long-term safety profile not yet fully understood Common side effects are deranged urea and electrolytes and gastrointestinal upset Requires some monitoring

Note: see Section 5.11.C for doses of newer iron chelation treatments

### Prevention of infection

Prevention of infection is the mainstay of reducing mortality and morbidity in sickle-cell disease.

- All children should receive immunisation against *Pneumococcus*, *Haemophilus influenzae*, meningococcus and hepatitis B, in addition to any standard immunisation schedule.
- Pneumococcal immunisation should be as broad as possible, including pneumococcal conjugate vaccine **and** Pneumovax. Pneumovax should be given from the age of 2 years, every 5 years for life.
- All children should receive prophylactic penicillin V (erythromycin or clarithromycin can be used as an alternative):
  - age up to 1 year: penicillin 62.5 mg twice a day
  - age up to 5 years: penicillin 125 mg twice a day
  - age 5 years or over: penicillin 250 mg twice a day into adulthood.
- All children should be protected from malaria infection (see Section 6.3.A.d).
- Families should be counselled about prevention, risks and signs of infection, so that they can seek prompt treatment.

### Prevention of crises

- Maintain good fluid intake, especially during gastroenteritis or other infections.
- Folic acid:
  - age up to 1 year: 1 mg daily
  - age up to 5 years: 2.5 mg daily
  - age 5 years or over: 5 mg daily into adulthood.
- Families should be taught how to feel their child's abdomen in order to identify the onset of a sequestration crisis.
- Hydroxyurea (hydroxycarbamide) may raise baseline haemoglobin levels by promoting fetal haemoglobin (HbF) production. This may reduce the frequency and severity of crises in children. However, it is myelosuppressive and should be used with caution and only where facilities for monitoring blood counts exist and the dose can be monitored carefully.

### Splenectomy (and surgery) in sickle-cell disease

Splenectomy is not routinely undertaken in children with

sickle-cell disease, although it does have a role in allowing the baseline haemoglobin to rise by approximately 2 grams/dL in children with evidence of hypersplenism.

Splenectomy may also be indicated in children who have had an episode of life-threatening splenic sequestration.

As with all surgical procedures in sickle-cell disease, careful risk assessment should be undertaken before a planned procedure involving a general anaesthetic, due to the risk of post-operative sickling secondary to hypoxaemia and cold. Current advice suggests that children with sickle-cell disease undergoing moderate- or low-risk surgical procedures should be considered for a pre-operative transfusion to bring their haemoglobin level up towards (but not higher than) 10 grams/dL, to maximise oxygen-carrying capacity.

### Growth

Growth failure and delayed puberty are common in children with sickle-cell disease, especially in those with hypersplenism or who have had multiple acute sickle crises. Weight tends to be affected more than height, and malnutrition is a major factor in determining whether children achieve their full growth potential.

Puberty may be delayed because of hypersplenism or malnutrition because of the hyper-metabolic state and inadequate nutrition.

Dietary advice, treatment of any chronic infections and possibly splenectomy (if hypersplenism is present) may be helpful. Occasionally, children may benefit from temporary use of the monthly transfusion programme to assist them into puberty.

### Priapism

Priapism is a serious but under-reported complication of sickle-cell disease. If untreated, it can lead to fibrosis of the corpus cavernosa and impotence, a risk which appears to be lower in pre-pubertal boys. The duration of an episode predicts the overall outcome. Therefore prompt recognition and management are essential.

Patients typically present with an erect painful penis, which may be precipitated by a painful sickle crisis, fever, dehydration, use of recreational drugs, or sexual activity.

Acute fulminant priapism is characterised by a prolonged and sustained episode, more than 4 hours in

duration. In stuttering priapism, episodes are repetitive and may be individually brief. Patients may have a combination of both of these events.

Treatment of acute priapism is still the subject of much debate. Current best practice suggests the initial use of warm baths, exercise, hydration and gentle sedation while preparing for a more definitive intervention. Subsequent definitive treatment choices include aspiration of blood from the corpus cavernosum followed by surgical washout using saline (irrigation) or adrenergic agonists, which can be performed under conscious sedation. The goal is rapid detumescence within 4–12 hours of the procedure. Ideally, treatment should start within 2 hours of an episode. After 12 hours the patient may require surgical intervention to achieve detumescence. Exchange transfusion (the target haemoglobin concentration is approximately 10 grams/dL, with a haematocrit no higher than 0.4) may be required.

There is still considerable debate about the best treatment options for stuttering priapism, and this is the subject of an ongoing international trial (PISCES). Currently patients with stuttering priapism can be advised to try gentle exercise and warm baths. A preventative approach may be needed, and the following options are available:

- Pseudoephedrine at 30 mg/kg/day, increasing to 60 mg/kg four times a day:
  - alternatively give etilefrine 0.25 mg/kg twice a day
  - both of these drugs are part of the ongoing PISCES trial (2011).
- Hydroxyurea at 10–30 mg/kg/day.
- Use of the long-term transfusion programme.

#### Other problems

- Around 30% of SS children suffer from **sleep-related upper airways obstruction** with consequent hypoxaemia. Nocturnal hypoxaemia has been increasingly

identified as a risk factor for acute chest syndrome (and possibly an independent risk factor for stroke) in children with sickle-cell disease, and marked improvement can occur after adeno-tonsillectomy. Treatment is as indicated for other children with upper airways obstruction (see Section 5.1.D).

- Chronic pain resulting from damage caused by acute vaso-occlusive crises occurs, and other pain secondary to the haemolytic process can occur.
- Avascular necrosis of the hip or shoulder can occur as young as 6 years, although it is uncommon before adolescence. The initial presentation may be with the acute vaso-occlusive crisis, but once disintegration of the femoral head occurs, the pain is of a chronic osteoarthritic type, and should be managed as such.
- Leg ulcers that can become seriously infected are common, and their prevalence rises with age. Appropriate antibiotics such as erythromycin and flucloxacillin, wound cleaning and protection together with rest and elevation of the leg are helpful. Compression stockings may also be of benefit.
- Children develop a renal tubular concentrating defect by the age of 2 years. During adolescence, proteinuria, the nephrotic syndrome or chronic renal failure may develop.
- Renal papillary necrosis may produce haematuria, urinary tract infection and renal colic. Rarely the haematuria is severe and blood transfusion is required. Renal colic is treated with copious fluids and adequate analgesia.
- Many patients are chronically jaundiced with exacerbations. There is no treatment, and reassurance should be given that this rarely represents liver failure.
- Gallstones are common, due to pigment from haemolysis. The pain can mimic an acute painful crisis. Treatment is surgical. Antibiotic treatment of cholecystitis with amoxicillin and metronidazole may be required.

## 5.11.C Haemolytic anaemias

### BOX 5.11.C.1 Minimum standards

- Folic acid.
- Screened blood for transfusion.
- Splenectomy.
- Iron chelation therapy: desferrioxamine.
- Pneumococcal vaccine/penicillin.
- Meningococcal vaccine.
- *Haemophilus influenzae* type B (HiB) vaccine.

### Definition

Haemolytic anaemias are disorders characterised by a reduction in the lifespan of red blood cells, and may be congenital or acquired.

### Clinical features of haemolytic anaemia

These include **pallor, jaundice, splenomegaly** and **gallstones**.

The degree of splenomegaly can be a useful clue to the cause of haemolytic anaemia.

TABLE 5.11.C.1 The differences between congenital and acquired haemolytic anaemia

Congenital	Acquired
Haemoglobin defects: sickle-cell disease, thalassaemia	Infection: malaria, visceral leishmaniasis
Red cell enzyme defects: G6PD, pyruvate kinase deficiency	Alloimmune: haemolytic disease of the newborn, transfusion reactions
Red cell membrane defects: spherocytosis, elliptocytosis	Red cell fragmentation: haemolytic-uraemic syndrome
	Autoimmune infection (e.g. EBV, CMV, HIV, mycoplasma), malignancies (lymphomas, leukaemias), immune deficiencies
	Drugs
	Burns

**TABLE 5.11.C.2 Degree of splenomegaly in haemolytic anaemias**

With minor splenomegaly	With marked splenomegaly
G6PD deficiency	Sickle-cell disease
Autoimmune haemolytic anaemia	Beta-thalassaemia major
Haemolytic-uraemic syndrome	Hb E beta-thalassaemia
Beta-thalassaemia minor	Hereditary spherocytosis
Hb H alpha-thalassaemia syndrome	Hyper-reactive malarial splenomegaly (tropical splenomegaly)
	Visceral leishmaniasis (kala-azar)

### Laboratory features of haemolytic anaemias: general

These include low haemoglobin, increased reticulocyte count, raised and predominantly unconjugated bilirubin, pink plasma after centrifuging of blood (due to free haemoglobin) in severe cases, reduced haptoglobin, and increased urinary urobilinogen.

### Hereditary haemolytic anaemias Red cell membrane defects (dominant inheritance)

#### Spherocytosis

This is the most common haemolytic anaemia due to a membrane defect. It may present at any time from birth to old age, and varies in severity from patients with haemoglobin concentrations of 4–5 grams/dL to asymptomatic individuals with normal haemoglobin levels. Acute haemolytic or aplastic crises may be triggered by viral infections. These usually last for 10–14 days, but may result in sudden severe anaemia requiring transfusion.

#### Diagnosis

- Along with a positive family history, the clinical features are mild jaundice, pallor and splenomegaly. Gallstones may occur in children.
- Laboratory features: blood film shows spherocytes, increased osmotic fragility of red cells, increased reticulocytes, negative antiglobulin (Coombs') test.

#### Treatment

- Folic acid 1 month–12 years 2.5–5 mg daily; 12–18 years 5–10 mg daily.
- Severely anaemic and symptomatic moderately anaemic children may benefit from splenectomy if the facilities available make this a low-risk procedure.
  - **Splenectomy carries a major risk of life-long increased vulnerability to infection with capsulated bacteria such as pneumococci, meningococci and *Haemophilus influenzae* type B. The risks and benefits need to be weighed up very carefully before splenectomy is undertaken.**
  - Delay splenectomy until after the age of 5–10 years if possible.
- Administration of **pneumococcal, meningococcal and HiB vaccine** prior to splenectomy, and lifelong prophylactic oral **penicillin** thereafter (under 12 months of age,

62.5 mg twice daily; 1–5 years 125 mg twice daily; over 5 years 250 mg twice daily).

#### Elliptocytosis

This condition is less common than spherocytosis. It is rare in European populations, but is seen more often in West Africa. In South-East Asia there is a variant, South-East Asian ovalocytosis (SAO), which causes oval-shaped red cells and neonatal hyperbilirubinaemia, but little haemolysis later in life.

#### Diagnosis

- Blood film shows 25–90% of oval, elliptical or rod-shaped red blood cells.
- Homozygotes tend to have severe haemolytic anaemia from infancy.

#### Treatment

This is the same as for spherocytosis.

#### Stomatocytosis

Hereditary stomatocytosis is rare, but it can be acquired in several conditions, especially liver disease. The hereditary form may cause neonatal oedema and ascites which resolves spontaneously.

#### Diagnosis

Blood film shows erythrocytes with a central mouth-like slit (stomatocytes).

#### Treatment

This is the same as for spherocytosis, but **splenectomy is ineffective and may be harmful**, leading to a thrombotic tendency.

#### Metabolic defects

#### Glucose-6-phosphate dehydrogenase deficiency (G6PD) (X-linked)

There are two types of normal G6PD enzymes (types A and B). Worldwide, there may be 100 million people with diminished red cell G6PD activity. G6PD A deficiency is common in black children, and their G6PD function is reduced to about 10% of normal. G6PD B deficiency (G6PD Mediterranean) is less common, and the enzyme activity is reduced to 1–3%; this and the Chinese variant of G6PD deficiency are the more severe forms of the disease.

#### Clinical features

Severe enzyme deficiency causes chronic haemolytic anaemia and jaundice.

Haemoglobinuria may occur with less than 10% enzyme activity, and severe episodes of haemolysis occur with oxidant stress:

- favism due to ingestion of the fava broad bean or inhalation of its pollen
- oxidant drugs such as antimalarial drugs, sulphonamides, high-dose aspirin, non-steroidal anti-inflammatory drugs (NSAIDs), quinidine, quinine, nitrofurantoin, phenacetin and vitamin K analogues
- other chemicals, such as those in mothballs, can also trigger an episode.

**Diagnosis**

- Blood film shows 'blister' and 'bite' cells. Heinz bodies may be seen on unstained blood film.
- Enzyme assay (if available) is needed to make the diagnosis (but this may be normal if reticulocyte numbers are raised). It may be necessary to wait several weeks after an acute episode before measuring enzyme levels.

**Treatment**

- Avoid drugs that cause oxidant stress (i.e. chloroquine, primaquine, sulphonamides, nitrofurantoin, quinolones, dapsone, high-dose aspirin, phenacetin) or fava beans. If primaquine is necessary, this can be given weekly for 8 weeks.
- Patients usually recover spontaneously once the precipitating factors have been removed.
- Transfusion may be necessary if there is severe haemolysis.

**Pyruvate kinase deficiency (autosomal recessive)**

This is the second commonest enzyme defect of the glycolytic pathway, and affects mainly northern Europeans.

**Clinical features**

These are very variable.

- Neonates may have severe haemolysis and present with early jaundice (within 48 hours), anaemia and hyperbilirubinaemia.
- In older children, haemolysis is variable and may be asymptomatic or lead to poor growth, delayed puberty and the skeletal changes associated with chronic haemolysis, such as maxillary prominence and frontal bossing and an increased tendency to long bone fractures.

**Diagnosis**

- Blood film shows increased reticulocytes, Heinz bodies and mild macrocytosis.
- Enzyme assay for pyruvate kinase.

**Treatment**

- Folic acid (250 micrograms/kg once daily).
- Splenectomy (only if the facilities available make this a low-risk procedure).
- Transfusion if there is severe anaemia or an aplastic crisis.

**Haemoglobin defects**

- Abnormal variants: sickle (see Section 5.11.B), Hb C, Hb E, Hb D, etc.
- Defective synthesis: thalassaemias.
- Beta-thalassaemia major (autosomal recessive).

**Beta-thalassaemia major**

In this condition there is a complete or almost complete absence of the beta-globin chain synthesis. There is a high incidence of the beta-thalassaemia gene (1–15%) in southern Europe, the Middle East, India, Pakistan and South-East Asia.

**Clinical features**

- Anaemia, which becomes obvious by 3 months.
- Weakness and tiredness.

- Failure to thrive, intermittent fever and poor feeding.
- Cardiac failure may develop.
- Infections and splenomegaly.
- Stunted growth with skeletal changes (e.g. frontal bossing, maxillary hyperplasia, increased tendency to fractures).
- Increased skin pigmentation.
- Delayed puberty.

**Diagnosis**

- Blood film shows microcytosis, anisocytosis, and hypochromic and nucleated red cells.
- Haemoglobin electrophoresis: Hb F increased (10–90%), Hb A absent, Hb A<sub>2</sub> can be reduced, normal or occasionally elevated.
- Serum iron and ferritin levels are increased.
- Reticulocyte numbers are often lower than expected for the degree of anaemia.

**Management of beta-thalassaemia major**

Management is by regular blood transfusion and iron chelation therapy to reduce iron deposition in tissues, especially the heart, liver and endocrine glands (transfusion haemosiderosis).

**Blood transfusion**

- Monitor haemoglobin levels, growth and development, and **transfuse when the child stops developing or when the haemoglobin concentration is less than 7 grams/dL in the absence of infection.**
- **Blood should be ABO, rhesus (Dd, Cc, Ee) and Kell matched and filtered to avoid allo-immunisation and transfusion reactions.**
- Immunise against hepatitis B prior to transfusion.
- Transfuse 20 mL/kg of filtered red cell concentrate over 2–3 hours.
- To monitor, calculate the transfused red cell concentrate in mL/kg yearly. If blood consumption is > 300 mL/kg, investigate the cause.
- Increased blood consumption may be due to large spleen, large liver, autoimmune haemolytic anaemia or multiple allo-antibodies.
- To prevent bone deformities, osteoporosis and extramedullary haematopoiesis, **aim for a pre-transfusion level of not less than 9 grams/dL.**
- Pre-transfusion haemoglobin is mandatory. Post-transfusion haemoglobin is optional.
- As a rule, the haemoglobin level drops by 1 gram/week in splenectomised children, whereas in non-splenectomised patients it drops by 1.5 grams/week.
- Monitor serum ferritin levels (normal range is 7–200 micrograms/litre in children over 5 months old).

**Iron chelation**

- To avoid damage to the endocrine glands, liver and heart, iron chelation should be started when the **serum ferritin level is around 1000 micrograms/litre.**
  1. Desferrioxamine infusion IV or subcutaneous given slowly over 10–12 hours. The initial dose should not exceed 30 mg/kg desferrioxamine in 10 mL of water for injection, followed by maintenance doses of 20–50 mg/kg each over 10–12 hours on 3–7 nights a week.  
Too much desferrioxamine can cause growth,

hearing and eyesight problems. Give 100–200 mg vitamin C orally at the same time as desferrioxamine. This enhances iron excretion in the urine, but it should be given separately from food as it also enhances iron absorption from food. Desferrioxamine should not be given to children with cardiac dysfunction.

2. Oral chelation (Deferiprone or Deferasirox) may be used when desferrioxamine is not available or not tolerated. These drugs are much more acceptable to children than desferrioxamine as they are oral rather than a long overnight infusion but they have significant side effects.

- Deferiprone by mouth: child 6–18 years 25 mg/kg 3 times daily (maximum 40 mg/kg daily).
- Deferasirox by mouth: child 2–18 years initially 10–30 mg/kg once daily according to serum-ferritin concentration. For maintenance, consult product literature.
- The most serious side effect is neutropenia.
- Monitor the neutrophil count every 2 weeks.
- If the neutrophil count is less than  $1.0 \times 10^9$ /litre, stop iron chelation and monitor recovery.
- If infection is present, the neutrophil count is less than  $0.5 \times 10^9$ /litre and there are symptoms, take blood cultures and treat with a broad-spectrum antibiotic to prevent septicaemia.
- Other side effects are joint pain, nausea, fluctuating liver enzymes and zinc deficiency.

#### Monitoring treatment

- Measure height and weight, plot height velocity and watch for delayed puberty.
- To avoid psychological trauma and ensure the development of secondary sexual characteristics, treat if no signs of sexual development have occurred by 16 years of age (see Section 5.8.C).
- Check the following at least twice yearly: serum ferritin (iron overload), liver function tests, calcium, phosphate, alkaline phosphatase (hypoparathyroidism, tetany).
- Undertake yearly screening for HCV and HIV infection.
- If HCV is positive, assess viraemia (serotype) if possible, perform a liver biopsy and give interferon with or without ribavirin to avoid cirrhosis and hepatoma.
- If HIV-positive, continue transfusions and give the latest available antiviral treatment.
- All blood donors should be tested for HCV and HIV.

#### Acquired haemolytic anaemia

##### Immune mediated

- Haemolytic transfusion reaction.
- Haemolytic disease of the newborn (see Section 3.4).

- Hypersplenism.
- Secondary to infection: EBV, CMV, *Mycoplasma*, rarely HIV.
- Secondary to malignancies: lymphomas, leukaemias.
- Secondary to autoimmune diseases: SLE, rheumatoid arthritis.

#### Diagnosis

- Anaemia with increased reticulocytes.
- Splenomegaly.
- Positive direct Coombs' test.

#### Management

- Most secondary cases (70–80%) are transient, lasting about 3 months.
- Infants and older children may develop the chronic form.
- Treatment may not be needed if the symptoms are not severe.
- Transfusion may be necessary if there is severe haemolysis.
- Steroids: prednisolone 2 mg/kg/day (up to 6 mg/kg/day in severe cases) can be given if treatment is needed until the rate of haemolysis declines, and then stopped gradually.

#### Malaria

See Section 6.3.A.d.

#### Secondary to organ disease

Renal failure (see Section 5.6.C).

Liver disease (see Section 5.7.B).

#### Burns

See Section 7.3.I.b.

#### Miscellaneous

- Chemicals and drugs.
- Toxins (e.g. *Haemophilus influenzae* type B, staphylococcal, streptococcal, clostridial).
- Venoms (e.g. cobra, viper, rattlesnake, bee, wasp, yellow jacket).

## 5.11.D Blood clotting disorders

### BOX 5.11.D.1 Minimum standards

- Regional/national centre.
- Prednisolone.
- Immunisation; hepatitis B.
- Blood clotting products.
- Desmopressin and tranexamic acid.

### Factor deficiencies

The incidence of haemophilia is similar worldwide, at around 1 in 5000–10 000 male births. Major advances have been made in both separating haemophilia A (factor VIII deficiency) and haemophilia B (factor IX deficiency) and delivering safe therapeutic intervention with replacement therapy. However, this is only available to the 20% of haemophiliacs who live in well-resourced countries. For those in resource-limited countries, severe haemophilia continues to be a personal and social disaster, with affected boys becoming progressively crippled during childhood from spontaneous painful intractable haemorrhages into muscles and joints. These boys commonly die in childhood or early adulthood. Severe deficiencies of the other coagulation factors (X, XI, VII, V, XIII, fibrinogen and von Willebrand factor) are also associated with severe and sometimes life-threatening or fatal haemorrhage.

- The largest barrier to providing replacement therapy is its high cost.
- There are also non-financial barriers, including insufficient knowledge even among the medical community, lack of a proper healthcare structure, and low levels of literacy.
- In the last decade the WHO and the World Federation of Haemophilia (WFH) have made considerable progress in setting up programmes in resource-limited countries.
- The WHO has identified the following as core components:
  - training of care providers and the establishing of care centres
  - identification and registration of people with haemophilia
  - improving social awareness of haemophilia
  - prevention of haemophilia
  - providing safe therapeutic products
  - developing a programme of comprehensive care.

### How can delivery of haemophilia care be implemented in resource-limited countries?

- National haemophilia societies are crucial. In addition to supporting affected families, they can lobby for support from the healthcare budget.
- The WHO and WFH have visiting teams that have contributed to education and improvement through these national groups. They include international haemophilia training fellowships, workshops and twinning programmes, in order to transfer knowledge and diagnostic expertise to these embryonic services.
- It is important that those planning healthcare fully appreciate that provision of laboratory diagnostic services for

haemophilia and the development of safe blood transfusion services to provide safe replacement therapy will benefit a wide range of medical services.

### How should the service be built and structured?

- At least one national centre should be created where the laboratory, scientific and medical expertise exists to make an accurate diagnosis, which will then allow the appropriate counselling, including genetic counselling, of the patient's family (similar to a national centre for cancer therapy with links to centres in well-resourced countries: see Section 5.14). With advances in molecular biology, carriers of haemophilia can currently be identified and antenatal diagnosis provided so that a choice can be made to prevent the birth of haemophilic boys, particularly if treatment is not available.
- National registers should be set up for service planning.
- A clinical service involving paediatricians, dentists, orthopaedic surgeons and adult physicians needs to be set up. Safe replacement therapy, probably initially derived from donated plasma, should be developed.
- Donor screening and product treatment to remove the risk of at least HIV and hepatitis B and C infection must be provided.
- Haemophiliacs should be vaccinated at an early age against hepatitis B.

### What treatment should be given in the absence of replacement therapy?

Spontaneous haemorrhages into muscles and joints can be extremely painful and will lead to progressive crippling deformities. The acute episode must be managed with bed rest. For bleeds such as those in the knees, splinting with a back slab to restrict movement may help. Analgesia for the pain is also required (see Section 1.15). Opiates may be needed to obtain adequate pain relief. Bleeding with loss of first dentition may be severe enough to warrant blood transfusion.

In mild to moderate cases, desmopressin (DDAVP) can be helpful.

- **By intravenous infusion over 20 minutes:** Child 1 month–18 years 300 nanograms/kg as a single dose immediately before surgery or after trauma; may be repeated at intervals of 12 hours if no tachycardia.
- **Intranasally:** Child 1–18 years 4 micrograms/kg as a single dose. For pre-operative use, give 2 hours before procedure.

**Avoid drugs that impair haemostasis, such as aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) (e.g. ibuprofen).**

### Platelet deficiencies: idiopathic thrombocytopenic purpura (ITP)

- Isolated thrombocytopenia usually follows a viral infection 1–3 weeks previously.
- Boys and girls are equally affected, and the peak incidence is in those aged 2–4 years.

- There is a 90% probability of complete remission, but those presenting over the age of 10 years are more likely to have chronic ITP.
- ITP that persists for 6 months is defined as chronic.
- Children with chronic ITP are more likely to have an underlying cause (e.g. autoimmune disease).
- Bleeding manifestations include petechiae, purpura, epistaxes, haematuria, gastrointestinal haemorrhage and (rarely) intracerebral haemorrhage. The child has no hepatosplenomegaly and is usually well.
- Other causes of thrombocytopenia must be excluded. If there is any doubt, a bone-marrow aspirate will show normal haematopoiesis with increased numbers of megakaryocytes in ITP.

### Management

- Treatment is based on symptoms, **not platelet count**, and many patients require no treatment.
- Petechiae on the head and neck, and gastrointestinal and oral bleeding, are indicators for prednisolone (1–2 mg/kg/day after food in two divided doses for no more than 14 days or 4 mg/kg for no more than 4 days;

reduce over 5 days and stop irrespective of the platelet count if the patient is asymptomatic). Prednisolone does not alter the course of the disease. The time to remission is very variable.

- Tranexamic acid can be useful in the treatment of mucosal bleeding. Give 10 mg/kg IV slowly over 10 minutes in children 6–18 years (maximum 1 gram) followed by 25 milligrams/kg orally (maximum 1.5 gram) three times daily for 2–8 days.
- Hormonal treatment can benefit girls with menorrhagia. In addition Tranexamic acid 1 gram orally 3 times daily for up to 4 days can help (initiate when menstruation starts).
- Chronic ITP with serious bleeding into the gastrointestinal tract or brain may require splenectomy. However, in resource-limited countries there is a high risk of infection following splenectomy, and long-term penicillin prophylaxis and pneumococcal vaccination are required.

## 5.12 Gastrointestinal disorders

### 5.12.A Acute diarrhoea

#### BOX 5.12.A.1 Minimum standards

- Reduced-osmolarity ORS.
- ReSoMal for children with severe malnutrition.
- IV fluids: Hartmann's or Ringer-lactate solution with glucose 5% or 10% to prevent hypoglycaemia.
- Potassium: oral and IV.
- ABC resuscitation for shock.
- Antibiotics: co-trimoxazole, amoxicillin, nalidixic acid, ciprofloxacin, cefotaxime, chloramphenicol, erythromycin, metronidazole, tetracycline, vancomycin, doxycycline.

### Important issues

- Shock management, rehydration therapy and continued feeding are key strategies.
- Antibiotics are **not** given routinely, but they are indicated in bloody diarrhoea (probable *Shigella* infection) and suspected cholera.
- Antidiarrhoeal drugs and anti-emetics should never be given and can be dangerous in children.
- Zinc supplementation speeds recovery and helps to prevent further episodes.

### Introduction

Diarrhoeal diseases are a leading cause of childhood morbidity and mortality in resource-limited countries. In 2001, an estimated 1.5 million children under 5 years of age died from diarrhoea, 80% of them in the first 2 years of life. Around 50% of these deaths are due to watery diarrhoea and occur either because of lack of access to oral rehydration solution (ORS) or because of incorrect case management. About one-third of deaths are caused by persistent diarrhoea and the remainder (approximately 15%) are caused by dysentery.

This section is primarily aimed at the management of the infant and child under 5 years as they are the most seriously affected. There are particular problems in managing children with severe co-morbidities: these include significant malnutrition and anaemia (Hb below 6 G/dL see Sections 5.10.B and 5.11.A). In these children, assessment is more difficult and there is likely to be an abnormal response to a fluid load because of poor cardiac function. Modifications to the management plans for these children largely involve slower shock management and rehydration, the careful use of blood transfusion and diuretics and very frequent re-assessment.

ORS has been a simple and effective solution, reducing morbidity and mortality in diarrhoeal illness. The new low-osmolarity ORS reduces by 33% the need for supplemental

IV fluid therapy after initial rehydration compared with the previous standard WHO ORS solution. The new ORS also reduces the incidence of vomiting by 30% and stool volume by 20%.

In addition, zinc supplementation has been shown to significantly reduce the severity and duration of diarrhoea.

### Definition

Diarrhoea is the passage of loose or watery stools, usually at least three times in a 24-hour period. However, it is the consistency of the stools rather than the number that is most important. Mothers usually know when their children have diarrhoea, and may provide useful working definitions in local situations. The volume of fluid lost through the stools in 24 hours can range from 5 mL/kg (near normal) to 200 mL/kg, or more. Dehydration occurs when these losses are not replaced adequately and a deficit of water and electrolytes develops. The concentrations and amounts of electrolytes lost also vary. The total body sodium deficit in young children with severe dehydration due to diarrhoea is usually about 70–110 millimoles/litre of water deficit. Potassium and chloride losses are in a similar range.

The most common causes of diarrhoea are rotavirus, enterotoxigenic *E. coli* (ETEC) and, during epidemics, *Vibrio cholerae* O1 or O139.

### Classification of diarrhoea

- **Acute watery diarrhoea** (including cholera): this lasts from several hours to days. The main danger is dehydration, and malnutrition also occurs if feeding is not continued. If there is a current epidemic, cholera is likely and causes severe dehydration with a positive stool culture for *Vibrio cholerae* O1 or O139.
- **Acute bloody diarrhoea**, or dysentery (blood is mixed in with stool): the main dangers are intestinal damage, sepsis and malnutrition. Other complications, including dehydration, may also occur.
- **Persistent diarrhoea**: this is defined as passage of three or more loose watery stools in a 24-hour period, which lasts for 14 days or longer. The main danger is malnutrition and serious non-intestinal infection; dehydration may also occur (see Section 5.12.B).
- **Diarrhoea with severe malnutrition** (marasmus or kwashiorkor): the main dangers are severe systemic infection, dehydration, heart failure and vitamin and mineral deficiency (see Section 5.10.A).
- **Diarrhoea associated with a recent course of broad-spectrum oral antibiotics.**

### Assessment of the child with diarrhoea

- Fever, vomiting and loose stools are the common symptoms of acute gastroenteritis.
- If possible, rule out other serious illness (e.g. meningitis, malaria, bacterial sepsis).
- Assess for degree of dehydration, bloody diarrhoea, persistent diarrhoea, malnutrition and serious non-intestinal infections.

### History

Specific points to enquire about in the history include the following:

- duration of diarrhoea
- presence of blood in the stool

- local knowledge or reports of a cholera epidemic
- recent use of antibiotics
- the presence of fever, cough or other important problems (e.g. convulsions, measles)
- usual feeding practices
- the type and amount of fluids (including breast milk) and food taken during the illness
- drugs or other remedies taken
- immunisation history.

### Physical examination

First assess the patient for shock and treat this urgently as a priority if it is present. Children with shock will have reduced consciousness, a high and increasing heart rate, weak pulse, poor skin circulation time with prolonged capillary refill time (> 3 seconds), and low or even unmeasurable blood pressure.

**Children with shock require immediate resuscitation (ABC)**, including high concentrations of oxygen (if available) and an IV bolus of 10–20 mL/kg of either Ringer-lactate or Hartmann's solution given as rapidly as possible (see Section 5.5.B). If IV access is not possible (often the veins are collapsed), consider the intra-osseous route (see Section 8.4.B). If shock is not relieved by 20 mL/kg, give another bolus of 10–20 mL/kg, but watch very carefully for fluid overload and in particular pulmonary oedema (this is most likely if the patient is also severely anaemic and will be shown by increasing breathlessness, crepitations may be heard).

The examination includes measurement of vital signs together with clinical correlation. The degree of dehydration is graded according to signs and symptoms that reflect the amount of fluid lost (see Table 5.12.A.2). Infants with acute diarrhoea are more apt to dehydrate than are older children, because they have a higher body surface area to weight ratio, have a higher metabolic rate, and are dependent on others for fluid. Although the most accurate assessment of fluid status is acute weight change, the patient's premorbid weight is often not known.

In severe dehydration, prolonged skin retraction time and decreased perfusion are more reliably predictive of dehydration than a sunken fontanelle or the absence of tears. A good correlation has been reported between capillary refill time and fluid deficit. However, fever, ambient temperature and age can affect capillary refill time as well.

**In severe dehydration, shock and death soon follow if rehydration is not started quickly.**

Children with some dehydration or severe dehydration should be weighed without clothing when estimating their fluid requirements. If weighing is not possible, the child's age may be used to estimate their weight:

- Weight = (age in years + 4) × 2 for children less than 10 years old.
- For an infant up to 1 year old, birth weight doubles by 5 months and triples by 1 year.

**Treatment should never be delayed because facilities for weighing are not rapidly available.**

In addition:

- Look for an abdominal mass or abdominal distension.
- In an infant less than 1 week old, diarrhoea is sometimes a sign of neonatal sepsis (see Section 3.4). In an infant, blood in the stool may be due to an intussusception (see Section 5.19).

**Remember other diagnoses**, including typhoid, antibiotic-associated colitis and (rarely) inflammatory bowel disease (see Section 5.12.D).

### Investigations

Laboratory investigations are rarely needed at the outset. Serum electrolytes, especially sodium or potassium concentrations, are useful in severe dehydration and for monitoring progress, if available. Stool cultures should be undertaken if at all possible in dysentery (bloody diarrhoea), but are not needed to initiate treatment in the usual case of acute watery diarrhoea. Stool microscopy can be useful for diagnosing *Giardia lamblia*, *Cryptosporidium* and amoebic dysentery.

### Principles of case management

There are five essential elements of the management of all children with diarrhoea:

- **Resuscitation from shock, if present:** Give IV boluses of Hartmann's solution or Ringer-lactate solution. This needs to be done rapidly (caution is required in malnutrition and anaemia; see Section 5.10.B). Improvement in conscious level is a good indicator of response to circulatory shock treatment.
- **Rehydration therapy:** this should be done more slowly, so as not to cause rapid metabolic change.
- **Maintenance therapy:** this is to replicate the normal fluid needs and any ongoing extra losses.
- **Zinc supplementation.**
- **Continued feeding.**

### Calculating fluid requirements

WHO Plans A to C for gastroenteritis in children (see Appendix to this section) include estimates of total fluid requirements, and assume that most children will be drinking by 4 hours into treatment and thus able to 'self-regulate'. For patients for whom this is not the case, fluid management can be undertaken using the following guidelines.

### Estimating fluid requirements

The amount of fluid that the child needs over a 24-hour period needs to be calculated. It is the sum of:

$$\text{estimated fluid deficit} + \text{maintenance requirements} + \text{ongoing losses.}$$

### Deficit

**If an accurate recent pre-illness weight is available**, subtract the current weight to estimate lost fluid (1 kg = 1 litre of fluid).

For example, a child who weighed 9.2 kg is seen with diarrhoea and weighs 8.3 kg:

$$\text{estimated fluid loss is } (9.2 - 8.3) \text{ kg} = 0.9 \text{ kg} = 900 \text{ mL deficit, i.e. } 10\% \text{ dehydrated.}$$

**If no recent weight is available, or the recorded weight is considered to be unreliable**, assess the degree of dehydration as described in Table 5.12.A.2.

Weigh the child (or estimate their weight from their age as follows: weight (kg) = 2 × [age (years) + 4]) if over one year.

Then use the following formula: percentage dehydration × weight (kg) × 10 = deficit (in mL).

For example, a child whose weight is estimated to be 10 kg is 10% dehydrated.

$$\text{Their estimated fluid loss is } 10 \times 10 \times 10 = 1000 \text{ mL} \\ \text{(40 mL/hour if replaced over 24 hours).}$$

### Maintenance

**TABLE 5.12.A.1 Estimated maintenance fluid requirements based on body weight for a child**

Body weight	Fluid needed per day	Fluid needed per hour
First 10 kg of body weight	100 mL/kg	4 mL/kg
Second 10 kg of body weight	50 mL/kg	2 mL/kg
Subsequent kg	20 mL/kg	1 mL/kg

### Ongoing losses

**For each diarrhoeal stool:**

- < 2 years of age: give 50–100 mL or 10 mL/kg
- ≥ 2 years of age: give 100–200 mL or a cup or small glass if drinking or tolerating NG fluid.

**For each vomit:** use 2 mL/kg ORS, and give small frequent volumes (e.g. 5 mL/minute in a child) via a spoon, syringe or cup. Gradually increase the amount given and closely supervise this.

**For nasogastric tube aspirates:** replace volume for volume with either ORS or Ringer-lactate solution with 5% or 10% glucose or Hartmann's solution with 5% or 10% glucose.

### Signs of over-hydration

- Oedematous (puffy) eyelids.
- Heart failure (especially in severe malnutrition), chronic malnutrition or protein-losing enteropathy: look for tachycardia, tachypnea, crepitations at the lung bases, hepatomegaly or gallop rhythm (see Section 5.4.B).
- A chest X-ray may be helpful in showing pulmonary plethora or oedema.

Stop giving ORS, but give breast milk or plain water, and food.

Do not give a diuretic unless there is pulmonary oedema (lung crepitations), in which case give furosemide 1 mg/kg IV.

### Treatment phases in dehydration with shock

In the shock phase, the circulating volume must be improved sufficiently to perfuse vital organs, this will be identified by an improvement in conscious level, falling heart rate and stronger pulse volume.

- In the rehydration phase, the fluid deficit should be replaced and clinical hydration achieved.
- In the maintenance phase, adequate dietary and fluid intake should be maintained.
- In all phases, excess fluid losses must be replaced continuously.

TABLE 5.12.A.2 Estimated degrees of dehydration with symptoms, signs and treatment

Degree of dehydration with diarrhoea	Symptoms and signs present	Treatment
No dehydration	None Increased thirst	<ul style="list-style-type: none"> <li>• Treat at home with extra fluids. WHO Treatment Plan A (see below)</li> <li>• Breastfeeding or standard diet must continue</li> <li>• Warn mother about danger signs of some or severe dehydration and when to return</li> <li>• Zinc supplements</li> </ul>
Some dehydration (5–9% fluid deficit)	Two or more of the following signs: <ul style="list-style-type: none"> <li>• Restless and irritable</li> <li>• Sunken eyes</li> <li>• Drinks eagerly/thirsty</li> <li>• Loss of skin turgor; tents when pinched and goes back slowly</li> </ul> Any one additional sign of severe dehydration below	<ul style="list-style-type: none"> <li>• Treat with WHO Treatment Plan B in hospital for at least 24 hours (if feasible)</li> <li>• Give ORS or ReSoMal if there is malnutrition</li> <li>• Breastfeeding or standard feeding to continue</li> <li>• Zinc supplements</li> </ul>
Severe dehydration (10% or greater)	Two or more of the following signs <ul style="list-style-type: none"> <li>• Prostration</li> <li>• Sunken eyes</li> <li>• Loss of skin turgor; tents when pinched and goes back very slowly (<math>\geq 2</math> seconds)</li> <li>• Not able to drink or drinks poorly</li> </ul> In addition may show: <ul style="list-style-type: none"> <li>• Rapid deep breathing from acidosis</li> <li>• Lack of urine output</li> </ul>	<ul style="list-style-type: none"> <li>• WHO Treatment Plan C</li> <li>• Rapid IV rehydration, giving ORS while IV cannula is put in place</li> <li>• Test for and treat any hypoglycaemia</li> <li>• Breastfeeding or standard feeding as soon as possible</li> <li>• Zinc supplements</li> </ul>
Shock	As above with: <ul style="list-style-type: none"> <li>• High and increasing heart rate; weak pulse volume</li> <li>• Poor skin circulation time (cool and poorly perfused extremities) with prolonged capillary refill time (<math>&gt; 3</math> seconds)</li> <li>• Low or even unmeasurable blood pressure</li> <li>• Very reduced conscious level or coma</li> </ul>	<ul style="list-style-type: none"> <li>• Urgent IV or intra-osseous access</li> <li>• Urgent IV/intra-osseous fluid bolus of 10 mL/kg Ringer-lactate or Hartmann's solution</li> <li>• Repeat 10 mL/kg boluses if remains shocked, up to a total of 40 mL/kg, then beware of fluid overload</li> <li>• Then rehydrate more slowly</li> <li>• Use NG or oral ORS/breast milk as soon as tolerated</li> </ul>

A child's fluid deficit can be estimated as follows:

- Mild or no signs of dehydration:  $< 5\%$  fluid deficit;  $< 50$  mL/kg.
- Some dehydration: 5–10% fluid deficit; 50–100 mL/kg.
- Severe dehydration:  $> 10\%$  fluid deficit;  $> 100$  mL/kg.

Rehydration therapy is based on degree of dehydration.

### Treatment with low-osmolality ORS

The formula for standard ORS and the latest low-osmolality ORS recommended by the WHO and UNICEF is given in Table 5.12.A.3. The quantities shown are for preparation of 1 litre of ORS, by adding one sachet of oral rehydration salts to 1 litre of clean water.

When prepared and given correctly, ORS provides sufficient water and electrolytes to correct the deficits associated with acute diarrhoea. Potassium is provided to replace the large potassium losses associated with acute diarrhoea, especially in infants, thus preventing serious hypokalaemia. Citrate (or bicarbonate) is provided to prevent or correct base deficit acidosis. Glucose is essential because, as it is absorbed, it promotes the absorption of sodium and water in the small intestine. This is true irrespective of the cause of the diarrhoea. Without glucose, ORS solution would be ineffective.

Healthcare workers and mothers criticised standard ORS because it did not reduce stool output or the duration of diarrhoea. Reduced-osmolality ORS is as effective as

standard ORS for preventing and treating diarrhoea, but it also reduces stool output/volume by 25%, reduces vomiting by almost 30%, and reduces the need for supplemental IV rehydration by 33%. This means that there is less need for hospital care, less disruption of breastfeeding, less use of needles and, where IV treatment is not available, less risk of dying from acute diarrhoea.

It is as effective as standard ORS in the treatment of cholera in adults, but may produce transient hyponatraemia. In children it appears to be as effective as standard ORS in cholera, but careful observations for hyponatraemia should be undertaken if possible.

### Use ReSoMal instead of low-osmolality ORS in

TABLE 5.12.A.3 Composition by weight of WHO/UNICEF oral rehydration salts to be dissolved in boiled water to produce 1 litre

Ingredient	Original standard ORS (grams/litre clean water)	New and recommended low-osmolality ORS (grams/litre clean water)
Sodium chloride	3.5	2.6
Trisodium citrate dihydrate	2.9	2.9
Potassium chloride	1.5	1.5
Glucose anhydrous	20	13.5

**TABLE 5.12.A.4 Resulting molar concentration of components of standard and reduced-osmolarity WHO oral rehydration solutions**

ORS	Standard osmolarity (mEq/litre)	Reduced osmolarity (mEq/litre)
Glucose	111	75
Sodium	90	75
Chloride	80	65
Potassium	20	20
Citrate	10	10
Osmolarity	311* mOsm/litre	245 mOsm/litre

\* Hyperosmolar with respect to plasma osmolality (normal = 276–295 mOsm/litre).

If using bicarbonate ORS there are 30 mmol/litre of bicarbonate instead of citrate.

**children with severe malnutrition, as this product is specifically designed for such children.**

### Zinc supplementation

Zinc is an important micronutrient for children's overall health and development. It is lost in greater quantity during diarrhoea. Replacing the lost zinc is therefore important both for helping the child to recover and for keeping them healthy in the coming months. It has been shown that zinc supplements given during an episode of diarrhoea reduce the duration and severity of the episode, and lower the incidence of diarrhoea in the following 2–3 months. For these reasons, all patients with diarrhoea should be given zinc supplements as soon as possible after the diarrhoea has started. **Give 10 mg/kg for infants less than 6 months old and 20 mg/kg for older infants and children for 14 days.**

### Treatments for different degrees of dehydration with/without shock

Dehydration does not neatly fit into discrete categories, although texts such as this one and the WHO publications show practicality in this way for clarity and guidance. Similarly, it can be very difficult to distinguish severe dehydration from dehydration with shock, and the two 'categories' overlap. The essential point to understand is that each severely ill patient must be reassessed frequently to ascertain whether the treatment protocol is having the desired effect of reversing the life-threatening signs of fluid loss. Look for the following:

- increasing awareness and response to stimuli
- gradually strengthening pulse with a decreasing rate (however, a slow weak pulse is a pre-terminal sign).

#### Children severely dehydrated with shock: shock treatment phase

**Children with shock will have a high and increasing heart rate, weak pulse, poor skin circulation time with prolonged capillary refill time (> 3 seconds), depressed conscious level, and low or even unmeasurable blood pressure.**

**These children require immediate resuscitation (ABC) and emergency treatment (see also Section 5.5.B).**

#### Airway (if patient has a reduced conscious level)

- Use an opening manoeuvre if the airway is not open or

if it is partially obstructed. Then keep the airway open. If there is immediate improvement but the airway closes without active opening support, consider using airway adjuncts to support the airway.

- Suction if necessary, but not routinely.
- If the child is deeply unconscious (P or less on the AVPU scale), the airway may need to be secured by intubation using experienced senior help (if available).

### Breathing

- Give 100% oxygen (mask with reservoir and flow rate of at least 6 litres/minute) regardless of SpO<sub>2</sub> (this increases oxygen delivery as well as improving tissue oxygenation).
- For inadequate ventilation or depressed conscious level (as indicated by the AVPU score) with hypoventilation, respiration should be supported with oxygen via a **bag and mask**, and experienced senior help summoned (if available).

### Circulation

- Obtain vascular access to give boluses quickly. Insert an IV cannula and if facilities available send blood for a full blood count, urea and electrolytes blood glucose, cross-matching (if anaemic) and clotting. If peripheral veins are difficult to access an intra-osseous infusion (e.g. EZIO) is rapid and effective. In the absence of IO equipment, the **external jugular vein** or **long saphenous vein cut-down** are good alternatives (see Section 8.B for circulatory procedures). If a skilled operator is available, an internal jugular vein central line is ideal, once an initial rapid infusion has been given, if the patient is very severely shocked and likely to need ongoing high dependency care, as it can also allow **CVP** measurements (if available).
- Give an initial **rapid** bolus of 10 mL/kg of Ringer-lactate or Hartmann's solution and reassess. **Do not use 5% glucose or 0.18% saline/4% glucose solutions for resuscitation, as these can cause hyponatraemia and cerebral oedema.** Boluses should be manually pushed in using a 20- to 50-mL syringe (utilising a three-way tap and link to an IV giving set).
- The re-assessment after the first bolus allows the clinician to ascertain whether the child has any contraindications to large volume resuscitation. Assess for:
  - malnutrition (this should be obvious: see Section 5.10.B) severe anaemia or cardiac problem. **Rapid fluid infusion can be fatal in malnutrition, severe anaemia or cardiac problems. Stop the rapid infusion and proceed more slowly with reference to Sections 5.10.B malnutrition, 5.11.A anaemia and 5.4.B heart failure and consider a blood transfusion.**
- Further 10 mL/kg boluses with reassessment will usually be required if shock continues. In a child with shock from severe dehydration caused by diarrhoea, it would be very unusual to need more than 30–40 mL/kg to improve the child's circulation. Reconsider the diagnosis. For example:
  - surgical abdominal pathology (e.g. intussusception or volvulus) (see Section 5.19)
  - additional pathology e.g. septicaemia (see Section 5.5.C)
  - ongoing severe diarrhoea, particularly if there is a cholera epidemic.

- Once a **total** of 40 mL/kg of boluses have been given IV, complications such as pulmonary oedema may occur. If available, expert help (including CVP monitoring and facilities for positive pressure ventilation) is essential. If expert help is not available and there is ongoing severe diarrhoea, continue with fluid resuscitation until there is some improvement in conscious level.
- If a blood glucose shows hypoglycaemia (< 2.5 mmol/L) or glucose stick test has not been available, give a dose of 5 mL/kg of 10% glucose IV to any child who still has a depressed conscious level, as hypoglycaemia may be contributing to this problem. Increased alertness confirms hypoglycaemia (and see below).
- Keep the patient warm, but do not overheat them as this will cause peripheral vasodilatation and reduce the blood supply to vital centres. Hypothermia will exacerbate poor peripheral perfusion, acidosis and coagulation abnormalities.
- Elevate the legs (raise the foot of the bed).
- Give a 10 mL/kg bolus of fresh blood as soon as possible if severe anaemia is present, but watch for circulatory overload.
- Consider using broad-spectrum IV antibiotics.
- Monitor urine output.
- If the child has a reduced level of consciousness or has a convulsion, particularly if they are an infant or young child, hypoglycaemia may be present. Always measure the blood glucose level in this situation. However, if blood glucose measurement is not possible, always treat as for presumed hypoglycaemia and, in addition to the IV fluids given above, give 5 mL/kg of 10% glucose IV or, if there is no IV access, by intra-osseous needle.

As shock is being treated, reassess the child's vital signs: alertness, pulse, respiratory rate etc. after each bolus and at least every 15–30 minutes until signs of shock are improving. Increased alertness, lower pulse and respiratory rate are encouraging signs, but the easiest and most sensitive to recognise is the degree of responsiveness.

### Children severely dehydrated with shock: rehydration phase

The best route for rehydration is the oral or nasogastric one, but in children who were sick enough to require rapid IV boluses, further IV fluid is likely to be needed initially.

At this stage, also, there is a need to again consider hypoglycaemia (which may have been identified earlier on stick testing). See below.

#### Fluid requirement for replacing in the rehydration phase

Fluid requirement falls into the three categories mentioned above:

- 1 Correction of deficit
  - Weigh the child again or estimate the weight as above
  - Re-assess the clinical signs of dehydration as shown in Table 5.12.A.2 and estimate the percentage of dehydration: fluid deficit in mL = weight in kg × % dehydrated × 10
  - e.g. a 6 kg child with a 5% dehydration will have 6 × 5 × 10 = 300 mL deficit.
- 2 Replacement of ongoing losses
  - For each diarrhoeal stool: < 2 years of age: give

50–100 mL or 10 mL/kg and ≥ 2 years of age: give 100–200 mL

- For each vomit: use 2 mL/kg ORS
- For nasogastric tube aspirates: replace volume for volume
- e.g. a 6 kg child of 7 months with 5 loose watery stools will need another 300 mL as replacement.

3 Maintenance fluids (see Table 5.12.A.5).

TABLE 5.12.A.5 IV maintenance fluids

Weight	Total fluid in 24 hours	Fluid/ hour
First 10 kg of body weight	100 mL/kg	4 mL/kg
Second 10 kg of body weight	50 mL/kg	2 mL/kg
Subsequent kg	20 mL/kg	1 mL/kg

The 6 kg child will need 600 mL in 24 hours for maintenance

Total fluid in 6 kg child with 5 loose watery stools who is 5% dehydrated is 300 + 300 + 600 mL = 1200 in 24 hours. The IV would be set to run at 50 mL/hr. initially. Adjustments to the volume will have to be made in the presence of further large watery stools or vomits or nasogastric aspirate. If available, a check on the plasma electrolytes is very useful at least daily to monitor response to treatment and to guide further therapy. Clinical observations should be done at least hourly and include looking for evidence of urine output.

#### Choice of IV fluid

As described before, a solution such as **Ringers's lactate or Hartman's** solution is preferable to Normal (0.9%) Saline as it contains less chloride and contains potassium which is vital in diarrhoea treatment. If N saline must be used, add 10 mmol of potassium chloride to each 500 mL bag **once urine has been passed**. If Ringers's lactate or Hartman's solution are being used, add 5 mmol to each 500 mL bag **once urine has been passed**.

There is an advantage in managing these children with a urinary catheter as urine volume measurement is a useful guide to fluid need in the absence of cardiac failure but its use must be weighed against the risk of infection.

There is always a possibility of hypoglycaemia as the child is not eating (see below) so for this reason, add glucose to the infusion fluid.

To make a 5% solution of dextrose in Ringers's lactate, Hartman's solution or N saline, remove 50 mL from the 500 mL bag and replace with 50 mL of 50% dextrose

To make a 10% solution of dextrose in Ringers's lactate, Hartman's solution or N saline, remove 100 mL from the 500 mL bag and replace with 100 mL of 50% dextrose.

Start the rehydration fluid regime, review the child's vital signs at least hourly, including assessing urine output and looking for signs of fluid overload, such as puffy face or limbs or increased breathlessness. Also review if there is any change reported by the mother. Once the child is regaining a degree of responsiveness and has a gag reflex, consider introducing oral or nasogastric (enteral) fluids to replace the IV route.

#### Re-introduction of enteral fluid

Re-assess the child's dehydration status by checking skin pinch, level of consciousness, and ability to drink, at least

every hour, in order to confirm that hydration is improving. Sunken eyes recover more slowly than other signs, and are less useful for monitoring.

As has been mentioned earlier, enteral fluid is the safest way to rehydrate the child. Enteral rehydration can be achieved when:

- The child is conscious enough to be fed by a nasogastric tube without aspiration i.e there is a gag reflex present OR
- The child is conscious enough to take sufficient fluid orally AND
- The child is not vomiting a significant volume of the fluid

The enteral rehydration fluid should be reduced osmolarity ORS (or ReSoMal if malnutrition is present). ORS should be introduced while the IV infusion is still running and the IV fluid volume reduced accordingly. Allow the child to breast feed whenever they want.

Once volumes approaching those required (see WHO Plan B in the Appendix to this section) are reached, the IV infusion can be discontinued and WHO Plan B rehydration continued alone.

All the WHO Plans for rehydration with details on prevention fluids, home fluids and advice for parents can be found in the Appendix to this section (see below).

### **Hypoglycaemia in diarrhoea (blood glucose < 2.5 mmol/L or < 45 mg/dL)**

If the child has a reduced level of consciousness or has a convulsion, particularly if they are an infant, hypoglycaemia may be present. Always measure the blood glucose level in this situation. However, if blood glucose measurement is not possible, always treat as for presumed hypoglycaemia. Give 2–5 mL/kg of 10% glucose IV or, if there is no IV access, by intra-osseous needle. If there is no circulatory access, while further attempts are made to access the circulation, any hypoglycaemia can be temporarily managed as below, if there are sufficient staff.

### **Sublingual sugar (sucrose) for treatment of hypoglycaemia**

- Sublingual sugar may be used as an immediate 'first-aid' measure for managing hypoglycaemia in an unconscious child in situations where IV administration of glucose may be impossible or delayed.
- Give 1 teaspoonful of sugar, moistened with 1–2 drops of water, under the tongue. More frequent repeated doses are needed to prevent relapse. Children should be monitored for early swallowing, which leads to delayed absorption, and in this case another dose of sugar should be given. If sublingual sugar is given, repeat doses at 20-minute intervals.
- Recheck the blood glucose concentration in 20 minutes, and if the level is low (< 2.5 mmol/litre or < 45 mg/dL) repeat the sublingual sugar.
- Clearly, once an IV or IO access has been established, glucose can be given into the circulation if necessary.

### **Electrolyte disturbances in dehydration from diarrhoeal illnesses**

Knowledge of the levels of serum electrolytes rarely changes the management of children with diarrhoea. Indeed, these values are often misinterpreted, leading to inappropriate

treatment. The disorders described below are usually adequately treated by oral rehydration therapy (ORT).

### **Hypernatraemia**

Some children with diarrhoea develop hypernatraemic dehydration, especially when given drinks that are hypertonic due to their sugar content (e.g. soft drinks, commercial fruit drinks) or salt. These draw water from the child's tissues and blood into the bowel, causing the concentration of sodium in extracellular fluid to rise. If the solute in the drink is not fully absorbed, the water remains in the bowel, causing osmotic diarrhoea.

Children with hypernatraemic dehydration (serum Na<sup>+</sup> > 150 mmol/litre) have thirst that is out of proportion to other signs of dehydration. Their most serious problem is convulsions, which usually occur when the serum sodium concentration exceeds 165 mmol/litre, and especially when intravenous therapy is given. Seizures are much less likely to occur when hypernatraemia is treated with ORS, which usually causes the serum Na<sup>+</sup> concentration to become normal within 24 hours.

**It is absolutely essential that intravenous rehydration does not lower the serum Na<sup>+</sup> too rapidly. Intravenous glucose solutions (5% glucose or 0.18% saline/4% glucose) are particularly dangerous and can result in cerebral oedema, which is usually fatal or permanently disabling.**

### **Hyponatraemia**

Children with diarrhoea who drink mostly water, or watery drinks that contain little salt, may develop hyponatraemia (serum Na<sup>+</sup> < 130 mmol/litre). Hyponatraemia is especially common in children with shigellosis and in severely malnourished children with oedema. It is occasionally associated with lethargy and (less often) with seizures. ORS is safe and effective therapy for nearly all children with hyponatraemia. An exception is children with oedema, for whom ORS may provide too much sodium. ReSoMal (see Section 5.10.B) may be helpful here.

### **Hypokalaemia**

Inadequate replacement of potassium losses during diarrhoea can lead to potassium depletion and hypokalaemia (serum K<sup>+</sup> < 3 mmol/litre), especially in children with malnutrition. This can cause muscle weakness, paralytic ileus, impaired kidney function and cardiac arrhythmias. Hypokalaemia is worsened when base (bicarbonate or lactate) is given to treat acidosis without simultaneously providing potassium. Hypokalaemia can be prevented, and the potassium deficit corrected, by using ORS for rehydration therapy and by giving foods rich in potassium during diarrhoea and after it has stopped (e.g. bananas, coconut water, dark green leafy vegetables).

It is also essential to check blood potassium levels, especially if the child has not passed urine, prior to replacing potassium IV, in order to avoid complications of hyperkalaemia secondary to pre-renal failure.

If it is necessary to give potassium intravenously (e.g. if serum K<sup>+</sup> is < 2.0 mmol/litre or there are ECG signs of hypokalaemia, namely ST depression, T-wave reduction and prominent U waves), great care must be taken. In acute depletion, an infusion at the rate of 0.2 mmol/kg/hour can be used and the serum K<sup>+</sup> level checked after 3 hours. The potassium for injection **must** be diluted before use and thoroughly mixed before being given. **The maximum**

concentration of potassium that can be given through a peripheral vein is 40 mmol/litre. The maximum infusion rate of potassium is 0.5 mmol/kg/hour. The recommended concentration is 20 mmol/litre.

**Note:** The injectable form of KCl usually contains 1.5 grams (i.e. 20 mmol of potassium in 10 mL), and can be given orally. The daily potassium requirement is 2.5–3.5 mmol/kg.

## Supportive treatments

### Dietary therapy

During diarrhoea, a decrease in food intake, lack of nutrient absorption and increased nutrient requirements combine to cause weight loss and failure to grow. In turn, malnutrition can make the diarrhoea more severe, more prolonged and more frequent, compared with diarrhoea in non-malnourished children. Therefore give nutrient-rich foods during the diarrhoea and when the child is recovering.

- Breastfed infants: continue feeding on demand.
- Bottle-fed infants: administer full-strength formulas immediately after rehydration (no longer than 4 hours). Lactose intolerance may develop and cause an exacerbation of diarrhoea with a lactose-containing formula. If this happens, temporarily reduce or remove lactose from the diet.
- Older children: continue their usual diet during diarrhoea. Recommended foods include starches, cereals, yoghurt, fruits and vegetables. Foods high in simple sugars and fats should be avoided. Excess fluid losses via vomiting or diarrhoea must be replaced with ORS (see above).

### Zinc treatment

Zinc is an important micronutrient which is lost in diarrhoeal illnesses. Replacement speeds recovery and reduces severity as well as reducing the frequency of diarrhoeal illnesses in the ensuing 2 to 3 months.

Dose under 6 months of age 10 mg (½ tablet) daily for 10–14 days; dose over 6 months of age 20 mg (1 tablet) daily for 10–14 days.

### Drug therapy: use of antimicrobial and ‘anti-diarrhoeal’ drugs

Antimicrobial drugs should not be used routinely. This is because, except as noted below, it is not possible to distinguish clinically episodes that might respond, such as diarrhoea caused by enterotoxigenic *E. coli*, from those caused by agents unresponsive to antimicrobials, such as rotavirus or *Cryptosporidium*. Moreover, even for potentially responsive infections, selecting an effective antimicrobial drug requires knowledge of the likely sensitivity of the causative agent, and such information is usually unavailable. In addition, use of antimicrobials adds to the cost of treatment, risks adverse reactions and enhances the development of resistant bacteria.

**Antimicrobial drugs are reliably helpful only for children with bloody diarrhoea (probable shigellosis), suspected cholera with severe dehydration, and serious non-intestinal bacterial infections such as pneumonia. Antiprotozoal drugs are rarely indicated except as described below when a definite diagnosis is available.**

## Antimicrobial drugs for acute diarrhoea

### Neonates

Diarrhoea and vomiting may be a symptom of septicaemia. If septicaemia is suspected, parenteral antibiotics are required (see Section 3.4).

### Bloody diarrhoea

- **Bacterial causes:** *Campylobacter jejuni*, *Shigella sonnei*, *Shigella flexneri* and *Shigella dysenteriae*, and less commonly *Salmonella*, *E. coli* O157:117 and *Aeromonas*.
- May be accompanied by abdominal pain and rectal prolapse.
- As culture facilities may not be available, sick toxic children with bloody diarrhoea should be treated for shigella dysentery.
- Children with diarrhoea and blood in stool (dysentery) should be treated with ciprofloxacin as first-line treatment and ceftriaxone as second-line treatment if they are severely ill and local antimicrobial sensitivity is not known. Where local antimicrobial sensitivity is known, local guidelines should be followed:
  - ciprofloxacin: 20 mg/kg/dose twice daily for 5 days
  - ceftriaxone: 80 mg/kg IV or IM once daily for 5 days.
- Mild infections due to *Shigella sonnei* are usually self-limiting. *Shigella* in resource-limited countries is commonly resistant to co-trimoxazole and ampicillin. Nalidixic acid, ciprofloxacin, ceftriaxone **or the antibiotic of choice for the area** should be used for a 5-day course.
- In infants and young children, exclude surgical causes (e.g. intussusception) (see Section 5.19).

### Salmonella

If non-typhoidal *Salmonella* is suspected in infants under 1 year of age or in immunocompromised children, blood cultures should be undertaken. If these are positive or the infant is toxic, an appropriate parenteral antibiotic should be given (e.g. chloramphenicol, ceftriaxone or ciprofloxacin) for 7–10 days. Be alert for pneumonia or metastatic abscesses in bone, brain or elsewhere. Otherwise *Salmonella* gastroenteritis is not treated with antibiotics.

**Systemic *Salmonella* infection is common in malnutrition, HIV infection, sickle-cell disease and schistosomiasis.**

*Campylobacter jejuni* (and also *Shigella* and *Salmonella*) may cause severe abdominal pain, mimicking a surgical emergency. Otherwise the disease is self-limiting and does not require antibiotics. If treatment is considered appropriate, erythromycin (12.5 mg/kg four times daily) for 5 days is the antibiotic of choice.

### Other causes of diarrhoea that warrant antimicrobial treatment

- **Amoebic dysentery:** this is diagnosed by microscopy of fresh warm stool. Treatment is with metronidazole 10 mg/kg three times daily (maximum dose 2 grams) for 5–7 days.
- **Cholera:** this is usually only diagnosed during epidemics. If the child has severe watery diarrhoea, suspect cholera or enterotoxigenic *E. coli* (only diagnosed by specialist laboratories). Treatment for cholera is with tetracycline 12.5 mg/kg four times a day for 3 days in children aged over 8 years. The alternative for young children is chloramphenicol 25 mg/kg 8-hourly for 3 days. In addition to rehydration, give an antibiotic to which local

strains of *Vibrio cholerae* are sensitive. These include tetracycline, doxycycline, co-trimoxazole, erythromycin and chloramphenicol.

- **Giardiasis:** this is diagnosed by microscopy of stool, and is usually self-limiting or asymptomatic. If symptomatic in a malnourished child or the disease is prolonged, it is justified to treat with metronidazole for 5 days (as for amoebic dysentery). Tinidazole is an alternative (50–75 mg/kg once only (maximum dose 2 grams), a second dose may be given if necessary).
- *Clostridium difficile* usually occurs after a course of antibiotics for some other illness, and is associated with antibiotic-associated pseudomembranous colitis (there is a danger of bowel perforation). Antibiotics, especially clindamycin, may alter the flora of the gastrointestinal tract and allow overgrowth of *C. difficile*. The latter produces a toxin which causes damage to the gut mucosa, resulting in pseudomembranous colitis. Confirmation is by culture of *C. difficile* in the faeces. Treatment is with oral vancomycin for 7–10 days, which clears *C. difficile* from the gut. The doses are orally:
  - **Child 1 month–5 years:** 5 mg/kg 4 times daily for 10–14 days (increased up to 10 mg/kg 4 times daily if infection fails to respond or is life threatening)
  - **Child 5–12 years:** 62.5 mg 4 times daily for 10–14 days (increased up to 250 mg 4 times daily if infection fails to respond or is life threatening)
  - **Child 12–18 years:** 125 mg 4 times daily for 10–14 days (increased up to 500 mg 4 times daily if infection fails to respond or is life threatening).

### Symptomatic drugs

**'Antidiarrhoeal' drugs and anti-emetics have no practical benefits for children with acute or persistent diarrhoea. They do not prevent dehydration or improve nutritional status, which should be the main objectives of treatment. Some, like loperamide, have dangerous and sometimes fatal side effects. These drugs should never be given to children under 5 years of age.**

### Treatment of rectal prolapse

Gently push back any tissue that has come out of the anus using a surgical glove or wet cloth, or if it is oedematous and cannot be reduced, warm compresses of magnesium sulphate may reduce the oedema.

### Haemolytic–uraemic syndrome

If laboratory tests are not available, suspect this syndrome when purpura, pallor, altered level of consciousness and low or absent urine output are present. If laboratory tests are available, blood smear shows fragmented red cells and decreased or absent platelets. There will be an increase in blood urea and creatinine levels (see Section 5.6.A).

## Appendix

### WHO Treatment Plan A: home therapy to prevent dehydration and malnutrition

Children with no signs of dehydration need extra fluids and salt to replace their losses of water and electrolytes due to diarrhoea. If these are not given, signs of dehydration may develop.

Mothers should be taught how to prevent dehydration at home by giving the child more fluid than usual, how to

prevent malnutrition by continuing to feed the child, and why these actions are important. They should also know what signs indicate that the child should be taken to a health worker. *These steps are summarised in the four rules of Treatment Plan A.*

### Rule 1: Give the child more fluids than usual, to prevent dehydration

#### What fluids to give

Many countries have designated recommended home fluids. *Wherever possible, these should include at least one fluid that normally contains salt* (see below). Plain clean water should also be given. Other fluids should be recommended that are frequently given to children in the area, that mothers consider acceptable for children with diarrhoea, and that mothers would be likely to give in increased amounts when advised to do so.

#### Suitable fluids

Most fluids that a child normally takes can be used. It is helpful to divide suitable fluids into two groups:

##### Fluids that normally contain salt, such as:

- ORS solution
  - salted drinks (e.g. salted rice water or a salted yoghurt drink)
  - vegetable or chicken soup with salt.
- Insert

Teaching mothers to add salt (about 3g/L) to an unsalted drink or soup during diarrhoea is also possible, but requires a sustained educational effort.

A home made solution containing 3g/L of table salt (one level teaspoon) and 18g/l of common sugar (sucrose) is effective but is not generally recommended because the recipe is often forgotten, the ingredients may not be available or too little may be given.

##### Fluids that do not contain salt, such as:

- plain water
- water in which a cereal has been cooked (e.g. unsalted rice water)
- unsalted soup
- yoghurt drinks without salt
- green coconut water
- weak tea (unsweetened)
- unsweetened fresh fruit juice.

#### Unsuitable fluids

A few fluids are potentially dangerous and should be avoided during diarrhoea. Especially important are drinks sweetened with sugar, which can cause osmotic diarrhoea and hypernatraemia. Some examples are:

- commercial carbonated beverages
- commercial fruit juices
- sweetened tea.

Other fluids to avoid are those with stimulant, diuretic or purgative effects, for example

- coffee
- some medicinal teas or infusions.

#### How much fluid to give

The general rule is: give as much fluid as the child or adult

wants until the diarrhoea stops. As a guide, after each loose stool, give:

- children under 2 years of age: 50–100 mL (a quarter to half a large cup) of fluid
- children aged 2 up to 10 years: 100–200 mL (a half to one large cup)
- older children and adults: as much fluid as they want. Insert

**Rule 2: Give supplemental zinc (10–20 mg) to the child every day for 10 to 14 days**

Zinc can be given as a syrup or as dispersible tablets, whichever formulation is available and affordable. By giving zinc as soon as diarrhoea starts, the duration and severity of the episode as well as the risk of dehydration will be reduced. By continuing zinc supplementation for 10–14 days, the zinc lost during diarrhoea is fully replaced and the risk of the child having new episodes of diarrhoea in the following 2 to 3 months is reduced.

**Rule 3: Continue to feed the child, to prevent malnutrition**

The infant's usual diet should be continued during diarrhoea and increased afterwards. Food should never be withheld, and the child's usual foods should not be diluted. Breastfeeding should always be continued. The aim is to give as much nutrient-rich food as the child will accept. Most children with watery diarrhoea regain their appetite after dehydration is corrected, whereas those with bloody diarrhoea often eat poorly until the illness resolves. These children should be encouraged to resume normal feeding as soon as possible.

When food is given, sufficient nutrients are usually absorbed to support continued growth and weight gain. Continued feeding also speeds the recovery of normal intestinal function, including the ability to digest and absorb various nutrients. In contrast, children whose food is restricted or diluted lose weight, have diarrhoea of longer duration, and recover intestinal function more slowly.

**What foods to give**

This depends on the child's age, food preferences and pre-illness feeding pattern; cultural practices are also important. In general, foods suitable for a child with diarrhoea are the same as those required by healthy children. Specific recommendations are given below.

**Milk**

- Infants of any age who are breastfed should be allowed to breastfeed as often and as long as they want. Infants will often breastfeed more than usual; this should be encouraged.
- Infants who are not breastfed should be given their usual milk feed (or formula) at least every three hours, if possible by cup. Special commercial formulas advertised for use in diarrhoea are expensive and unnecessary; they should not be given routinely. Clinically significant milk intolerance is rarely a problem.
- Infants below six months of age who take breast milk and other foods should receive increased breastfeeding. As the child recovers and the supply of breast milk increases, other foods should be decreased (if fluids other than breastmilk are given, use a cup, not a bottle).

This usually takes about 1 week. If possible, infants of this age should become **exclusively** breastfed.

There is no value in routinely testing the stools of infants for pH or reducing substances. Such tests are oversensitive, often indicating impaired absorption of lactose when it is not clinically important. It is more important to monitor the child's clinical response (i.e. weight gain, general improvement). Milk intolerance is only clinically important when milk feeding causes a prompt increase in stool volume and a return or worsening of the signs of dehydration, often with loss of weight.

**Other foods**

If the child is at least 6 months old or is already taking soft foods, he or she should be given cereals, vegetables and other foods, in addition to milk. If the child is over 6 months old and such foods are not yet being given, they should be started during the diarrhoea episode or soon after it stops.

Recommended foods should be culturally acceptable, readily available, have a high content of energy and provide adequate amounts of essential micronutrients. They should be well cooked, and mashed or ground to make them easy to digest; fermented foods are also easy to digest. Milk should be mixed with a cereal. If possible, 5–10 mL of vegetable oil should be added to each serving of cereal. (Most staple foods do not provide enough calories per unit weight for infants and young children. This is improved by adding some vegetable oil.) Meat, fish or egg should be given, if available. Foods rich in potassium, such as bananas, green coconut water and fresh fruit juice, are beneficial.

**How much food and how often**

Offer the child food every three or four hours (six times a day). Frequent small feedings are tolerated better than less frequent large ones.

After the diarrhoea stops, continue giving the same energy-rich foods and provide one more meal than usual each day for at least 2 weeks. If the child is malnourished, extra meals should be given until the child has regained normal weight for height.

**Rule 4: Take the child to a healthcare worker if there are signs of dehydration or other problems**

The mother should take her child to a healthcare worker if the child:

- starts to pass many watery stools
- has repeated vomiting
- becomes very thirsty
- is eating or drinking poorly
- develops a fever
- has blood in the stool
- does not get better in 3 days.

**WHO Treatment Plan B: oral rehydration therapy for children with some dehydration**

Children with some dehydration should receive oral rehydration therapy with ORS in a healthcare facility following the treatment plan described below.

Children with some dehydration should also receive zinc supplementation as described above.

**TABLE 5.12.A.6 Guidelines for treating children with some dehydration: approximate amount of ORS to give in the first 4 hours**

Age	< 4 months	4–11 months	12–23 months	2–4 years	5–14 years	15 years or older
Weight (kg)	< 5	5–7.9	8–10.9	11–15.9	16–29.9	30 kg or more
Volume (mL)	200–400	400–600	600–800	800–1200	1200–2200	2200–4000

**How much ORS is needed?**

Use Table 5.12.A.6 to estimate the amount of ORS needed for rehydration. If the child's weight is known, this should be used to determine the approximate amount of solution needed. The amount may also be estimated by multiplying the child's weight in kg by 75 mL. If the child's weight is not known, select the approximate amount according to the child's age.

The exact amount of solution required will depend on the child's dehydration status. Children with more marked signs of dehydration, or who continue to pass frequent watery stools, will require more solution than those with less marked signs or who are not passing frequent stools. *If the child wants more than the estimated amount of ORS, and there are no signs of over-hydration, give more.*

Oedematous (puffy) eyelids are a sign of *over-hydration*. They may be a sign of chronic malnutrition. If this occurs, stop giving ORS, but give breast milk or plain water, and food. Do not give a diuretic. When the oedema has gone, resume giving ORS or home fluids according to Treatment Plan A.

**How to give ORS**

A family member should be taught to prepare and give ORS. The solution should be given to infants and young children using a clean spoon or cup. Feeding bottles should *not* be used. For babies, a dropper or syringe (without the needle) can be used to put small amounts of solution into the mouth.

Children under 2 years of age should be offered a tea-spoonful every 1 to 2 minutes. Older children (and adults) may take frequent sips directly from the cup.

Vomiting often occurs during the first hour or two of treatment, especially when children drink the solution too quickly, but this rarely prevents successful oral rehydration, as most of the fluid is absorbed. After this time vomiting usually stops. If the child vomits, wait 5–10 minutes and then start giving ORS again, but more slowly (e.g. a spoonful every 2–3 minutes).

**Monitoring the progress of oral rehydration therapy**

Check the child from time to time during rehydration to ensure that ORS is being taken satisfactorily and that signs of dehydration are not worsening. If at any time the child develops signs of severe dehydration, switch to WHO Treatment Plan C.

**After 4 hours**, reassess the child fully, following the guidelines in Table 5.12.A.2. Then decide what treatment to give next:

- If signs of *severe dehydration* have appeared, intravenous (IV) therapy should be started following Treatment Plan C. This is very unusual, however, occurring only in children who drink ORS poorly and pass large watery stools frequently during the rehydration period.
- If the child still has signs indicating *some dehydration*, continue oral rehydration therapy by repeating Treatment Plan B. At the same time start to offer food, milk and

other fluids, as described in Treatment Plan A (see above), and continue to reassess the child frequently.

If there are *no signs of dehydration*, the child should be considered fully rehydrated. When rehydration is complete:

- the skin pinch is normal
- thirst has subsided
- urine is passed
- the child becomes quiet, is no longer irritable and often falls asleep.

Teach the mother how to treat her child at home with ORS and food following Treatment Plan A. Give the mother enough ORS sachets for 2 days. Also teach her the signs that mean she should bring her child back.

- Use the patient's age only when you do not know their weight. The approximate amount of ORS required (in mL) can also be calculated by multiplying the patient's weight in kg by 75.
- If the patient wants more ORS than is shown above, give more.
- Encourage the mother to continue breastfeeding her child.
- For infants under 6 months who are not breast fed, if using the old WHO ORS solution containing 90 mmol/L of sodium also give 100–200 mL clean water during this period. However, if using the new reduced (low) osmolality ORS solution containing 75 mmol/L of sodium, this is not necessary.

**Note:** During the initial stages of therapy, while still dehydrated, adults can consume up to 750 mL per hour, if necessary, and children up to 20 mL/kg body weight/hour.

**Meeting normal fluid needs**

While treatment to replace the existing water and electrolyte deficit is in progress, the child's normal daily fluid requirements must also be met. This can be done as follows:

- **Breastfed infants:** continue to breastfeed as often and for as long as the infant wants, even *during* oral rehydration.
- **Non-breastfed infants** under 6 months of age: if using the old WHO ORS solution containing 90 mmol/L of sodium also give 100–200 mLs clean water during this period. However, if using the new reduced (low) osmolality ORS solution containing 75 mmol/L of sodium, this is not necessary.
- **Older children:** throughout rehydration and maintenance therapy, offer as much plain boiled water to drink as they wish, in addition to ORS.

**If oral rehydration therapy must be interrupted**

If the mother and child must leave hospital before rehydration with ORS is completed:

- Show the mother how much ORS solution to give to finish the 4-hour treatment at home.

- Give her enough ORS packets to complete the 4-hour treatment and to continue oral rehydration for two more days, as shown in Treatment Plan A.
- Show her how to prepare ORS solution.
- Teach her the four rules in Treatment Plan A for treating her child at home.

### When oral rehydration fails

With the previous ORS, signs of dehydration would persist or reappear in about 5% of children. With the new reduced (low) osmolality ORS it is estimated that such treatment 'failures' will be reduced to 3% or less. The usual causes for these 'failures' are:

- continuing rapid stool loss (more than 15–20 mL/kg/hour), as occurs in some children with cholera
- insufficient intake of ORS due to fatigue or lethargy
- frequent severe vomiting.

Such children should be given ORS by nasogastric (NG) tube or Ringer Lactate Solution intravenously (IV) (75 mLs/kg in four hours) usually in hospital. After confirming that the signs of dehydration have improved, it is usually possible to resume ORT successfully.

### Rarely, oral rehydration therapy should not be given. This is true for children with:

- abdominal distension with paralytic ileus, usually caused by opiate drugs (e.g. codeine, loperamide) and hypokalaemia
- glucose malabsorption (indicated by a marked increase in stool output, failure of the signs of dehydration to improve, and a large amount of glucose in the stool).

In these situations, rehydration should be given IV until the diarrhoea subsides; nasogastric therapy should *not* be used.

### Giving zinc

Begin to give supplemental zinc, as in Treatment plan A, as soon as the child is able to eat, following the four hour rehydration period.

### Giving food

Except for breast milk, food should not be given during the initial 4-hour rehydration period. However, children who are continued on Treatment Plan B for longer than 4 hours should be given some food every 3–4 hours as described in Treatment Plan A. All children older than 6 months of age should be given some food before being sent home. This helps to emphasise to mothers the importance of continued feeding during diarrhoea.

### WHO Treatment Plan C: intravenous rehydration therapy for patients with severe dehydration

The preferred treatment for children with severe dehydration is initial rapid intravenous rehydration following Treatment Plan C. If possible, the child should be admitted to hospital. Guidelines for IV rehydration are given in Table 5.12.A.7.

Children who can drink, even poorly, should be given ORS by mouth until the IV drip is running. In addition, all children should receive some ORS solution (about 5 mL/kg/hr) when they can drink without difficulty, which is usually within 3–4 hours for infants and 1–2 hours for older patients.

This provides additional base and potassium which may not be adequately supplied by the IV fluid.

### Monitoring the progress of intravenous rehydration

Patients should be reassessed every 15–30 minutes until a strong radial pulse is present. If it is not, the intravenous drip should be given more rapidly.

When the planned amount of intravenous fluid has been given (after 3 hours for older patients, or 6 hours for infants), the child's hydration status should be reassessed fully as in Table 5.12.A.2.

Look and feel for all the signs of dehydration

- If signs of severe dehydration are still present, **repeat** the intravenous fluid infusion as outlined in Treatment Plan C. This is very unusual, however, occurring only in children who pass large watery stools frequently during the rehydration period.
- If the child is improving (able to drink) but still shows signs of *some dehydration*, **discontinue** the intravenous infusion and give ORS for 4 hours, as specified in Treatment Plan B.
- If there are *no signs of dehydration*, follow Treatment Plan A. If possible, observe the child for at least six hours before discharge while the mother gives the child ORS, to confirm that she is able to maintain the child's hydration. Remember that the child will require therapy with ORS until the diarrhoea stops.

If the child cannot remain at the treatment centre, teach the mother how to give treatment at home following Treatment Plan A, give her enough ORS packets for two days and teach her the signs that mean she should bring her child back.

### What to do if intravenous therapy is not available

- If IV therapy is not available at the facility, but can be given nearby (i.e. within 30 minutes), send the child immediately for intravenous treatment. If the child can drink, give the mother some ORS and show her how to give it to her child during the journey.
- If IV therapy is not available nearby, healthcare workers who have been trained can give ORS by NG tube, at a rate of 20 mL/kg body weight per hour for 6 hours (total of 120 mL/kg body weight). If the abdomen becomes

**TABLE 5.12.A.7 Guidelines for intravenous treatment of children with severe dehydration**

Start IV fluids immediately. If the patient can drink give ORS by mouth until the drip is set up. Give 100 mLs/kg of Ringers Lactate Solution <sup>a</sup> divided as follows		
Age	First give 30 mL/kg in:	Then give 70 mL/kg in:
Infants under 12 months	1 hour <sup>b</sup>	5 hours
Older	30 minutes <sup>b</sup>	Over 2.5 hours

Reassess the patient every 1–2 hours. If hydration is not improving, give the IV drip more rapidly. After six hours (infants) or three hours (older patients), evaluate the patient using the assessment chart. Then choose the appropriate Treatment Plan (A, B or C) to continue treatment

- If Ringers Lactate Solution is not available, normal saline may be used
- Repeat once if radial pulse is still very weak or not detectable

swollen, ORS should be given more slowly until the abdomen becomes less distended.

- If NG treatment is not possible but the child can drink, ORS should be given by mouth at a rate of 20mL/kg body weight per hour for 6 hours (total of 120mL/kg body weight). If this rate is too fast, the child may vomit repeatedly. In this case, give ORS more slowly until the vomiting subsides.
- Children receiving NG or oral therapy should be reassessed at least every hour. If the signs of dehydration do not improve after 3 hours, the child must be taken immediately to the nearest facility where intravenous therapy is available. Otherwise, if rehydration is progressing satisfactorily, the child should be reassessed after

6 hours and a decision on further treatment made as described above for those given IV therapy.

- If neither NG nor oral therapy is possible, the child should be taken *immediately* to the nearest facility where IV or NG therapy is available.

## 5.12.B Post-infectious prolonged or persistent diarrhoea

### BOX 5.12.B.1 Minimum standards

- Low-osmolality ORS and ReSoMal in severely malnourished children.
- Ringer-lactate or Hartmann's solution with potassium: oral and IV.
- Antibiotics: amoxicillin, gentamicin.
- Vitamin A and zinc.
- Electrolyte and mineral mix.
- Folic acid.

### Introduction

#### Epidemiology

- Diarrhoeal episodes that start acutely and last for 7–14 days are usually labelled as prolonged diarrhoea, and may be associated with greater morbidity and more severe nutritional consequences.
- Persistent diarrhoea is commonly defined as diarrhoea that starts acutely, but lasts for more than 14 days and is associated with growth faltering.
- Most cases are thus post-infectious in origin, and other disorders such as inflammatory bowel disease and coeliac disease are therefore excluded.
- Around 4–20% of all episodes of diarrhoea in resource-limited countries become prolonged, with associated case-fatality rates that may exceed 50% in severe cases.
- In parts of sub-Saharan Africa, the association of persistent diarrhoea with HIV infection is often the terminal event.

#### Risk factors for prolonged and persistent diarrhoea

Appropriate case management of acute diarrhoea is key to the prevention of prolonged episodes.

**Specific pathogens:** although some studies have identified an association between persistent diarrhoea and infections with organisms such as entero-aggregative *E. coli* or *Cryptosporidium*, this is by no means pathognomonic, nor is there a particular pattern of small bowel microbial colonisation or overgrowth seen in most cases. In HIV-endemic parts of Africa an association of persistent diarrhoea with cryptosporidiosis is well recognised, but may

represent a manifestation of immunodeficiency. Evidence from Bangladesh does suggest that recurrent bouts of infection with bacterial pathogens such as *Shigella* lead to prolongation of the duration of successive diarrhoeal episodes, and thus there is a link between prolonged and persistent diarrhoea as an epidemiological continuum.

**Malnutrition:** persistent diarrhoea is commonly seen in association with significant malnutrition, and the relationship may be bidirectional. It is widely recognised that diarrhoeal episodes, especially if invasive, may become prolonged in malnourished children. The recent evidence of micronutrient deficiencies, especially of zinc and vitamin A in malnourished children with persistent diarrhoea, may indicate impaired immunological mechanisms for clearing infections, as well as ineffective mucosal repair mechanisms.

**Dietary risk factors:** although many children with persistent diarrhoea are lactose-intolerant, there is no role of specific dietary allergies in inducing and perpetuating enteropathy of malnutrition or post-infectious prolonged diarrhoea. Several studies have highlighted the high risk of prolonged diarrhoea with lactation failure and early introduction of artificial feeds in resource-limited countries.

**Inappropriate management of acute diarrhoea:** the association of prolongation of diarrhoea with food deprivation and inappropriately prolonged administration of parenteral fluids is well recognised. Unnecessary food withdrawal, and replacement of luminal nutrients, especially breast milk, with non-nutritive agents is prolonging the mucosal injury after diarrhoea. In particular, blanket administration of antibiotics and **any administration of antimotility agents must be avoided**. Optimal management of acute diarrhoea episodes with ORS, zinc and appropriate diets is a key factor in reducing the risk of recurrence and prolongation of diarrhoeal episodes.

### Principles of management of persistent diarrhoea

In general, the management of persistent diarrhoea in malnourished children (see Figure 5.12.B.1) represents a blend of the principles of management of acute diarrhoea and malnutrition (see Section 5.12.A and Section 5.10.B).

Associated malnutrition may be quite severe in affected children, necessitating appropriate and rapid nutritional rehabilitation, sometimes in hospital. Given the chronicity of the disorder, prolonged hospitalisation may be quite problematic in resource-limited countries, and whenever possible the importance of ambulatory or home-based therapy must be emphasised.

The following represent the basic principles of management of persistent diarrhoea, and a suggested therapeutic approach is shown in Figure 5.12.B.1.

#### Rapid resuscitation and stabilisation

- Most children with persistent diarrhoea and associated malnutrition are not severely dehydrated, and oral rehydration is adequate.
- However, acute exacerbations and associated vomiting may require brief periods of intravenous rehydration with Ringer-lactate solution.
- Acute electrolyte imbalance such as hypokalaemia and severe acidosis may require correction (see Section 5.6.A).
- Associated systemic infections (bacteraemia, pneumonia and urinary tract infections) are well recognised in severely malnourished children with persistent diarrhoea, and are a frequent cause of early mortality. These must be screened for at admission. In severely ill children requiring hospitalisation, it may be best to cover with

intravenous antibiotics at admission (usually ampicillin, IV 25 mg/kg three times daily up to a maximum of 4 grams/day, and gentamicin, IV 7.5 mg/kg once daily) while awaiting cultures. In other instances with suspected severe pneumonia, oral amoxicillin will suffice.

- It should be emphasised that there is little role for oral antibiotics in persistent diarrhoea, as in most cases the original bacterial infection that triggered the prolonged diarrhoea has disappeared by the time the child presents.

#### Oral rehydration therapy

This is the preferred mode of rehydration and replacement of ongoing losses. Although in general the standard low-osmolality WHO oral rehydration solution (containing 75 mmol/litre of Na<sup>+</sup>) is adequate, some evidence indicates that the hypo-osmolar rehydration fluid ReSoMal (containing 45 mmol/litre of Na<sup>+</sup>) as well as cereal-based oral rehydration fluids may be advantageous in severely malnourished children. In general, replacing each stool with about 50–100 mL of ORS or ReSoMal is safe.

#### Enteral feeding and diet selection

- Most children with persistent diarrhoea are not lactose intolerant, although administration of a lactose load exceeding 5 grams/kg/day is associated with higher rates of stooling and treatment failure. In general,

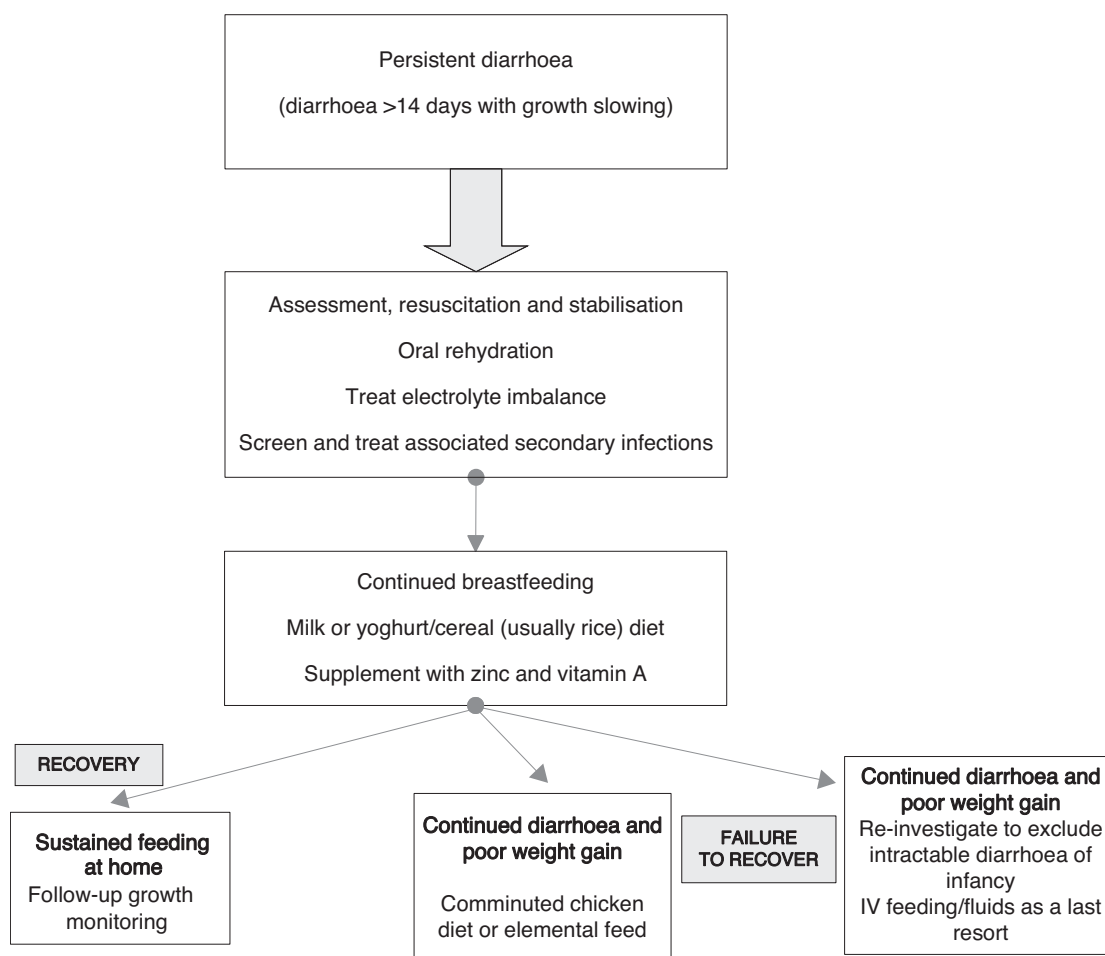

FIGURE 5.12.B.1 Management of persistent diarrhoea in malnourished children.

therefore, withdrawal of milk and replacement with specialised (and expensive) lactose-free formulations is unnecessary.

- Alternative strategies for reducing the lactose load in malnourished children with persistent diarrhoea include reducing the overall amount of milk intake, addition of lactose-free milk to cereals, and replacement of milk with fermented milk products such as yoghurt. These measures have now been extensively evaluated in successive studies of the management of persistent diarrhoea in South Asia, and found to be extremely effective.
- It is rare to find persistent diarrhoea in breastfed infants, and **it must be emphasised that breastfeeding must not be stopped under any circumstances.**
- Rarely, when dietary intolerance precludes the administration of cow's-milk-based formulations or milk, it may be necessary to administer specialised milk-free diets such as a comminuted or blenderised chicken-based diet or an elemental formulation. However, the latter may be almost unaffordable in most resource-limited countries. A choice of enteral diets and formulations is given in Table 5.12.B.2. It must be emphasised that this

is extremely rare, and most infants will recover with the approach outlined above.

- The usual energy density of any diet used for the therapy of persistent diarrhoea should be around 1 kcal/gram, aiming to provide an energy intake of at least 110 kcal/kg/day and a protein intake of 2–3 grams/kg/day (in meals given six times daily). Nasogastric feeding may be required during the first 2–3 days of care, particularly while infection is being treated.
- There should be at least 3 successive days of increasing weight before a response can be verified.
- Dietary failure is shown by an increase in stool frequency (> 10 watery stools/day) or a failure to establish a daily weight gain within 7 days.
- In selected circumstances when adequate intake of energy-dense food is problematic, the addition of amylase to the diet through germination techniques which increase the endogenous amylase content of foods may be helpful. The ready-to-use therapeutic foods (RUTFs) can be used in moderate amounts in children with severe malnutrition and persistent diarrhoea, and the diets below also offer a suitable alternative.

**TABLE 5.12.B.2 Suggested composition of selected diets in children with persistent diarrhoea**

Component	Khitchri (rice-lentils) (per 100 grams)	Home made version of F-75 diet (WHO) (per 1000 mL)	Comminuted chicken (per 100 grams)	Semi-elemental diet (per 100 mL)
Protein	Mung lentils, 30 grams	Dried skimmed milk, 25 grams	Protein, 8 grams	Protein, 2.25 grams (hydrolysed)
Fat	Oil, 2 grams	Vegetable oil, 27 grams	Fat, 4 grams	Fat, 1.65 grams (medium-chain triglycerides)
Minerals and micronutrients	Salt (to taste)	Vitamin mix, 140 mg Mineral mix, 20 mL	Electrolytes (sodium, 0.4 mmol; potassium, 1.3 mmol; calcium, 0.2 mmol; phosphorus, 1.5 mmol)	Electrolytes (sodium, 1.9 mmol; potassium, 2.3 mmol; calcium, 1.8 mmol)
Carbohydrate	Rice, 60 grams	Cereal flour, 35 grams Sugar, 70 grams		Caloreen, 5 grams

#### **First diet: a starch-based reduced milk concentration (low-lactose) diet**

The diet should contain at least 70 kcal/100 grams, provide milk or yoghurt as a source of animal protein, but no more than 3.7 grams of lactose/kg body weight/day, and should provide at least 10% of calories as protein. The following example provides 83 kcal/100 grams, 3.7 grams of lactose/kg body weight/day and 11% of calories as protein:

- full-fat dried milk: 11 grams (or whole liquid milk: 85 mL)
- rice: 15 grams
- vegetable oil: 3.5 grams
- cane sugar: 3 grams
- water to make up to 200 mL.

Of the children who do not improve on this first diet, more than 50% will improve when given the second diet, from which the milk has been totally removed and starch (cereals) partly replaced with glucose or sucrose.

#### **Second diet: a no-milk (lactose-free) diet with reduced cereal (starch)**

The second diet should contain at least 70 kcal/100 grams, and provide at least 10% of calories as protein (egg or chicken). The following example provides 75 kcal/100 grams:

- whole egg: 64 grams

- rice: 3 grams
- vegetable oil: 4 grams
- glucose: 3 grams
- water to make up to 200 mL.

Finely ground, cooked chicken (12 grams) can be used in place of egg to give a diet that provides 70 kcal/100 grams.

Of the children who do not improve on the first diet, more than 50% will improve when given the second diet, from which milk has been totally removed and starch (cereals) partly replaced with glucose or sucrose.

#### **Micronutrient supplementation**

Most malnourished children with persistent diarrhoea have associated deficiencies of micronutrients, including zinc, iron and vitamin A. This may be a consequence of poor intake and continued enteral losses. It is therefore important to ensure that all children with persistent diarrhoea and malnutrition receive an initial dose of vitamin A orally, or if that is not possible by deep intramuscular injection (< 6 months of age, 50 000 units; 6–12 months, 100 000 units; > 1 year, 200 000 units). They should also receive a daily intake of the following for the next 2 weeks:

- a multivitamin supplement

- folic acid, 250 micrograms/kg on day 1, then 75 micrograms/kg/day
- zinc, 3–5 mg/kg/day.
- copper, 0.3 mg/kg/day
- magnesium, 0.2 mmol/kg/day.

Although the association of significant anaemia with persistent diarrhoea is well recognised, iron replacement therapy should not be initiated until recovery from diarrhoea has started (ferrous sulphate 18 mg/kg/day, or 6 mg/kg/day of elemental iron in two divided doses).

### Follow-up and nutritional rehabilitation

Given the high rates of relapse in most children with persistent diarrhoea, it is important to address the underlying risk factors and institute preventive measures. These include appropriate feeding (breastfeeding, complementary feeding) and close attention to environmental hygiene and sanitation. This poses a considerable challenge in communities deprived of basic necessities such as clean water and sewage disposal.

By the time they return home, children should be receiving a diet that provides at least 110 kcal/kg/day (including milk and fresh fruit and well-cooked vegetables).

## 5.12.C Constipation

### BOX 5.12.C.1 Minimum standards

- Movicol – osmotic laxative – softens
- Lactulose – osmotic laxative – softens
- Docusate sodium – softener and weak stimulant
- Senna or sodium picosulphate-stimulant laxative
- Glycerine suppositories – lubricant and rectal stimulant
- Small volume of phosphate enema (e.g. fleet enema)
- Sodium citrate enema (e.g. Micralax enema).

### Introduction

#### Definition

Constipation is defined as difficulty with, delay in or pain on defecation.

#### Normal defecation patterns

- Breastfed babies average three stools per day and formula-fed babies two stools per day. However, the range of normal stool frequency in breastfed babies is very wide, from one stool every few days to a stool with every feed.
- Children average one stool per day after 3 years, but the normal range is from once on alternate days to three times daily.

#### Pathophysiology

Most children with constipation have no underlying medical cause. An episode of constipation can be triggered by inadequate food or fluid intake, an intercurrent illness, or excessive intake of cow's milk.

#### Constipation cycle

The child passes a hard painful stool. On subsequent

occasions they try to withhold the stool in order to avoid experiencing pain (faecal holding). The stool remains in the rectum, becoming harder still, and so causing even more pain when it is eventually passed.

If this cycle is allowed to continue, eventually the rectum may become enlarged, resulting in a 'megarectum'. The child by this stage has lost the normal urge to defecate, and the large rectal mass of stool holds open the anal sphincter, which leads to soiling with liquid faeces. This is involuntary and should not be confused with encopresis, which occurs when the child voluntarily passes normal stools in unacceptable places.

### Diagnosis

Diagnosis can usually be made by taking a good history.

- On examination of the abdomen, faecal masses may be palpable. These are often in the left and right iliac fossae, but sometimes suprapubically. On inspection of the anus, anal tags and fissure may be seen in chronic constipation.
- On rectal examination, hard impacted faeces may be felt. Rectal examination is usually not necessary. If there is an anal fissure, rectal examination should be done with topical lignocaine jelly (1%) and terminated if it is too painful.
- Abdominal X-ray is not a useful examination for diagnosis of constipation.

### Pathological causes

The vast majority of constipation is idiopathic, but there are a few uncommon causes that are important not to miss.

### Hirschsprung's disease

Suspect this when there is infancy-onset constipation and a delay of more than 48 hours in passing meconium at birth. In more advanced cases there will be abdominal distension and sometimes failure to thrive and vomiting. There may be alternating constipation and diarrhoea and surprisingly little soiling for the degree of constipation. On rectal examination an explosive gush of faeces occurs when the examining finger is withdrawn.

### Anal lesions that cause pain or create an obstruction

These include anal fissures, perianal skin infections and (rarely) congenital anterior anus and anal stenosis. One cause of painful anal lesions is sexual abuse, a rare but important cause which should not be missed.

### Endocrine conditions

Hypothyroidism, renal tubular acidosis, diabetes insipidus and hypercalcaemia can be associated with constipation. There should be a high level of suspicion for a metabolic or endocrine cause if constipation and failure to thrive coexist.

### Neurogenic constipation

Spinal cord lesions involving sensation in the rectum will cause neurogenic constipation. These can be excluded by a normal neurological and spinal examination.

### Management of idiopathic constipation

Parental understanding of the aetiology and sequence of events in developing chronic constipation is crucial to successful physical and psychological management (see Figure 5.12.C.1). Each and every element of this flow diagram should be addressed and treated if management is to be completely successful.

### Explanation

A careful and thorough explanation of the problem should be given to the parent and child. Emphasise that soiling

is not deliberate, and that the child needs support, not condemnation. Assess the need for psychological as well as physical treatment.

### Evacuation of hard impacted faeces

- 1 To soften and lubricate the retained faeces, initially give a softener. This could be a macrogol such as Movicol or another softening laxative such as docusate sodium. The dose will vary according to age.
- 2 Alongside the softener, in order to expel the retained mass, give a stimulant laxative (e.g. sodium picosulphate).
- 3 If sodium picosulphate is not available, a large dose of senna can be tried, but may need to be used for longer.
- 4 Only if the above fails give suppositories (glycerine) once daily (infant, 1 gram; child < 12 years, 2 grams; child > 12 years, 4 grams).
- 5 If the oral and suppository methods are unsuccessful, if excessive abdominal pain develops and/or there is vomiting, stimulant enemas will be required. Phosphate enemas should not be used in children under 2 years of age. For children aged 2–10 years give 60 mL (half a phosphate enema) and for those over 10 years of age give 120 mL (full enema). If phosphate enemas are not available, a small-volume sodium citrate enema (micro-enema) can be used. However, the use of enemas can add to the child's fear of defecation. **The child should never be forcibly held down to receive an enema.** Give enemas **once a day** in the morning. Most children need two or three enemas to clear a faecal mass.
- 6 If these measures fail, the child should undergo manual evacuation of faecal mass under general anaesthetic, **but only if this is available and can be done safely.**

### Maintenance laxatives to keep the stool soft, defecation pain-free and overcome faecal holding

- Softening agents such as Movicol or docusate sodium to keep the stool soft.
- Stimulant laxatives, usually senna or sodium picosulphate, to expel the soft stool. The aim is to produce

FIGURE 5.12.C.1 Sequence of events in faecal soiling.

loose stools initially and then subsequently reduce the dose to produce at least one soft stool per day. Often large doses will be required initially to overcome the child's faecal holding.

#### Behaviour changes

- Encourage increased fluid intake and a high-roughage diet (fruit, vegetables and cereals).
- Give positive praise and encouragement for regular toileting, and for passage of stool into the toilet.

#### Length of treatment

Children are likely to require several months of stimulant laxatives until their fear of defecation resolves, and often months to years of continuous or intermittent treatment with softening laxatives. A general rule of thumb is that the child will need laxatives for the same length of time that they were constipated before treatment started.

## 5.12.D Inflammatory bowel disease

### BOX 5.12.D.1 Minimum standards

- Aminosalicylates.
- Prednisolone.
- Methylprednisolone.
- Corticosteroid enemas.
- Blood transfusion.
- Polymeric diet.
- Metronidazole.

### Introduction

Inflammatory bowel disease (IBD) is uncommon in children in resource-limited countries, where abdominal tuberculosis is more common. However, in the UK about 18% of children with IBD are non-white, of whom most are of either Indian or Caribbean origin. Although IBD may present in younger children, the mean age in the UK is approximately 12 years. Crohn's disease is more than twice as common as ulcerative colitis. A family history is common.

### Diagnosis

- Clinical symptoms of ulcerative colitis are almost invariably bloody diarrhoea with predefecation abdominal pain and tenesmus. Crohn's disease may have a wide variety of symptoms, especially extra-intestinal ones. Iron-deficiency anaemia is common in both.

- The interval between onset of symptoms and diagnosis is often over 6 months in Crohn's disease, and may be 2–3 months in ulcerative colitis. Denial of symptoms is common, especially in adolescents.

### Investigations

- Growth parameters and investigations are a guide to the severity and duration of disease and the nutritional state of the child.
- Examination of the mouth and anus is essential.
- Stool examination is essential to exclude bacterial and parasitological causes of diarrhoea, especially before corticosteroids are prescribed.
- Normal investigations: acute-phase reactants (erythrocyte sedimentation rate or C-reactive protein), haemoglobin, platelet count, albumin; do not exclude ulcerative colitis, but normal blood tests would be very unusual in Crohn's disease.
- Children with ulcerative colitis often have little or no weight loss or growth failure.
- Children with Crohn's disease and severe involvement of the colon may present similarly to those with ulcerative colitis, but generally have larger haematological changes.

TABLE 5.12.D.1 Comparison between Crohn's disease and ulcerative colitis

Feature	Ulcerative colitis	Crohn's disease
Pathology	Mucosal disease	Transmural disease, skin lesions, strictures, fistulae
Site	Recto-colonic (rectum always involved). In children over 70% have a pancolitis	Panenteric disease is common in children: small bowel and colon, 50%; colon, 35%; ileum, 6%; upper gastrointestinal tract, 50%
Common presenting symptoms	Diarrhoea mixed with blood/mucus Pain (lower abdominal) Often no or little weight loss	Pain in the right iliac fossa Diarrhoea with or without blood Growth failure and weight loss Peri-anal and oral disease
Extra-intestinal features (finger clubbing, arthritis, skin disorders, fever)	Uncommon	Common

### General investigations

#### Stool

- Blood, mucus.

- Microscopy for *Entamoeba histolytica*, *Schistosoma*, *Trichuris trichiura*, *Giardia lamblia*.
- Culture for bacteria.

**Full blood count**

- Haemoglobin level decreased.
- White blood cell count increased.
- Platelet count increased.

**Acute-phase reactants**

- Erythrocyte sedimentation rate raised.
- C-reactive protein raised.

**Chemical pathology**

- Electrolytes (if diarrhoea severe).
- Ferritin (may be spuriously raised – acute-phase reactant).
- Albumin level low.

**Specific investigations**

Specific investigations depend on the availability of paediatric gastrointestinal facilities.

- Sigmoidoscopy is essential.
- Flexible endoscopy of the lower and upper gastrointestinal tract should ideally be undertaken.
- Barium enema (double contrast) is required in colitis **only** if colonoscopy is not available.
- Normal macroscopic appearance of the lower or upper gut **does not exclude IBD. Histology is essential.**
- 'Indeterminate colitis' is a term used to describe patients whose histology is not typical of ulcerative colitis or Crohn's disease. They are usually treated initially as having ulcerative colitis.

**TABLE 5.12.D.2 Specific investigations for Crohn's disease and ulcerative colitis**

Feature	Ulcerative colitis	Crohn's disease
Endoscopy*	Proctoscopy Sigmoidoscopy Colonoscopy	Lower gut Upper gut*
Radiological studies	Barium enema† (double contrast)	Barium meal and follow-through
White blood cell scan (technetium labelled)‡	Screening	Screening

\* Depending on availability.

† Only required if colonoscopy is unavailable.

‡ Only available in well-resourced countries.

**Management of ulcerative colitis**

- Initial management depends on severity.
- Follow-up: parents and older children should be taught so that they understand how to recognise and treat any relapse promptly.

**Management of active colitis (see Table 5.12.D.3)**

- **Mild disease:** less than four motions per day, intermittent blood, normal acute-phase reactants, no toxicity:
  - Aminosalicylates.
  - Mesalazine (1 g rectally) or corticosteroid (20 mg) enema until the bleeding stops, and then given alternate nights for 1 week.

– Corticosteroids given orally if there is no response within 2 weeks.

- **Moderate disease:** four to six motions per day, moderate blood, slight toxicity, anaemia and raised acute-phase reactants:

– As above plus oral steroids immediately. If there is a poor response, treat as for severe disease.

- **Severe disease:** more than six bloody motions per day, nocturnal stools, toxicity, fever, anaemia and hypoalbuminaemia:

– Intravenous pulse methylprednisolone or hydrocortisone dose for 3–5 days.

– Antibiotics (e.g. metronidazole) (benefit is not proven).

– Intravenous fluids and correction of electrolyte deficits.

– Blood transfusion if required.

– Intravenous cyclosporine (500 micrograms–1 mg/kg aged 3–18 years) or oral cyclosporine (2 mg/kg twice daily maximum 5 mg/kg aged 2–18 years) may be of value if there is no response to intravenous corticosteroids.

- **Toxic dilation:** if there is no response to intensive therapy by 12–24 hours, perform colectomy.

**Relapse**

Prompt commencement of rectal mesalazine or a corticosteroid enema is essential. If there is no response, give a course of oral corticosteroids.

**Maintenance**

- Aminosalicylic acid preparations are generally given life-long. Mesalazine 10 mg/kg 2–3 times daily 5–12 years, 2G once daily 12–18 years.
- If relapses occur when corticosteroids are reduced, give azathioprine for up to 3–5 years.

**TABLE 5.12.D.3 Drug dosages for ulcerative colitis**

<i>Corticosteroids</i>	
Prednisolone:	2 mg/kg/day (maximum 40 mg) for 3 weeks, then reduce by 5 mg/week
Methylprednisolone:	IV 1–1.5 mg/kg/day (maximum 60 mg)
Hydrocortisone:	IV 4 mg/kg 6-hourly
Prednisolone enema or foam (20 mg in 100 mL):	50–100 mL at night
<i>Aminosalicylates</i>	
Sulphasalazine: (tablets 10 mg and 50 mg)	10 mg/kg 4- to 6-hourly for acute episodes. Decrease the dose by half for maintenance as soon as possible. Urine and tears will turn orange. Report sore throat
Mesalazine: (oral tablets 500 mg)	Under 40 kg body weight aged 5–12 years give 10 mg/kg 2–3 times daily; over 40 kg body weight aged 12–18 years, give 2 G once daily
Mesalazine: rectal	Aged 12–18 years, 1 gram daily
<i>Metronidazole:</i> (orally)	7.5 mg/kg three times daily
<i>Azathioprine:</i> (orally)	1.5–2.5 mg/kg once daily

- Regular monitoring of the blood count (every 1 to 2 months) is important.

#### Indicators for colectomy

- Toxic megacolon (see above), intractable disease and growth failure.
- The risk of cancer relates to the extent of disease and its duration. Good maintenance therapy is important for prevention. Two-yearly colonoscopy should be considered in those with pancolitis for 10 years after the commencement of disease.
- Colectomy and ileostomy would be the usual operation in resource-limited settings, and are curative symptomatically, but the patient then has the ileostomy for life.

#### Management of Crohn's disease

- The key to management is to maintain growth and nutrition and control symptoms.
- Most children will have recurrent relapses.
- Many will require surgery at some stage.
- Nutritional treatment and support are essential.

#### Polymeric diet

A polymeric diet can be any liquid nutritional preparation that is nutritionally complete. Examples would include PaediaSure/Ensure (Abbott Nutrition), Modulen IBD/Resource Junior (Nestle) and Alicalm/Fortini (Nutricia). Polymeric diet is effective in producing 70% remission in small bowel disease and 50% remission in colonic disease. The advantages over corticosteroids are the positive effect on growth and lack of side effects. The diet is given for 6 weeks, usually orally, during which time no other food is given (but the child can drink water), and then the normal diet is re-introduced.

Maintenance therapy with polymeric diet can also be used.

#### Drug therapy

See Table 5.12.D.3 for drug dosages in ulcerative colitis.

- Prednisolone 2 mg/kg/day (maximum 40 mg/day) is effective in small and large bowel disease. Continue this dose for 3 weeks, then reduce it by 5 mg/week and then stop. If required to maintain remission, alternate-day therapy may have fewer side effects.
- Mesalazine but not sulphasalazine can be effective for maintaining remission in ileal as well as colonic disease (dose is aged 5–12 years 10–15 mg/kg orally 2–3 times daily, aged 12–18 years 2 G once daily).
- Azathioprine is effective in long-term maintenance and has steroid-sparing effects. It may be useful for healing perianal fistulae. It takes many months to act, and it should be continued for at least 4 years. Blood counts should be undertaken every 1–2 months.
- Metronidazole may be effective in controlling perianal disease and fistulae. It may also reduce small bowel overgrowth. Ciprofloxacin is an alternative.
- Infliximab is a very expensive monoclonal antibody that inhibits tumour necrosis factor alpha (TNF $\alpha$ ). It is used in severe Crohn's disease that is not responding to conventional treatment. It is administered IV at intervals. Because of its immunosuppressive effects there are real dangers from infection, especially **latent TB**. Other side effects include anaphylaxis, lymphoma and possibly demyelinating disorders.

#### Surgery

Indications for surgery include failure of medical therapy, intestinal obstruction and growth failure. Strictureplasty may be an effective method of avoiding excision of bowel when strictures are present.

#### Follow-up and support for IBD

Patients and their families require long-term understanding and support. Psychological therapy may be helpful in some cases.

## 5.12.E Upper gastroenterological disorders

### Introduction

Upper gastrointestinal disorders are not common complaints in the population presenting to hospitals in resource-limited countries. It may be that symptoms are under-reported or overlooked because of more common problems, such as gastroenteritis, persistent diarrhoea, intestinal helminths and malnutrition. However, certain life-threatening conditions do occur, including obstruction of the oesophagus due to a foreign body, strictures due to caustic soda poisoning, haematemesis due to peptic ulcer or portal hypertension, and volvulus due to malrotation.

In well-resourced communities, particularly **where facilities for upper gastrointestinal paediatric endoscopy** are available, similar symptoms to those that occur in well-resourced countries present. These include recurrent abdominal pain, epigastric and substernal pain, recurrent/persistent vomiting, dyspepsia and water-brash/heartburn.

### Gastro-oesophageal reflux

TABLE 5.12.E.1 Gastro-oesophageal reflux

Symptoms	Complications
Vomiting (regurgitation)	<i>In Infants</i>
Water-brash/heartburn	Apnoea
Nausea	Life-threatening event
Epigastric/retrosternal pain	<i>All ages</i>
	Failure to thrive*
	Aspiration pneumonia
	Haematemesis
	Anaemia
	Oesophageal stricture

\*Particularly in children with cerebral palsy.

Gastro-oesophageal reflux (GOR) is a normal physiological condition in infants, children and adults. If GOR is associated with complications (as below) then it is termed gastro-oesophageal reflux disease (GORD). GORD is common in children with cerebral palsy.

**Note:** Sandifer–Sutcliffe syndrome is dystonic posturing associated with GOR.

### Diagnosis

Often no investigations are needed and a diagnosis can be made by taking a good clinical history. The following investigations are helpful if they are needed and available:

- **Barium swallow:** This is often the only diagnostic facility available in resource-limited countries. It is a much less sensitive method for diagnosing reflux than pH monitoring, but will detect associated or other conditions such as oesophageal stricture, hiatus hernia, diaphragmatic hernia and malrotation.
- **Endoscopy and biopsy** (particularly looking for oesophagitis).
- pH monitoring: this grades the frequency and duration of exposure of the lower oesophagus to acid (pH < 4.0).

### Management

- Simple GOR in the thriving child: reassurance is all that is needed.
- Excessive regurgitation causing failure to thrive in an infant, or mild symptoms of oesophagitis: treatment by thickening feeds with Carobel (Cow & Gate) or an alginate preparation (e.g. Gaviscon) can be tried.
- Moderate to severe GOR with oesophagitis: H<sub>2</sub>-receptor antagonists, such as ranitidine (2–4 mg/kg twice daily, maximum 150 mg twice daily) or the proton pump inhibitor, omeprazole (700 micrograms to 3 mg/kg once daily) should be given. Motility stimulants such as domperidone (200–400 micrograms/kg every 4–8 hours) may be effective, particularly in children with cerebral palsy. However, proof of their efficacy is lacking.
- Surgery: Nissen fundoplication would be considered if, despite medical management, there **was** severe oesophagitis, failure to thrive or aspiration pneumonia. It is sometimes required in children with cerebral palsy and GOR.

### *Helicobacter pylori*

*Helicobacter pylori* is a ubiquitous bacterium that commonly infects the stomach (especially the antrum) of children in resource-limited countries from an early age. Child-to-child transmission is important. In developed countries up to 40–60% of adults are infected, probably mainly during childhood. Conditions associated with *H. pylori* include the following:

- **Chronic gastritis:** often asymptomatic; not a major cause of abdominal pain in children.
- **Duodenal ulcer:** *H. pylori* has a strong association with duodenal ulcer and must be eradicated to ensure healing.

### Diagnosis

Testing for *H. pylori* should only be undertaken if the child has symptoms of ulcer dyspepsia. Diagnostic tests (outlined

below) are rarely available as routine in resource-limited countries.

- Serology: this is good for epidemiological studies, but has reduced sensitivity in children under 7 years of age.
- Urea breath test (13C-UBT): this is sensitive and specific, especially in children over 6 years of age.
- Faecal antigen testing: this is sensitive and specific in both children and adults.
- Endoscopy: histological demonstration and culture of *H. pylori*.

### Management

Selection of optimal antibacterial agents is difficult because of the development of resistance.

### Suggested regimen

- 1 Omeprazole
  - Aged < 2 years 700 micrograms/kg to 3 mg/kg once daily up to a maximum of 20 mg.
  - Aged > 2 years, body weight 10–20 kg, give 10 mg once daily up to maximum 20 mg once daily.
  - Aged > 2 years, body weight > 20 kg, give 20 mg once daily up to a maximum of 40 mg once daily.
- 2 **plus** antibiotics, such as amoxicillin (< 1 year, 62.5 mg; 1–4 years, 125 mg; 5–12 years, 250 mg; > 12 years, 250–500 mg, three times daily)
- 3 **plus** clarithromycin (7.5 mg/kg twice daily) **or** metronidazole (7.5 mg/kg three times daily).

Treatment should be continued for 1–2 weeks. Strict compliance in order to avoid the development of resistance is imperative.

### Duodenal ulcer

Duodenal ulcers are uncommon in children, but can be life-threatening due to haematemesis, melaena and perforation.

There is often a family history. Common symptoms include epigastric pain that typically:

- is worsened by fasting
- is improved by eating or antacids
- causes **nocturnal waking**.

### Diagnosis

- **Endoscopy, including biopsy for *H. pylori*, is the optimal method.**
- Barium swallow: this is less sensitive for diagnosing acute ulceration and better at detecting scarring.

### Management

- Unless facilities to diagnose *H. pylori* are available, all children should be treated for eradication of presumed *H. pylori*.
- Give H<sub>2</sub> antagonists or a proton pump inhibitor for 6–8 weeks: ranitidine 2–4 mg/kg twice daily (maximum 150 mg twice daily); omeprazole 10 mg for 10–20 kg (can increase to 20 mg) and 20 mg for > 20 kg once daily (can increase to 40 mg).

## 5.12.F Gastrointestinal bleeding

### BOX 5.12.F.1 Minimum standards

- Full blood count.
- Stool examination, microscopy and culture, parasite identification.
- Ultrasound.
- Barium X-ray studies.
- Gastroscopy.
- Colonoscopy.

### Introduction

- The causes of bleeding from the gastrointestinal tract are many, and relate to the age of the child. A good history

and clinical examination are essential and will indicate specific investigations.

- In haematemesis, it is important to exclude swallowed blood due to disorders of the nose and mouth.
- In children the commonest cause of fresh rectal bleeding is an anal fissure.
- Melaena has to be differentiated from dark stools associated with medication (e.g. iron preparations) and colouring from foods.
- A large bleed from the upper gastrointestinal tract may present as red blood at the anus because of rapid transit.

TABLE 5.12.F.1 Causes of gastrointestinal haemorrhage

Site of bleeding	Clinical features/further information
<b>Upper gut</b>	
Poisoning with or treatment with salicylates	'Coffee-ground' vomit
Mallory–Weiss syndrome	
Oesophagitis, gastro-oesophageal reflux	See Section 5.12.E
Portal hypertension, oesophageal varices	See Section 5.7.B (liver disease) See Section 6.3.C.c (schistosomiasis)
<b>Midgut</b>	
Intussusception, volvulus	Infants (see Section 3.4 and 5.19)
Meckel's diverticulum	Often symptomless
<b>Colorectal</b>	
Infection (e.g. shigellosis, amoebiasis)	See Section 5.12.A and Section 6.3.B
Inflammatory bowel disease	Abdominal pain, diarrhoea, weight loss See Section 5.12.D
Milk protein intolerance	See Section 5.12.G
Polyps (single, multiple, Peutz–Jeghers syndrome)	Blood separate from normal stool
<b>Anus</b>	
Fissure	Infants, constipation, tags (see Section 5.12.C)
Crohn's disease	See Section 5.12.D
Miscellaneous	
Necrotising enterocolitis (see Section 3.4), Henoch–Schönlein purpura (see Section 5.13), AIDS (see Section 6.2.D)	
Any coagulation or blood malignancy disorder (see Section 5.11.D and Section 5.14)	

### Investigations

The investigations chosen will depend on the suspected site of bleeding and the clinical features.

See appropriate sections as indicated in the tables above.

It is important to consider the following:

- Stool:
  - Direct observation: blood, mucus.
  - Microscopy: *Cryptosporidium*, *Salmonella*, *E. coli*, *Shigella*, *Campylobacter*, ova, cysts and parasites.
  - Faecal occult blood.
- Full blood count, grouping and cross-matching.
- Serum ferritin and iron levels.
- Isotope scan: diagnosis of Meckel's diverticulum (30% false negative).
- Barium studies: diagnosis of malrotation.
- Ultrasound: diagnosis of intussusception.
- Upper endoscopy: diagnosis and treatment of oesophageal, gastric and/or duodenal bleeding.
- Colonoscopy: diagnosis and treatment of colitis and/or polyps.

TABLE 5.12.F.2 Features of gastrointestinal bleeding

History/examination	Looking for:
<i>History</i>	
Acute/chronic, amount of blood	Severity
Endemic area	Schistosomiasis
Haematemesis	Upper gastrointestinal disorder
Nose and mouth lesions	Swallowed blood
Site of any pain	Upper or lower gastrointestinal tract
<i>Stool:</i>	
Hard/loose	Constipation/diarrhoea
Blood mixed in stool	Inflammation/infection
Blood around or separate	Anal fissure/polyp

History/examination	Looking for:
Inflammatory bowel disease, family history	See Section 5.12.D
Bleeding tendency	Clotting disorder, malignancy
<i>Examination</i>	
Nose and mouth lesions	Swallowed blood
Pallor, capillary refill, blood pressure	Anaemia, shock
Petechiae, telangiectasia	Thrombocytopenia, hereditary telangiectasia
Abdomen	Tenderness, hepatosplenomegaly
Anus	Fissure, tags, infection

## 5.12.G Malabsorption, including coeliac disease

### Malabsorption

Malabsorption is an abnormality in absorption of food nutrients from the gastrointestinal tract.

Common causes of malabsorption and resultant failure to thrive in resource-limited countries include recurrent respiratory infection, persistent diarrhoea and HIV infection. None of these require bowel investigation. The main emphasis is on nutritional rehabilitation which regenerates the small bowel atrophy and the immune system (see management of persistent diarrhoea and severe malnutrition in Sections 5.12.B and 5.10.B, respectively). Only a limited response to nutritional support is expected in HIV infection, depending generally on the stage of disease and the response to antiretroviral (ARV) drugs.

#### Types of malabsorption

- **Selective:** as seen in lactose intolerance.
- **Partial:** as observed in Crohn's disease and HIV infection.
- **Total:** as seen in coeliac disease.

#### Pathophysiology

The gastrointestinal tract functions to digest and absorb nutrients (fat, carbohydrate, protein and fibre), micronutrients (vitamins and trace minerals), water and electrolytes. This is dependent on the proper processing of food by mechanical (chewing and gastric churning) and enzymatic (gastric, pancreatic, biliary or intestinal) means. The final products of digestion are then absorbed through the intestinal epithelial cells.

Malabsorption constitutes the pathological breakdown of the normal physiological sequence of digestion (i.e. intraluminal process), absorption (i.e. mucosal process) and transport (post-mucosal events) of nutrients.

#### Clinical features

Symptoms can be intestinal or extra-intestinal, and include the following:

- diarrhoea/steatorrhoea: watery, diurnal and nocturnal, bulky, frequent stools

- bloating
- flatulence
- abdominal discomfort/cramping abdominal pain
- growth retardation
- weight loss
- failure to thrive
- delayed puberty
- swelling or oedema from loss of protein
- anaemia (vitamin B<sub>12</sub>, folic acid and iron deficiency)
- fatigue
- weakness
- muscle cramp
- osteomalacia and osteoporosis
- bleeding tendencies.

#### Diagnosis

Investigation is guided by symptoms and signs. Since a range of different conditions can produce malabsorption, it is necessary to look for each of these specifically. Tests are also needed to detect the systemic effects of deficiency of the malabsorbed nutrients (e.g. anaemia with vitamin B<sub>12</sub> malabsorption).

Investigations may include the following:

- full blood count and blood film
- C-reactive protein and erythrocyte sedimentation rate
- serum albumin
- serum iron, ferritin and total iron-binding capacity (TIBC)
- serum folic acid
- serum cholesterol or triglyceride
- serum calcium, phosphate and alkaline phosphatase
- prothrombin time and activated partial thromboplastin time
- blood chemistry (electrolytes, glucose, HCO<sub>3</sub><sup>-</sup>, urea and creatinine)
- serum zinc levels
- stool studies, including cultures.

TABLE 5.12 G.1 Common causes of malabsorption

	Common causes of malabsorption
Due to infective agents	Intestinal tuberculosis
	HIV-related malabsorption
	Tropical sprue
	Traveller's diarrhoea
	Parasites, such as <i>Giardia lamblia</i> , fish tapeworm, roundworm, hookworm ( <i>Ancylostoma duodenale</i> and <i>Necator americanus</i> )
Due to structural defects	Blind loops
	Inflammatory bowel diseases (e.g. Crohn's disease)
	Intestinal hurry from surgical procedures (e.g. post-gastrectomy, gastro-jejunostomy)
	Fistulae, diverticulae and strictures
	Short bowel syndrome
Due to mucosal abnormality	Coeliac disease
	Cow's milk intolerance
	Soya milk intolerance
Due to enzyme deficiencies	Lactose intolerance (constitutional, secondary or rarely congenital)
	Sucrose intolerance
Due to digestive failure	Pancreatic insufficiencies
	Cystic fibrosis
	Chronic pancreatitis
	Bile salt malabsorption
	Terminal ileal disease
	Obstructive jaundice
	Bacterial overgrowth
Due to systemic diseases	Coeliac disease
	Hypothyroidism and hyperthyroidism
	Addison's disease
	Diabetes mellitus
	Hyperparathyroidism and hypoparathyroidism
	Malnutrition

### Serological studies

The following specific tests are carried out to determine the underlying cause:

- IgA anti-transglutaminase antibodies
- IgA anti-endomysial antibodies.

### Radiological studies

- Barium meal and follow-through.
- Barium enema.
- CT of the abdomen.

### Specialised tests (if available)

- Biopsy of small bowel.
- Colonoscopy can be helpful in colonic and ileal disease.
- Endoscopic retrograde cholangiopancreatography (ERCP) will show pancreatic and biliary structural abnormalities.
- Glucose hydrogen breath test for bacterial overgrowth.

- Lactose hydrogen breath test for lactose intolerance.
- Magnetic resonance cholangiopancreatography (MRCP).

### Management

Treatment is directed largely towards management of the underlying cause. In severe nutritional deficiency, hospital admission may be required for total parenteral nutrition (TPN). Subsequently, advice and support from a dietitian is vital.

### Coeliac disease

#### BOX 5.12.G.1 Minimum standards

- Gluten-free diet.
- Full blood count and film.

Coeliac disease is an autoimmune disorder of the small intestine in genetically predisposed people of all ages from middle infancy onwards. It is caused by a reaction to gliadin, a gluten protein found in wheat and similar cereals. Therefore it is common among populations whose diet contains substantial amounts of wheat. Apart from people of European origin, in whom it commonly manifests, it is also frequently seen in North Africa, the Middle East, and the north of the Indian subcontinent where wheat is a staple diet. Other populations at increased risk for coeliac disease include children with Down's syndrome and Turner syndrome, type 1 diabetes and autoimmune thyroid disease, including both hyperthyroidism and hypothyroidism.

### Pathophysiology

Upon exposure to gliadin, the enzyme tissue transglutaminase (tTG) modifies the immune system to cross-react with the small-bowel villous lining, causing an inflammatory reaction. This leads to villous atrophy, which interferes with the absorption of nutrients, minerals and the fat-soluble vitamins A, D, E and K.

Coeliac disease appears to be polyfactorial. Almost all people with coeliac disease have either the HLA-DQ2 or the HLA-DQ8 allele. However, additional factors are needed for coeliac disease to manifest besides the HLA risk alleles. Furthermore, around 5% of those people who do develop coeliac disease may not have typical HLA-DQ2 or HLA-DQ8 alleles.

FIGURE 5.12.G.1 The spectrum of coeliac disease. Latent coeliac disease: positive anti-endomysial antibodies, normal small bowel, but risk of developing disease.

**Clinical features**

Clinical features may range from severe to almost non-existent. Severe coeliac disease in young children leads to the characteristic symptoms of pale, loose and greasy stools (steatorrhoea) with weight loss or failure to gain weight. Adolescents and older children with milder coeliac disease may have symptoms that are much more subtle and occur in other organs rather than in the bowel itself.

**TABLE 5.12.G.2 Clinical features of coeliac disease**

Under 2 years of age	Over 2 years of age
Steatorrhoea	Short stature
Vomiting	Delayed puberty
Abdominal distension	Iron-resistant anaemia
Irritability	Rickets/osteomalacia
Anorexia	Behaviour problems
Growth failure	<i>With or without the gut disorders that occur in younger children</i>

**Diagnosis**

The diagnosis of coeliac disease is based on two types of testing.

**Serological blood tests**

These are the first-line investigation and include the following:

- **IgA anti-tissue transglutaminase (tTG) antibodies:** this test is reported to have a high sensitivity (99%) and specificity (over 90%) for identifying coeliac disease. Therefore it should be done first. It is also an easier test to perform. An equivocal result on tTG testing should be followed by antibodies to endomysium.
- **IgA anti-endomysial antibodies:** this test has a sensitivity and specificity of 90% and 99%, respectively, for detecting coeliac disease.

It is important that the total serum IgA level is also checked, as coeliac patients with IgA deficiency may be unable to produce the antibodies on which these tests depend ('false-negative'). In such patients, IgG antibodies against transglutaminase (IgG-tTG) or IgG anti-gliadin antibodies (IgG-AGA) may be helpful in reaching a diagnosis.

**Dudeno-jejunal biopsies**

Because of the implications of a diagnosis of coeliac disease, guidelines recommend that a positive serological blood test may still be followed by a dudeno-jejunal biopsy. Similarly, a negative serology may still be followed by a recommendation for a biopsy if clinical suspicion remains high. Tissue biopsy is still considered the gold standard in the diagnosis of coeliac disease.

For this purpose, biopsies can be obtained using metal capsules attached to a suction device. The capsule is swallowed and allowed to pass into the small intestine. After X-ray verification of its position, suction is applied to collect part of the intestinal wall inside the capsule. Commonly used capsule systems are the Watson capsule and the Crosby-Kugler capsule. This method has now been largely replaced by fibre-optic endoscopy, which carries a higher sensitivity and a lower frequency of errors.

**TABLE 5.12.G.3 Investigations for malabsorption**

General	Specific
Full blood count plus film	Immunoglobulins IgA and IgG
Serum iron and ferritin	IgA tTG antibodies
Folate (red blood cell)	IgA anti-endomysial antibodies
Vitamin B <sub>12</sub> levels	IgA anti-gliadin (AGA)
Serum albumin	Small bowel biopsy:
Hydrogen breath test	● Villous atrophy
Serum calcium, phosphate and alkaline phosphatase	● Hyperplasia of crypts
Serum T <sub>4</sub> and TSH	● Increased inflammatory cells

There are several ways in which these tests can be used to assist in diagnosing coeliac disease. However, all tests become invalid if the patient is already taking a gluten-free diet. Intestinal damage begins to heal within weeks of gluten being removed from the diet, and antibody levels decline over a period of months. In such cases it may be necessary to perform a re-challenge with gluten-containing food over 2–6 weeks before repeating the investigations.

A histology compatible with coeliac disease on a gluten-containing diet, followed by a clinical improvement (i.e. gain in weight and height and resolution of symptoms) once the gluten is removed from the diet is often enough to establish the diagnosis. Most guidelines do not recommend a repeat biopsy unless there is no improvement in the symptoms on the gluten-free diet. In some cases a deliberate gluten challenge, followed by biopsy, may be conducted to confirm or refute the diagnosis. A normal biopsy and normal serology after the challenge indicates that the diagnosis may have been incorrect.

In resource-limited countries where facilities for biopsies may not exist, the same model can be used with serological tests. A positive serological test on a gluten-containing diet will revert to normal with clinical improvement once the patient is on a gluten-free diet.

**FIGURE 5.12.G.2 Diagnosis of coeliac disease.**

**BOX 5.12.G.2 Gluten challenge**

Do a gluten challenge if:

- the diagnosis is in doubt
- there is a possibility of another diagnosis, especially in children under 2 years of age (e.g. milk protein intolerance, persistent diarrhoea, giardiasis)
- the response to a gluten-free diet is not clear-cut
- the subject is asymptomatic (e.g. first-degree relatives).

**Note:** Gluten challenge should preferably be undertaken when the child is over 6 years old and before puberty, to reduce the effects on dentition and growth.

**Treatment**

At present, the only effective treatment is a lifelong gluten-free diet. Strict compliance allows the intestines to heal, with resolution of symptoms in most cases. Early intervention and good compliance can eliminate the heightened risk of intestinal cancer and in some cases sterility.

Dietitian input can be helpful in ensuring that the patient is aware of which foods contain gluten, which foods are safe, and how to have a balanced diet despite the limitations. The diet can be cumbersome, and failure to comply may cause relapse.

The commonly implicated cereals include wheat (and its subspecies, such as spelt, semolina and durum), barley, rye and oats.

Other cereals, such as maize (corn), millet, sorghum, teff and rice, are safe for patients to consume. Similarly, non-cereal foods such as fruits, vegetables and foods derived from animal sources (i.e. milk, fish, poultry and other meat) can be used.

## 5.13 Rheumatology

**BOX 5.13.1 Minimum standards**

- Penicillin.
- Aspirin.
- Prednisolone.
- Haloperidol, diazepam and lorazepam.
- Anti-endocarditis measures.
- IV gamma globulin if at all possible.
- Non-steroidal anti-inflammatory drugs (NSAIDs).
- Sulphasalazine.
- Ocular steroids and mydriatics.
- Intra-articular steroids.
- Physiotherapy and family support.

**Introduction**

Making a diagnosis of a rheumatic disease in a child relies primarily on clinical skill and experience, as there are few diagnostic laboratory tests. Although these diseases are rare in children, symptoms that raise the possibility of rheumatic disease are common. Rheumatic symptoms may be relatively specific, such as joint swelling, or relatively non-specific, such as fever, lethargy, pallor, anorexia, failure to thrive, muscle weakness, musculoskeletal pain, rash, headache and abdominal pain. The interpretation of these clinical features requires a meticulous approach to characterising the nature of each feature and considering the overall pattern of all the clinical features in the individual patient. The aims of this section are to assist in the recognition of common patterns of clinical features, and to provide guidance for appropriate treatment and monitoring of rheumatic disease in children.

pGALS (paediatric Gait, Arms, Legs and Spine) is a simple quick approach to joint examination and helps to discern abnormal from normal joints; this is especially useful in the context of non-specific features such as limp or fever. pGALS includes incorporates a series of simple manoeuvres to assess all joints quickly (takes approximately 2–3 minutes). It has been validated in school-aged children (although can be performed in younger children) and has been shown to be effective when performed by non-specialists in detecting significant joint abnormalities in acute paediatric practice (including in Africa). The interpretation of pGALS requires knowledge of normal musculoskeletal development and the clinical context to facilitate a differential diagnosis ([www.arthritisresearchuk.org/health-professionals-and-students/video-resources/pgals.aspx](http://www.arthritisresearchuk.org/health-professionals-and-students/video-resources/pgals.aspx)).

**Rheumatic fever**

Rheumatic fever is an abnormal immune response to group A streptococcal infection in genetically susceptible individuals. It is most common between the ages of 6 and 16 years. Symptoms of acute rheumatic fever follow streptococcal pharyngitis after a latent period of approximately 3 weeks. The disease usually presents with joint pain, but may have an insidious onset, especially if carditis is the predominant feature. There is no definitive test, and diagnosis depends on recognition of clinical signs known as the Jones criteria.

**TABLE 5.13.A.1 Jones criteria for diagnosis of rheumatic fever**

Major criteria	Minor criteria
Carditis	Previous history of rheumatic fever
Migratory large-joint polyarthrititis	Fever
Erythema marginatum	Arthralgia
Subcutaneous nodules	First-degree heart block
Chorea (onset 2–6 months after pharyngitis)	Elevated acute-phase reactants (ESR and CRP)

ESR, erythrocyte sedimentation rate; CRP, C-reactive protein.

### Diagnosis: Jones criteria

The diagnosis in an individual is made by the **Jones criteria** (revised by the WHO in 2003) on the basis of the presence of either **two major criteria** (which include polyarthrititis, erythema marginatum rash, subcutaneous nodules, carditis and chorea) or **one major criterion and two minor criteria** (minor criteria include persistent fever, arthralgia, raised ESR or CRP, persistent leukocytosis, abnormal ECG except if carditis is the major feature, and previous episode of rheumatic fever). Each combination must also include evidence of streptococcal infection, usually a **rising titre of antistreptolysin O**.

- Evidence of **streptococcal infection** (usually a pharyngitis secondary to group A beta-haemolytic streptococcus) with positive throat swab culture or, preferably, a positive serology for recent streptococcal infection. This is usually accompanied by a prolonged fever and followed by other clinical features after a 2- to 3-week period.
- **Arthritis** of the large joints. This is a reactive arthritis (rather than a septic arthritis), often affecting many joints, and it is migratory in nature. It usually responds dramatically to aspirin, up to 120 mg/kg/day in four to six divided doses by mouth after food, but do not exceed 75–80 mg/kg/day if facilities for assay of salicylate levels are not available. Alternatively, use non-steroidal anti-inflammatory drugs (NSAIDs; see below). The presence of joint pain without swelling (i.e. arthralgia alone) may still indicate rheumatic fever in the presence of the other clinical features compatible with a diagnosis of acute rheumatic fever.
- **Rash and subcutaneous nodules:** erythema marginatum is an uncommon feature. It has a 'snake-like' appearance, usually over the trunk, and occurs early in the disease, is usually transient, and disappears within a few hours. Subcutaneous nodules are not uncommon, occurring over bony prominences such as the elbows and knees.
- **Carditis:** this may range from a tachycardia with a prolonged PR interval seen on the ECG through to myocarditis with a systolic apical mitral murmur, pericarditis or cardiac failure. Cardiac inflammation may involve the endocardium (valvulitis mostly affecting the mitral and aortic valve), the myocardium (impaired cardiac function) or the pericardium in severe cases (pericarditis). Examination may reveal a pericardial friction rub, an apical pansystolic murmur from mitral regurgitation, or an early diastolic decrescendo murmur from aortic regurgitation. As the valves heal they may scar and fibrose. **Mitral regurgitation, mitral stenosis** and

**aortic regurgitation** are the commonest long-term consequences of acute rheumatic fever.

- **Chorea** is an involuntary movement disorder, often of the face, tongue and upper limbs. It may appear as dysarthria or clumsiness, and is associated with emotional lability. It is a late manifestation of acute rheumatic fever, and is more common in girls.

The disease may be prevented by detecting group A streptococcus in cases of pharyngitis (throat swab or rapid antigen test) and treating with penicillin (see below).

### Treatment

#### Management of acute rheumatic fever

- Eradicate streptococcal infection (give oral penicillin V 10–12.5 mg/kg/dose (maximum dose 500 mg) three times a day for 10 days).
- Commence aspirin 90–120 mg/kg a day in four divided doses after food. Monitor serum salicylate levels (the optimal level is 15–25 mg/dL). Reduce the dose to two-thirds of the original dose when there is a clinical response.
- When the CRP and ESR decrease to normal levels, taper the aspirin dose over 2 weeks.
- Give prednisolone 2 mg/kg/day (maximum 60 mg/day) in place of aspirin if there is moderate to severe carditis or pericarditis.
- If prednisolone is given, continue treatment for 3 weeks, and then taper the dose over a further 2–3 weeks. As the prednisolone dose starts to taper, commence aspirin 50 mg/kg/day in four divided doses and stop aspirin 1 week after prednisolone is stopped.
- Treat heart failure as described in Section 5.4.B.
- Urgent valve replacement is sometimes required.

The requirement for bed rest during the acute attack is controversial; it is also very difficult to enforce on young children.

For arthralgia, give aspirin as described above or an NSAID (e.g. ibuprofen 30–60 mg/kg daily up to a maximum of 2.4 G in three to four divided doses after food). Naproxen at 20 mg/kg/day in two divided doses appears to be a better alternative.

Treatment of streptococcal infection with IM benzylpenicillin (1.2 million units as a single injection, often given as 0.6 million units in each thigh) or a 10-day course of oral penicillin at high dose (12.5 mg/kg four times a day). Once there has been one episode of rheumatic fever a recurrence is likely. The recurrence risk is minimised by giving long-term penicillin prophylaxis, preferably for life. This is usually given as intramuscular injections of 1.2 million units of benzathine penicillin every 3 weeks (this drug must not be given IV). If oral penicillin is required, the highest dose generally recommended is 250 mg twice daily for all ages, as doses of oral penicillin in children below the age of 5 years need not be given because rheumatic fever does not occur in this age group. For patients who are allergic to penicillin, erythromycin in the same doses can be used.

For acute carditis, prednisolone given orally (2 mg/kg/day) for 2–3 weeks or by intravenous infusion is effective.

Chorea may respond to haloperidol, 12.5–25 micrograms/kg twice daily (maximum 10 mg a day). Extrapyramidal side effects may occur. Chorea usually becomes less of a problem within a few weeks.

## Vasculitis in children

Vasculitis in childhood may be primary, including Henoch–Schönlein purpura, Kawasaki disease and the rare vasculitides, or secondary to multisystem connective tissue diseases, including juvenile dermatomyositis and systemic lupus erythematosus (SLE). In all of these diseases, skin manifestations are usually prominent, but the combination with other clinical features helps to ascertain the diagnosis.

### Henoch–Schönlein purpura (HSP)

#### Presentation

- **Purpuric rash:** a palpable purpuric rash is most commonly seen over the buttocks and around the ankles and legs. The purpura occurs in crops and may range from small petechiae-like lesions to large ulcerating ecchymoses. Oedema and urticaria may precede the purpura, particularly at the ankles, scrotum and face.
- **Gastrointestinal pain:** abdominal pain is a prominent feature early in the disease, and is often accompanied by vomiting. Occasionally, frank gastrointestinal haemorrhage may occur.
- **Arthritis:** this typically affects the large joints of the lower limb, especially the ankles. Ankle swelling may be difficult to interpret in the presence of tissue oedema. The joint pain is usually transient. Arthritis in HSP is never erosive.
- **Renal disease:** haematuria and proteinuria are common manifestations of the disease, but are usually only detected on dipstick urine analysis. A small proportion of children (1–3%) may develop renal failure secondary to severe glomerulonephritis. Clinically significant renal disease is uncommon below 5 years of age.

#### Treatment

Henoch–Schönlein purpura is usually a self-limiting disease, requiring supportive care and symptomatic treatment with simple analgesia only. If the abdominal pain is severe, prednisolone (1–2 mg/kg/day) for 1 week may be helpful.

### Kawasaki disease

Kawasaki disease is characterised by a combination of most of the following features in a young child (usually less than 5 years old) who is extremely irritable.

- **Fever:** an irregular spiking fever that persists for 1–3 weeks despite antibiotics is characteristic during onset.
- **Skin involvement:** rash is variable and polymorphic, ranging from diffuse erythema of the trunk and face to minimal macular lesions on the limbs. The rash in Kawasaki disease is never vesicular. Tissue oedema of the dorsal surfaces of the hands, feet and perineum is characteristic. These changes are followed within days to weeks by desquamation, usually of the finger and toe tips (periungual desquamation), but occasionally more widespread.
- **Mucositis and conjunctivitis:** inflammation of the mucous membranes of the mouth and eyes results in a characteristic appearance of red eyes (conjunctival ‘injection’ rather than conjunctivitis) and red swollen cracked lips.
- **Lymphadenopathy:** this usually affects the cervical lymph nodes, often unilaterally.
- **Cardiac disease:** myocarditis with heart failure or pericarditis is a rare but serious complication of Kawasaki disease. Coronary artery aneurysms may be present

from early in the disease process. Clinical manifestations are relatively non-specific, but the two-dimensional echocardiography appearances are diagnostic of the condition. However, echocardiography may be completely normal in Kawasaki disease.

- It is important to exclude infections (e.g. measles, adenovirus or streptococci), as they may present in a similar manner, despite having distinct clinical characteristics.

**Kawasaki disease is a rheumatological emergency. Delays in recognition and treatment of this condition can result in the development of coronary artery abnormalities with disastrous long-term consequences, including fatalities.**

#### Treatment

- Hospitalisation and monitoring of cardiac status.
- Aspirin, 50–75 mg/kg/day in 4 divided doses after food until the acute inflammatory phase of the disease settles, then 1–10 mg/kg/day (usually 3–5 mg/kg/day) (antiplatelet doses).
- Intravenous gamma globulin 2 grams/kg immediately on diagnosis, if available. **Every effort must be made to procure intravenous gamma globulin for the treatment of these children, as this is the only effective therapy for Kawasaki disease.** This treatment reduces the likelihood of coronary artery aneurysms if given as early as possible during the illness (several inexpensive brands of intravenous gamma globulin are now available in resource-limited countries).
- Corticosteroids (e.g. prednisolone 1–2 mg/kg/day) may have a role in controlling the acute inflammation of Kawasaki disease, but are generally not recommended.
- Follow-up clinical examination and echocardiography (if available) is recommended at 6–8 weeks, as coronary artery aneurysms may appear after the initial presentation.

### Juvenile idiopathic arthritis

Juvenile idiopathic arthritis is one of the more common physically disabling chronic diseases of children. The most prominent clinical features include joint swelling, restriction of joint movement, joint pain and tenderness at the joint margins, muscle wasting and any of the features mentioned below. The most common mistake is to diagnose arthritis in the absence of objective evidence of persistent joint swelling.

#### Diagnosis of juvenile idiopathic arthritis

All of the following four criteria are required:

- 1 The presence of arthritis, defined by swelling of a peripheral joint. Loss of joint range of movement and pain on movement are sufficient for the definition of arthritis involving the hip or spine (in the absence of other causes for the pain).
- 2 Persistence of arthritis for more than 6 weeks.
- 3 Onset of arthritis before the child’s 16th birthday.
- 4 The absence of any known cause for the arthritis.

#### Classification and differential diagnosis

There are a variety of different forms of juvenile idiopathic arthritis that are important to consider when advising on the prognosis and most appropriate treatment of the illness.

- **Arthritis affecting only a few joints:** oligo-arthritis

carries the best prognosis; 30% of these children may have arthritis in adulthood.

- **Arthritis affecting many joints:** polyarthritis is likely to persist into adulthood in 40% of cases.
- **Arthritis affecting few or many joints with prominent extra-articular features:**
  - **Systemic arthritis:** with fever, rash, and enlargement of the liver, spleen and lymph nodes, Pericarditis and macrophage activation syndrome are life-threatening complications. Macrophage activation syndrome presents with persistent fever, encephalopathy, liver failure and clotting abnormalities and low platelet counts. The persistence of arthritis with this illness carries the worst prognosis: over 50% of these children have arthritis as adults.
  - **Psoriatic arthritis:** often associated with a psoriatic rash, nail pitting and a family history of psoriasis. This has a similar outcome to polyarthritis.
  - **Enthesitis-related arthritis:** the clinical manifestations of enthesitis include pain, tenderness and occasionally swelling localised to the exact site of tendon insertion. Other features include back pain, red painful eyes and urethritis. There is a 60% risk of development of ankylosing spondylitis in adulthood.

### Monitoring for complications and disease progress in juvenile idiopathic arthritis

There are several important complications of juvenile idiopathic arthritis, including joint failure, chronic anterior uveitis and local growth disorders, as well as the general complications of chronic inflammatory disease in children, such as anaemia, fatigue, delayed puberty and growth failure. Three of these complications, namely joint failure, chronic anterior uveitis and growth disorders, will be discussed in more detail.

#### Joint failure

- Inability to walk without pain and stiffness.
- Inability to write or perform activities of self-care without pain and stiffness.
- The integrity of joint cartilage and bone density is affected from the onset of the disease.
- If the inflammation remains poorly controlled, destruction of cartilage, joint space narrowing and erosion of bone will result in permanent loss of joint function.

### Differential diagnosis of juvenile idiopathic arthritis

- Transient arthritides: irritable hip, reactive arthritis.
- **Septic arthritis** and **osteomyelitis**, including immunodeficiency.
- **Acute lymphoblastic leukaemia, neuroblastoma, lymphoma and local neoplasia.**
- Bleeding diatheses: haemophilia.
- Haemoglobinopathies: thalassaemia, sickle-cell crisis.
- Epiphyseal disorders: dysplasia, avascular necrosis, osteonecrosis, slipped upper femoral epiphysis.
- Metabolic and endocrine disorders.
- **Traumatic joint disease, including non-accidental injury.**
- Hypermobility and inherited connective tissue diseases.
- Systemic connective tissue diseases, including systemic lupus erythematosus, dermatomyositis and vasculitis.
- Idiopathic musculoskeletal pain syndromes.

**TABLE 5.13.A.2 Important sites of joint contracture**

Joint affected	Type of contracture	Consequence of contracture
Tibio-talar gait	Plantar flexion	Circumduction or high-deformity stepping
Knee	Flexion	Quadriceps wasting, limping gait
Hip	Flexion	Limited 'swing-phase' gait
Wrist	Flexion	Poor writing
Neck	Flexion	Poor neck rotation

- Arthritis of inflammatory bowel disease.

**Note: diseases shown in bold type in the above list are emergencies, and require prompt expert management.**

### Initial minimal set of investigations for differential diagnosis

- Full blood count, including white blood cell differential and platelet counts.
- Plain radiographs of affected joints.
- Synovial fluid aspiration, microscopy and culture.
- Blood culture.

### Eye disease

- Chronic anterior uveitis is typically insidious and asymptomatic: all children with juvenile idiopathic arthritis (but especially those with oligo-arthritis) should undergo slit-lamp eye examination to detect cells in the anterior chamber and protein 'flare'. **Delay in the diagnosis can lead to blindness.**
- Inflammation is treated with ocular topical corticosteroids (hydrocortisone 1% eye drops or ointment 0.5%) three times daily and mydriatics (3 minutes after hydrocortisone) (atropine 0.5% eye drops or 1% ointment).
- Severe chronic anterior uveitis may require systemic treatment with corticosteroids or methotrexate.

### Growth disorders

- Generalised growth failure may be due to inadequate energy intake (chronic inflammatory disease increases energy demands) or the adverse effects of medication. It is usually treated with dietary energy supplements.
- Local growth disturbance: bony overgrowth of the knee with an increase in leg length, sometimes with a valgus knee deformity. Arthritis of the small joints of the hands is likely to cause premature fusion of the epiphyses and reduced growth of the affected fingers.

### Treatment of juvenile idiopathic arthritis

- The first priority is to exclude the differential diagnoses, especially the emergencies of septic arthritis, acute lymphoblastic leukaemia or other malignancies, and non-accidental injury. Septic arthritis will require large doses of intravenous antibiotics (see Section 5.17).
- The effective treatment of juvenile idiopathic arthritis usually requires a team of trained healthcare professionals, including therapists and medical staff.
- Education of the patient and family is important, especially concerning the risks and benefits of all treatment and the natural history of the disease.
- Physiotherapy, hydrotherapy and occupational therapy

work together to maintain joint function and muscle bulk, correct joint deformities and rehabilitate affected joints.

- Drug treatment should begin as soon as the diagnosis is made, with the following:
  - **Non-steroidal anti-inflammatory drugs (NSAIDs):** Give ibuprofen up to 60 mg/kg/day up to a maximum of 2.4 g in three or four divided doses after food. Naproxen at 20 mg/kg/day in two divided doses is possibly a better alternative. Avoid using more than one NSAID at a time.
  - Intra-articular corticosteroids: Strict aseptic conditions, no-touch technique, appropriate sedation, and local or general anaesthetic must be given. Triamcinolone hexacetonide is the most effective steroid, at a dose of 1 mg/kg/large joint (e.g. knee, hip or shoulder) or 0.5 mg/kg/small joint (e.g. ankle, wrist or elbow). This technique requires an experienced operator.

For children with polyarthritis or systemic arthritis, in addition to the above, the following should be considered:

- **Methotrexate:** Begin with 500 micrograms/kg/week (up to 15 mg/week) starting dose, given orally 1 hour before food, and increased if necessary by 2.5 mg every month until 1.0 mg/kg/week (maximum 30 mg/week). Alternative dosage is 10–15 mg/m<sup>2</sup> once weekly starting dose and increased if necessary to a maximum dose of 25 mg/m<sup>2</sup> once weekly (see Section 9 for chart showing how to calculate m<sup>2</sup> from weight). The drug may be given by subcutaneous injection in severe cases. The patient should be monitored monthly for cytopenia (with full blood counts) and liver function abnormalities. Administration is sometimes accompanied by nausea, a side effect that can be improved with folic acid 1 mg once daily (not on the day of methotrexate treatment, but beginning the day after the methotrexate dose).
- **Intravenous methylprednisolone:** This may be needed for severe disease flares or for complications such as pericarditis. Give 30 mg/kg/dose (maximum dose of 1 gram) once a day for 3 days by slow intravenous infusion over a 2- to 3-hour period. Blood pressure monitoring for acute hypertension during the administration of this medication should take place every 30 minutes.
- **Sulphasalazine:** Begin with 12.5 mg/kg/day for the first week, increasing by 12.5 mg/kg/day each week until the maximum dose of 50 mg/kg/day in two divided doses is reached, or until adverse drug reactions occur. These may include a rash, nausea, abdominal pain and pancytopenia. Monitoring with 2- to 3-monthly full blood counts is a sensible precaution.
- More recently, a new group of drugs have been developed which appear to slow the progress of disease in some patients. They work by opposing tumour necrosis factor alpha, which contributes to cell damage, and are immunosuppressants. They include etanercept and infliximab. These drugs are currently very expensive.

## Paediatric systemic lupus erythematosus (SLE)

### Pattern of clinical features in SLE

There is a malar rash and erythema of the hard palate with hair loss in a child with multiple constitutional symptoms.

Childhood SLE tends to be more severe than its adult counterpart, with a higher frequency of renal, neurological and haematological involvement. The clinical features are varied and wide-ranging (it has surpassed syphilis as the great imitator of signs and symptoms), but the more common presentations include the following:

- **Non-specific constitutional symptoms:** fever, fatigue and weight loss.
- **Skin rash:** malar erythema or discoid rash with photosensitivity. Erythema of the hard palate is common and specific. Occasionally oral or nasal ulcerations occur.
- **Haematological cytopenias:** anaemia, thrombocytopenia, lymphopenia and leukopenia.
- **Arthritis:** painful non-erosive arthralgias and overt arthritis.
- **Renal disease:** commonly nephrotic syndrome (proteinuria > 0.5 grams/day) with cellular casts. This is occasionally the sole presentation in paediatric SLE.
- **Neurological disease:** ranging from seizures to psychosis to chorea.
- **Endocrine abnormalities:** diabetes, autoimmune thyroid dysfunction, delayed menarche, lowered male virility, and reduced growth and bone mass.
- **Positive immunoserology (where available):** antinuclear antibody, anti-double-stranded DNA antibodies, antiphospholipid, anticardiolipin and lupus anti-coagulant antibodies.

### Treatments

- The first step is to rule out other conditions which can mimic SLE, such as infection, malignancy, post-streptococcal nephritis, other rheumatic diseases and drug-induced lupus-like syndromes.
- For mild musculoskeletal disease, NSAIDs (e.g. ibuprofen 20–40 mg/kg/day in three daily doses) are effective.
- For rapid control of acute moderate-to-severe disease, glucocorticoids (e.g. prednisone up to 2 mg/kg per day) are useful, tapering rapidly to the lowest tolerated dose.
- Hydroxychloroquine (5–7 mg/kg/day) is now a standard adjunctive therapy for limiting joint, skin and constitutional symptoms.
- Immunosuppressive agents (e.g. azathioprine, cyclophosphamide, mycophenolate mofetil) are useful additions in moderate to severe disease.
- Other general health measures that need to be considered include the following:
  - Bone health: weight-bearing exercises with calcium and vitamin D supplementation.
  - Cardiovascular health: education on modifiable risk factors for atherosclerosis, together with advice on reducing weight, smoking and cholesterol.
  - Health education (regarding vaccination, sun protection, dietary advice, exercise and reproductive health) and psychological support.
- Routine 2- to 3-month follow-up is necessary to monitor for complications. This should involve full blood count, renal and liver profiles, ESR, urinalysis, and urine:protein creatinine ratio, together with complement and anti-dsDNA antibody levels.

## Juvenile dermatomyositis (JDM)

### Pattern of clinical features in JDM

There is erythema over the face, shawl area, knuckles

**and knees, associated with proximal muscle weakness (which may be subtle).**

Juvenile dermatomyositis is the most common inflammatory myopathy of childhood, and the diagnosis is based on the following criteria:

- **Muscle weakness:** a symmetrical, usually progressive weakness affecting proximal muscles.
- **Skin rash:** erythematous rashes occurring over the face or extremities, heliotrope rash over the eyelids, and Gottron's papules over extensor joint surfaces. More severe complications include skin ulceration and calcinosis at pressure points, causing functional disabilities. Capillary loop abnormalities seen proximal to the cuticles with an auroscope are a very characteristic sign if present.
- **Laboratory evidence of muscle disease:** this can include increased activity of muscle enzymes in the

blood (creatine kinase, lactate dehydrogenase, transaminases), or results from more invasive tests, such as muscle biopsy or electromyography (if available).

**Treatment**

- High-dose corticosteroids are the standard treatment, namely early IV methylprednisolone 30mg/kg per day (maximum 1 gram daily) with or without low-dose daily oral corticosteroid (500 micrograms/kg per day).
- It can be useful to add methotrexate (15 mg/m<sup>2</sup>/week orally or subcutaneously) as a steroid-sparing agent and intravenous immunoglobulin in resistant cases (where available).
- Skin disease may also be helped by routine photoprotective agents and topical corticosteroids or tacrolimus.
- Physiotherapy and aerobic exercise are helpful for improving function and strength.

**TABLE 5.13.A.3 Differential diagnosis of childhood idiopathic inflammatory myopathies**

Weakness alone	Weakness with or without rash	Rash alone
Muscular dystrophies (e.g. Duchenne's, limb-girdle)	Viruses (enterovirus, influenza, coxsackie, echovirus, polio)	Psoriasis
Metabolic myopathies (e.g. glycogen- or lipid-storage disorders)	Bacterial ( <i>Staphylococcus</i> , <i>Streptococcus</i> , Lyme disease)	Eczema
Endocrine myopathies (hypothyroidism, hyperthyroidism, Cushing's syndrome, diabetes mellitus)	Parasitic (toxoplasmosis, trichinosis)	Allergy
Drug-induced myopathies (e.g. glucocorticoids, hydroxychloroquine, growth hormone)	Other rheumatic conditions (SLE, mixed connective tissue disease, scleroderma, juvenile idiopathic arthritis, vasculitis)	
Neurological (myasthenia gravis, spinal muscular atrophy)	Other inflammatory conditions (coeliac disease, inflammatory bowel disease)	

## 5.14 Cancer in children

**BOX 5.14.1 Minimum standards**

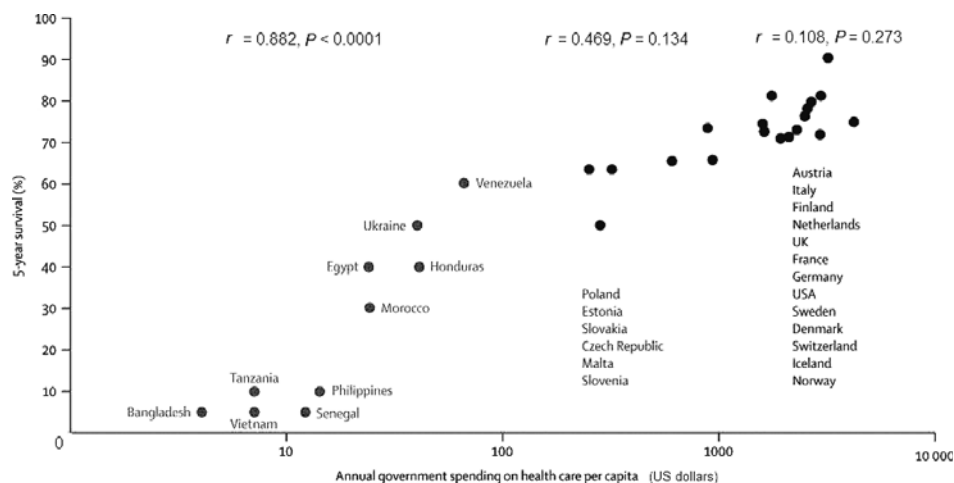

- Local enthusiastic clinical lead.
- Supporting team of doctors and nurses.
- Basic diagnostic pathology and imaging (X-ray and ultrasound).
- Centre with provision for some chemotherapy and surgery.
- Access to antibiotics.
- Access to blood products.
- Access to palliative care drugs (*see* Section 1.16).

**Ideal extra requirements**

- Imaging with computed tomography (CT) scan.
- Access to radiotherapy.
- Indwelling long-term vascular access.

**Introduction**

- **More than 85% of all newly diagnosed children with cancer and 95% of deaths in children with cancer occur in low- and middle-income countries.**
- With an increasing global population, principally in resource-limited countries, the number of children will continue to increase both in terms of absolute numbers and proportionally in these countries.
- As malnutrition and infection decline, particularly in young children, the worldwide contribution to mortality from cancer will increase.
- **Only a limited proportion of all children with cancer in resource-limited countries receive curative therapy, and most do not even receive any form of palliative care.**
- **A child diagnosed with cancer who lives in one of the poorest countries has an 80% probability of dying, compared with less than 30% in the most well-resourced countries (see Figure 5.14.1).**

**FIGURE 5.14.1** Correlation between annual government healthcare expenditure (US\$) per capita and childhood cancer survival (From Ribeiro RC, Steliarova-Foucher E, Magrath I *et al.* (2008) Baseline status of paediatric oncology care in ten low-income or mid-income countries receiving My Child Matters support: a descriptive study. *Lancet Oncology*. **9**: 721–9.). Reproduced with permission from Macdonald S, Magill-Cuerden J (ed.) *Mayes' Midwifery: a textbook for midwives*. Elsevier Health Sciences; 2010. © Elsevier

## Epidemiology

Globally, the reported incidence rate of cancer in children (aged < 15 years) ranges from 80 to 150 per million per year. Boys are around 20% more likely to develop cancer overall than girls. However, there are some differences between resource-limited and resource-rich countries. **The incidence rates in children from low- and middle-income countries are towards the lower end of the range, which may partly be due to both under-diagnosis and under-reporting. The ratio of boys to girls registered with childhood cancer increases with decreasing gross domestic product and with increasing infant mortality, suggesting a gender bias in diagnosing and registering cases in some resource-limited countries.**

There are clear variations in the incidence of different childhood cancers around the world – for example, a reported excess of retinoblastoma in India, Pakistan and sub-Saharan Africa. It is likely that some of this 'excess' is due to better diagnosis and recognition of retinoblastoma, which once at an advanced stage is easy to identify. On the other hand, the incidence of brain tumours and neuroblastoma is generally lower in resource-limited settings, and this may be due to varying levels of case ascertainment. In many countries, most noticeably those in sub-Saharan Africa, the HIV pandemic has been associated with a significant increase in cancers such as Kaposi's sarcoma and other tumours.

The cause of the majority of childhood cancers is unknown. Most cancers probably result from the interaction of environmental factors with a genetic predisposition. For example, African Burkitt lymphoma is related to infection with the Epstein–Barr virus (EBV) very early in life, with persistence of induced genetic rearrangements within B lymphocytes. However, the widespread use of medicinal plants which may increase the likelihood of cell transformation by EBV, chronic malnutrition that induces immunosuppression, and frequent infections that cause B-cell proliferation are all likely aetiological factors.

## Problems of treating children with cancer in resource-limited countries

The problems listed below are not exclusive to resource-limited countries, and not mutually exclusive (i.e. many factors interact, compounding the difficulties in treating cancer).

- **Poverty:** national, regional, local and personal. This is often associated with low government expenditure on healthcare, absence of social care, and lack of insurance for medical illnesses.
- **Lack of suitable treatment centres and training programmes.** Existing centres lack trained staff and resources.
- **Lack of trained staff,** especially nurses, but also lack of surgeons, pathologists and paediatricians (especially paediatric oncologists).
- **Healthcare professional resources**  
*Staff morale problems* (see Section 1.1)

Low morale may be due to low wages, overwork and dirty crowded conditions, compounded by too many patients and by becoming accustomed to low patient survival rates. Solutions may include better training and remuneration, better working and living conditions, and making staff feel valued.

It is important that all healthcare professionals recognise that nursing care is fundamental. Nurse bonus schemes for work effectively performed can be helpful (e.g. IV antibiotics and chemotherapy correctly administered for all patients).

Nurses often rotate every few months between departments. Try to ensure that, for paediatric oncology, a cohort of nurses remains permanently on the ward, as much of the work is very specialised (e.g. chemotherapy administration).

### Paediatric oncologists

An effective service needs good leadership in a major centre. This can develop the service through training and the development of fellowship programmes. There can be support from overseas experts, perhaps with

'twinning' of hospitals from a well-resourced country to share decision making on complex cases and to supply visiting experts. Much useful work can be done in oncology with email and web conferencing to facilitate knowledge sharing in both directions. As there is an increase in the number of trained and training staff, round-the-clock expertise in paediatric oncology can be achieved with the development of on-call rotas.

- **Late presentation**
  - Patients' families are often very poor.
  - They may present to traditional healers first, leading to a delay in diagnosis and referral.
  - They often cannot afford transport.
- **High cost of treatment**
  - Expensive cytotoxic agents, counterfeit medications, quality control problems, cold chain difficulties (e.g. asparaginase is an enzyme and must be kept cool), restrictions (e.g. on oral morphine).
  - Cost of diagnostic imaging and pathology.
  - Cost of supportive care: antibiotics and other antimicrobials, blood products.
  - Cost of caring for critically ill children: high-dependency/intensive care, postoperative care.
- There is a need for multiple support networks and institutions to develop the paediatric oncology service in the face of the poverty that causes the above problems. These will include individuals and their families, non-governmental organisations (NGOs), corporate business, public social responsibilities, twinning, and public private-partnership. Government involvement is vital.
- **Inadequate provision of analgesics and other drugs**
  - For all patients, and especially where cure is not possible, palliative care is a vital part of oncology treatment. Analgesics play a large part in supportive care and procedural sedation and analgesia, as well as in palliative care. The lack of these drugs is often coupled with a poor understanding and awareness of pain management in healthcare professionals.
- **There is often an interrupted supply and insufficient quality control of all drugs.**
- **Comorbidities**
  - There is often a high prevalence of co-infections, malaria, anaemia, helminths and malnutrition which can confound the diagnosis and cause decreasing tolerance of cytotoxic therapy.
- **Untimely and inappropriate cessation of treatment (i.e. abandonment of treatment)**
  - A lack of education and knowledge about uncommon diseases among families, communities and healthcare workers leads to a lack of understanding of the need for treatment.
  - There is then a lack of financial and social support as treatment is lengthy and the parent has to stay with the child in hospital. This makes it difficult to look after other children at home, and to work, leading to loss of employment.
  - Traditional beliefs include unrealistic preconceptions about cancer and reliance on traditional medicines. In Swahili, 'the never healing sore' refers to the fact that there is no expectation of cure, and therefore no point in treatment.
  - Adolescents frequently treated on adult wards.
  - Patients may be left on wards for months because of

a lack of diagnostic facilities (e.g. children with brain tumours or osteosarcomas). It is important to search the wards for such patients and to alert colleagues to refer children to an oncologist where the diagnosis is unknown.

- **Impact on family structure**

- The loss of parental income may result in disruption and potential disintegration of the family, and at the very least to a change in family roles, especially where both parents need to work to maintain the family income.

## Management of children with cancer in resource-limited countries

The following principles and practices should guide the management of children with cancer in resource-limited settings.

- Engage in twinning – that is, developing a link between a treatment centre in a resource-limited country and one in a resource-rich country, with the objective of sharing professional and technological expertise along with other resources.
- Initially, target curative treatment for cancers that are common and have a relatively good prognosis. When curative treatment is not an option or is not offered, it is essential to provide palliative care to reduce suffering. **Both curative and palliative care must be seen as active forms of therapy.**
- If curative treatments are to be undertaken, then whenever possible they should be given in a specialist children's cancer centre (see below). There is potential for greatly increasing suffering by only offering 'half treatment' of cancer for children. It has to be done fully and professionally, or alternatively the child must be given palliative care (see Section 1.16).
- Adapt treatment protocols in accordance with local infrastructure and facilities, maintaining a balance between treatment response and cure on the one hand and treatment toxicity and mortality on the other.
- Take steps to ensure compliance with and completion of treatment. Anticipate abandonment of treatment, and address the causes, which vary from country to country.
- Maintain a database of patients using free resources such as POND4kids ([www.pond4kids.org](http://www.pond4kids.org)).
- Engage in the education and training of healthcare professionals, including nurses and doctors, by using free resources such as cure4kids ([www.cure4kids.org](http://www.cure4kids.org)) as well as conducting in-house workshops.
- Aim to be part of regional, national and international collaborative groups to derive benefit from shared expertise and uniformity of treatment and supportive care.
- Develop parent support groups and provide resources for food, lodging and transport.

In countries where there is an improving infrastructure, the following cancers may have a good or reasonable chance of cure:

- **Standard-risk acute lymphoblastic leukaemia:** children aged 2–10 years, with a white blood cell count of  $< 50 \times 10^9/\text{litre}$ , may have a reasonable chance of cure with induction chemotherapy (vincristine, prednisolone, asparaginase) followed by maintenance chemotherapy as described below without the use of intensification

modules. However, **CNS-directed therapy with cranial radiotherapy plus limited intrathecal methotrexate or intrathecal methotrexate throughout therapy is required in all cases.**

- **Hodgkin's disease:** chlorambucil, vinblastine, procarbazine, prednisolone (ChVPP) or mustine, vinblastine, procarbazine, prednisolone (MVPP) – six to eight courses.
- **Burkitt's lymphoma:** single-agent cyclophosphamide with intrathecal methotrexate and hydrocortisone. Alternatively, cyclophosphamide, vincristine, methotrexate, prednisolone (COMP) chemotherapy with intrathecal methotrexate and hydrocortisone.
- **Non-Burkitt/non-Hodgkin's lymphoma:** early stage – surgery plus COMP or cyclophosphamide, Adriamycin, vincristine, prednisolone (CHOP).
- **Brain tumours:**
  - Resectable low-grade gliomas: surgery alone.
  - Medulloblastoma and ependymoma (resectable/non-metastatic): surgery followed by **radiotherapy**.
- **Retinoblastoma:** enucleation (radiotherapy in some cases).
- **Neuroblastoma** (stage I and II): surgery alone.
- **Wilms' tumour:**
  - Stage I: surgery plus 10 doses of vincristine (at weekly intervals).
  - Stage II (and possibly stage III): surgery plus vincristine/actinomycin for 6 months.
- **Resectable embryonal rhabdomyosarcoma** (certain sites): surgery plus vincristine/actinomycin D (four courses).
- **Germ-cell tumours:**
  - **Mature and immature teratoma:** surgery alone.
  - **Malignant germ-cell tumours (stage I):** surgery alone.

## Specialist cancer centres or units

### Establishment

- Specialist cancer centres or units, and the use of standard treatment protocols (discussed below), have both been fundamental to the ever-improving survival of children with cancer in resource-rich countries.
- Cancer is a relatively rare disease and its treatment is usually complex.
- Management requires a dedicated and experienced multidisciplinary team.
- **Every country should aim to have at least one adequately equipped and funded centre, and then develop shared care or a satellite centre.**

### Advantages of a specialist children's cancer centre or unit

- Development of medical, nursing and paramedical expertise.
- Improved supportive care, including pain relief for children.
- Facilities to protect cancer patients from other children suffering from contagious diseases.
- Opportunities for training and retention of staff, leading ultimately to accreditation as a principal care centre in paediatric oncology.
- Improved support, education and counselling of affected children and their families.

- Stimulus for the development of similar units in the same part of the world.
- Improved opportunities for research, including the development of treatment protocols relevant to the particular region or country.
- Development of links with national and international oncology units and organisations.

### Requirements of a specialist children's cancer centre or unit

- Dedicated paediatric oncologist(s) and nursing staff supported by nutritionists, psychologists and social care workers.
- General surgeon and neurosurgeon trained in paediatric surgery.
- Access to radiotherapy and services of a radiotherapist.
- Blood and platelet banking facilities.
- Pathologist with experience of paediatric tumours with adequate histology and cytology facilities (immunohistochemistry is desirable; this can be in a centralised laboratory if it provides a service for more than one centre or country).
- Haematology, biochemistry and microbiology laboratories with good quality control.
- Diagnostic imaging: X-ray, ultrasound; CT imaging is desirable, especially for brain tumours. Families may have to pay for these, which is often a limiting factor that determines whether a child is diagnosed and treated properly. Fine-needle aspiration is important, as are lumbar punctures performed under appropriate analgesia and sedation.
- It is vital to have good supportive care, including regular supplies of medication, good stock-keeping and drug ordering (ensure that drugs are not stolen and sold on the 'black market'), IV fluid management systems to avoid tumour lysis syndrome, and good post-operative care.
- Adequate bed capacity. Most units are constantly overcrowded, with two patients per bed, and as units develop it is essential to build the capacity to cope with increasing numbers of patients.
- Computer facilities with Internet connections (for emailing to the link centre, Medline searches, patient database).
- Active involvement in auditing practice and participating in research.

**Above all, there must be a keenness of all staff to work together to learn and make the unit successful.**

### Centre or unit database

All centres or units should keep a record of treatment, including details of patient demographics, diagnosis, treatment, side effects and survival. This will aid the identification of specific problems, the development of more effective treatment protocols for treatment and supportive care, and overall healthcare planning and development. The availability of free online and electronic resources such as POND4kids ([www.pond4kids.org](http://www.pond4kids.org)) makes this feasible.

### Links with other centres or units and organisations

Provision should be made for communication and transportation for patients from remote areas. Satellite or shared-care centres can be developed by linking with

healthcare facilities in other areas so that appropriate care can be continued (e.g. district hospitals).

### **Links with centres or units in resource-rich countries (twinning)**

Links with an established unit in resource-rich countries can have the following advantages:

- sharing information and experience on how to raise awareness of cancer and reduce delays in diagnosis
- helping to speed up diagnosis and make it more precise
- development of locally affordable supportive, palliative and curative care guidelines
- helping to train and retain staff
- helping to create patient data registration
- help to develop long-term sustainability
- providing support and advice for difficult problems (e.g. by email or web conferencing)
- pathology samples can be couriered for more complex testing (e.g. for immunophenotyping, special staining, VMMA, etc.)
- research collaboration.

In addition, links with international organisations are to be encouraged – for example, with the International Society of Paediatric Oncology (SIOP).

### **Principles of the curative treatment of children with cancer as undertaken in a specialised unit or centre**

#### **Diagnosis**

- A complete history and examination.
- Investigations to confirm histology, determine the extent of the tumour (staging) and identify any tumour-related toxicity (e.g. disturbance of renal, liver and/or bone-marrow function).

#### **Imaging**

- To define the dimensions of the primary tumour and to determine the degree of tumour spread (staging).
- Good plain posterior–anterior and lateral chest X-rays are generally adequate for chest imaging, while **CT scan of the chest may be more definitive if it is available.**
- Ultrasonography affords good visualisation of the abdomen and pelvis, although **CT of the abdomen and pelvis may have advantages over ultrasonography in some patients.**
- Intravenous urography and cavagrams may also be useful in patients with abdominal tumours.
- For the brain, CT scanning is a necessary part of investigation and management. **MRI of the brain has advantages over CT**, but the availability of this technique is very limited.
- **Nuclear imaging can further assist in accurate staging (e.g. technetium bone scan for bone and soft tissue sarcomas, and metaiodobenzylguanidine (MIBG) scan for neuroblastomas).**

#### **Biochemical markers**

These are useful in the diagnosis of a limited number of tumours (e.g. urinary catecholamines in neuroblastoma, and serum alpha-fetoprotein in hepatoblastoma and germ-cell tumours).

#### **Pathology**

- Good histopathology is essential for the individual, and is the only way to compile accurate incidence figures and survival data and to identify favourable histological subgroups.
- Close involvement of the pathologist is needed before biopsy or surgery so that the surgeon can obtain an optimal specimen in the right fixative.

#### **Multidisciplinary team meetings**

Following initial clinical assessment and investigation, all children with cancer should ideally be discussed at regular multidisciplinary team meetings that may include the oncologist, radiologist, surgeon and radiotherapist. Such discussions are also recommended at the time of significant events during treatment (e.g. progression or relapse). This ensures that the child benefits from the collective knowledge of the treating team and there is consistency in treatment. However, this can be difficult as staff will be very busy and may require extra funding.

#### **Treatment protocols**

- Each unit should use a standard protocol for each tumour type, with the necessary variations for tumour stage.
- Protocols should be based on established and effective protocols used by national and international groups.
- Protocols may require modification based on the resources, drug availability, cost and the level of supportive care that can be provided by the unit.
- Such protocols are currently being developed by the SIOP Paediatric Oncology in Developing Countries (PODC) Graduated Intensity Treatment Guidelines Working Group. The first such protocol for acute lymphoblastic leukaemia was recently published.

#### **Chemotherapy**

- Late diagnosed childhood malignant tumours are almost always disseminated, requiring treatment with systemic chemotherapy.
- Cytotoxic drugs prevent cell division by a variety of mechanisms.
- Although occasionally single-agent therapy is given (e.g. for stage I Wilms' tumour), the great majority of treatment protocols employ a combination of drugs used synergistically to produce maximal cell kill with acceptable toxicity, and to prevent tumour cell resistance.

#### **Surgery**

- This is important both for obtaining diagnostic material, and as local therapy to reduce tumour bulk. Surgeons should be specially trained and have experience in oncology.
- It is preferable for surgeons to have received specific training in operating on children and in tumour surgery.
- Operating facilities must be of high quality to reduce the risk of infection.
- There must be adequate support from blood transfusion services.
- Several treatment protocols use pre-operative chemotherapy, which may reduce tumour size, and thus reduce peri-operative risks.

### Radiotherapy

- Radiotherapy is used to treat regional tumour extension, including nodal disease, and as part of local tumour control to eradicate local residual microscopic (or sometimes macroscopic) disease following surgery.
- It has a particular role to play in certain brain tumours, and may also be used as curative therapy in early-stage Hodgkin's disease.
- It is also frequently used in the management of bone and soft tissue sarcomas and in the prevention of overt central nervous system disease in acute lymphoblastic leukaemia.
- Megavoltage machines have advantages over the older orthovoltage therapy in giving a more controllable beam and avoiding damage to skin and overlying tissues when administered to deep tissues.
- The whole of the original tumour volume is generally irradiated, plus a safety margin (usually 1–2 cm) of surrounding normal tissue.
- The combination of chemotherapy and radiotherapy can increase late local effects and should be avoided whenever possible.

### Procedures

#### Bone-marrow aspiration

- This is needed in the diagnosis of leukaemia and lymphoma, and also to identify any bone-marrow infiltration with solid tumours such as neuroblastoma.
- **It is a painful procedure and must be done under analgesia and sedation (e.g. ketamine 2 mg/kg) (see Section 1.15 and Section 1.24) along with infiltration of the skin and subcutaneous tissues down to periosteal level with a local anaesthetic.**
- Aspiration is preferably performed from the posterior iliac crest, but can also be taken from the anterior crest.

#### Lumbar puncture

- This is needed in the diagnosis of malignant meningitis, especially with leukaemia and lymphoma, but also in certain brain tumours (e.g. medulloblastoma) and other solid tumours, particularly those affecting the head and neck.
- **Lumbar puncture is a painful procedure, and in children should be done under analgesia and sedation along with local anaesthetic wherever possible (especially if multiple lumbar punctures are needed).**

#### Venous access

- Venepuncture for administration of chemotherapy and blood sampling is painful and especially difficult in the young child (analgesia and sedative cover may be needed).
- Repeated venepuncture results in loss of venous access due to venous thrombosis, and may significantly compromise therapy.
- Several agents, especially vinca alkaloids, are extremely damaging to tissues when extravasated.
- Short-term percutaneous placement of medium-length or long lines under local anaesthetic may provide an alternative means of venous access.
- **The placement of a long-term central venous catheter (e.g. Broviac line, Hickman line) (if available) can be considered in children receiving intravenous chemotherapy. It should be placed by an**

**experienced surgeon, and its use is associated with an increased risk of infection, particularly from skin organisms such as staphylococci.**

### Psychological support

Cancer and its treatment are frightening experiences for many patients, and every attempt should be made to reduce the child's fears. An explanation of the diagnosis and treatment, including the likely outcome, should be given in clear understandable terms to the child's family and also to the affected child or young adult wherever appropriate. Such information is best delivered over more than one conversation, allowing the family to understand it and come back to ask questions.

All aspects of treatment and associated side effects should be clearly explained, including details of supportive care, such as infection control, the **importance of seeking a healthcare worker if a fever develops**, mouth care, pain relief, care of lines, and procedures, such as surgery, bone-marrow aspirate and lumbar puncture. These conversations need to continue throughout treatment, thus establishing a relationship with the child and their family. The family must always be fully involved in the patient's care (e.g. by donating blood when it is needed). Parents want their child's doctor to focus on a potential cure and relief of symptoms, and then they can have faith in the doctor and derive hope for the future.

### Side effects of the disease and/or its treatment

TABLE 5.14.1 General side effects of chemotherapy

<i>Acute effects</i>	
Bone-marrow suppression	
<ul style="list-style-type: none"> <li>● Infection</li> <li>● Bleeding</li> <li>● Anaemia</li> </ul>	
Nausea and vomiting	
Mucositis	
Alopecia	
Fatigue and cachexia	
Tumour lysis syndrome	
<i>Late effects</i>	
Infertility	
Secondary malignancy	

TABLE 5.14.2 Specific side effects of chemotherapy

<b>Neurotoxicity</b>	Vincristine (muscle weakness due to peripheral neuropathy, constipation, rarely encephalopathy)
<b>Cardiomyopathy</b>	Doxorubicin/daunorubicin
<b>Respiratory system</b>	Bleomycin
<b>Urinary tract</b>	Cisplatin (renal), ifosfamide (renal and bladder), cyclophosphamide (bladder)
<b>Liver</b>	Thioguanine, actinomycin D
<b>Hearing</b>	Cisplatin

### Infection

- Neutropenia, both at diagnosis in leukaemia and following most chemotherapy, produces a risk of significant

bacterial and fungal sepsis derived from the patient's own flora when the neutrophil count is  $< 1.0 \times 10^9/\text{litre}$ , and particularly when it is  $< 0.2 \times 10^9/\text{litre}$ .

- The greatest risk is from Gram-negative bowel organisms such as *E. coli*, *Proteus*, *Klebsiella* and *Pseudomonas*.
- Gram-positive organisms from the skin and mucosal surfaces, especially staphylococci, may also cause significant morbidity.
- Life-saving measures include identification of those at risk, close observation, and the empirical administration of intravenous antibiotics to patients with a neutrophil count of  $< 1.0 \times 10^9/\text{litre}$  who develop fever (e.g.  $> 38^\circ\text{C}$  for 2 hours or  $> 38.5^\circ\text{C}$  on one occasion).
- The antibiotic regimen should be determined by each centre depending on the prevailing flora and the cost and availability of antibiotics.
- First-line therapy for febrile neutropenia should generally be with a combination of a broad-spectrum beta-lactam antibiotic and an aminoglycoside.
- If the temperature fails to remit, or if Gram-positive organisms are isolated, therapy with vancomycin or teicoplanin is recommended.
- For microbiologically proven septicaemia, antibiotics should be given for 5–7 days, the choice of drug depending on the antibiotic sensitivity of the isolated organism.
- Newer very broad-spectrum antibiotics, such as the carbapenems and quinolones, are best avoided as they are expensive and may promote fungal colonisation and bacterial resistance if commonly or repeatedly used.
- If systemic fungal infection is proven or suspected (e.g. if fever fails to remit after 4–5 days of antibiotics), then intravenous amphotericin, despite its renal toxicity, is still the drug of choice and is widely available. Newer lipid-based formulations of amphotericin are less toxic but very expensive.
- *Pneumocystis carinii* pneumonia, especially in patients with leukaemia, requires prophylaxis with co-trimoxazole (calculated as a dose of  $150\text{ mg}/\text{m}^2/\text{day}$  of trimethoprim given twice a week).
- Viral infections are generally tolerated, but chickenpox and measles cause life-threatening infections in immunosuppressed patients. Whenever possible, children must be isolated from direct contact with these infections. **Immunoglobulin therapy, including zoster immune globulin, may be life-saving but is rarely available.**
- High-dose aciclovir is the treatment of choice for zoster infections, but is expensive and not yet widely available globally.

### Bleeding and anaemia

- Adequate blood banking facilities with availability of blood component therapy such as packed red blood cells and platelets (see Section 1.7) are a fundamental part of therapy. Red blood cell transfusion should be reserved for symptomatic anaemia, or when the haemoglobin falls to a very low level (e.g.  $< 6\text{ grams}/\text{dL}$ ).
- Platelets should be reserved for patients with florid petechiae or overt bleeding, or to cover procedures such as lumbar puncture, when a platelet count of  $> 40 \times 10^9/\text{litre}$  is essential.
- Prophylactic platelet transfusions in response to specific platelet counts are not recommended.

- In the presence of fever, bleeding may occur at higher platelet counts than would normally be expected.

### Nausea and vomiting

- Nausea and vomiting are a very unpleasant side effect of chemotherapy and can lead to poor compliance with therapy and additional complications, such as metabolic disturbance, dehydration and oesophageal tears.
- Chemotherapeutic agents vary in their potential to produce vomiting, from very low (e.g. vincristine and etoposide) to very high (e.g. cisplatin). Anti-emetic therapy should be given wherever possible, preferably prophylactically, but certainly to patients with established retching and vomiting.

### Anti-emetic agents

- **Metoclopramide:** this is effective in high dose, but a greater risk of extrapyramidal side effects exists in children. Give  $100\text{ micrograms}/\text{kg}$  for 1/12 to 1 year, 1–3 years  $1\text{ mg}$ , 3–5 years  $2\text{ mg}$ , twice daily and 5–9 years  $2.5\text{ mg}$ , 9–18 years  $5\text{ mg}$  thrice daily orally or slowly (over 2 minutes) by IV injection. Over  $60\text{ kg}$  children can have  $10\text{ mg}$  three times daily. **Avoid the IM route.**
- **Chlorpromazine:** orally or IV (the IV route can cause severe hypotension), child 1–12 years  $500\text{ micrograms}/\text{kg}$  every 4–6 hours, maximum  $75\text{ mg}$  daily. For 12–18 years  $25\text{--}50\text{ mg}$  every 3–4 hours until vomiting stops.
- **Prochlorperazine:** orally or IV slowly over 10 minutes,  $250\text{ micrograms}/\text{kg}$  1–12 years every 8–12 hours (only if the child weighs over  $10\text{ kg}$  or is over 1 year of age). 12–18 years  $5\text{--}10\text{ mg}$  three times daily.

The following drugs are generally available but have a high incidence of side effects, including drowsiness. They may be more effective when combined with steroids.

- **Benzodiazepines:** the main effect is sedation and amnesia. These drugs are useful for anticipatory nausea.
- **Steroids:** the main effect is in combination with other agents (prednisolone  $0.5\text{ mg}/\text{kg}$  every 12 hours).
- **5HT<sub>3</sub> antagonists (e.g. ondansetron):** these are the most effective anti-emetics, especially when combined with steroids. However, they are expensive.

### Ondansetron dosage

Six months–18 years either  $5\text{ mg}/\text{m}^2$  or  $150\text{ micrograms}/\text{kg}$  (max single dose  $8\text{ mg}$ ) IV before chemotherapy then repeated every 4 hours for two further doses, then give orally. Oral dose  $< 10\text{ kg} = 2\text{ mg}$  12 hourly,  $> 10\text{ kg} = 4\text{ mg}$  12 hourly for up to 5 days.

### Oral mucositis

- This is a common side effect of many cytotoxic agents and also radiotherapy.
- **Scrupulous simple oral hygiene should be maintained. This can be achieved by regular thorough tooth brushing two to three times a day together with use of a mouthwash such as chlorhexidine if available.**
- Oral fluconazole and oral acyclovir may be of benefit in oral mucositis with secondary infection from candida and herpes infection, respectively.

### Alopecia

This is inevitable with most chemotherapy, but usually entirely reversible on completion of treatment. Some children are not upset by the appearance of alopecia, but for those who are distressed by it, a light but attractive head covering may be acceptable.

### Nutrition

Maintenance of adequate nutrition is essential. 'Cancer wasting' or cachexia is a well-recognised complication of paediatric tumours, and is subsequently associated with a decreased tolerance of chemotherapy and its side effects, and possibly an increase in cancer mortality.

Poor nutritional status may result from any of the following:

- stress
- pain
- increased metabolism (due to tumour or infection)
- anorexia
- altered sense of taste and smell
- chemotherapy-induced nausea and mucositis (e.g. stomatitis, oesophagitis)
- radiotherapy-induced mucositis and dry mouth (xerostomia)
- surgery-induced pain, bowel obstruction and appetite suppression.

In addition to this, an unacceptably high number of children in resource-limited countries who do not have cancer are malnourished. The effect of cancer and its treatment can be even more deleterious for such children.

**Each child should have a nutritional assessment, including measurement of height or length, weight, mid upper arm circumference and triceps fold thickness (using callipers). Height and weight should be plotted on a standard percentile chart (see Section 9).**

Nutritional support should be given to children who consistently show a decrease across percentile lines. It may also be indicated in children with baseline malnourished status. A high-calorie diet with adequate protein should be given to all children with cancer, supplemented if necessary with specific additives to provide additional calories and protein.

If sufficient food cannot be taken orally, enteral feeding via a nasogastric tube (particularly overnight) should be considered. Total parenteral nutrition should be avoided, as it is expensive and associated with a high risk of complications, including infection and metabolic disturbance.

### Tumour lysis syndrome (TLS)

This is a life-threatening complication that occurs when the rapid lysis of tumour cells, usually resulting from chemotherapy, leads to the release of excessive quantities of cellular contents into the systemic circulation, resulting in a metabolic disturbance characterised by the following:

- hyperkalaemia
- hyperphosphataemia
- hyperuricaemia
- hypocalcaemia.

This metabolic derangement may lead to acute oliguric renal failure and cardiac arrhythmias.

TLS can occur spontaneously in tumours with a very high proliferative rate, as well as following initiation of treatment. It can be classified as laboratory TLS (with no clinical

manifestations) or clinical TLS (with life-threatening clinical abnormalities).

### Management of TLS

- Most importantly, anticipate and recognise patients who are at high risk of tumour lysis, i.e. those with leukaemia and lymphoma (particularly T-cell or Burkitt's phenotype, and those with a high white cell count  $> 50 \times 10^9/\text{litre}$ , hepatosplenomegaly or mediastinal mass, or high LDH).
- Intravenous hydration with potassium-free fluids, at least 2.5–3.0 litres/m<sup>2</sup>/day, should be commenced prior to treatment and then continued for the first few days of treatment. Ensure that there is adequate urine output ( $\geq 1 \text{ mL/kg/hour}$ ).
- Regular allopurinol, 100 mg/m<sup>2</sup> dose every 8 hours, should be commenced prior to treatment and then continued for the first few days of treatment.
- Clinical and laboratory monitoring should be undertaken, including daily weight, input and output review, and assessment of blood biochemistry, with measurement of uric acid levels up to four times a day if needed.

### Infertility

- This mainly occurs in males and is a consequence of specific cytotoxic agents, especially the alkylating agents such as cyclophosphamide, or radiation to the gonads. Girls may suffer from ovarian failure causing a premature menopause after certain therapies.
- Families should receive counselling about infertility, and hormonal treatment may be offered.
- Sperm storage for adolescent boys before the start of treatment can be considered if this service is available.

### Second tumours

- Chemotherapy results in a small but important risk of second tumours, especially acute myeloid leukaemia.
- This is particularly associated with alkylating agents such as cyclophosphamide (especially if used with radiotherapy), anthracyclines and topoisomerase-2 inhibitors (e.g. etoposide).

### Treatment of individual tumour types

A detailed discussion of the presentation and management of every type of tumour is beyond the scope of this book.

### Acute lymphoblastic leukaemia (ALL)

Approximately one-third of all children under 15 years of age with cancer have acute leukaemia, and 75–80% of these have acute lymphoblastic leukaemia, making it the most common childhood cancer in well-resourced countries.

### Presentation

- Myelosuppression.
- Anaemia, infection (which can be life-threatening) and thrombocytopenia (bruising, bleeding, petechiae).
- Lymphadenopathy and hepatosplenomegaly.
- Bone pain and limp.

### Diagnosis

- Full blood count.
- Blood film can be diagnostic for patients with very high white cell counts.
- Bone-marrow aspirates (these are always required).

- Morphology (e.g. FAB system), cytochemistry and immunocytochemistry (if available).
- Lumbar puncture: CSF cell count and cytospin for lymphoblasts.
- Chest X-ray (T-cell leukaemia).
- Ultrasound scan of the abdomen for assessment of the liver, spleen and kidneys.

### Treatment

Rapid tumour lysis, which can sometimes be spontaneous, is a major risk, particularly for patients with high white cell counts leading to biochemical disturbances. **Intravenous fluids, allopurinol and close monitoring of renal function are required at the start of treatment.** The treatment of acute lymphoblastic leukaemia is divided into a number of phases, as described below.

### Induction

The aim is to get the patient into remission (defined as the presence of < 5% blasts in bone marrow). Four weeks of oral prednisolone or dexamethasone with weekly vincristine injections will result in a 90% remission rate, *although the addition of a third drug, asparaginase (9–12 doses every 48 hours), is associated with improved long-term survival. If asparaginase is not available or is too expensive, anthracyclines (e.g. doxorubicin) can be substituted.*

### CNS-directed therapy

*This is needed in all patients to prevent CNS relapse. Standard therapy is to give five to six doses of intrathecal methotrexate together with cranial irradiation (18 Gy). For standard-risk (not high-risk) patients, irradiation can be replaced with intrathecal methotrexate at regular intervals throughout the treatment period, although some units may find radiotherapy easier to administer than repeated lumbar punctures.*

### Intensification therapy

*The administration of periods of more intensive therapy (e.g. with drugs such as cyclophosphamide, daunorubicin and cytosine) has been associated with increased survival, although this treatment carries the risk of severe myelosuppression and should be used with caution unless a high level of supportive care is in place.*

### Continuation (maintenance) therapy

This essential part of treatment generally lasts for 2 to 3 years. Most regimens employ daily oral mercaptopurine and weekly oral methotrexate with vincristine and a short course of steroid given every month.

### Prognosis

With current therapy in specialised centres one can expect at least 50% of standard-risk patients (i.e. those with a white cell count at diagnosis of < 50 × 10<sup>9</sup>/litre, and aged 2–10 years) to survive.

### Acute myeloid leukaemia (AML)

This accounts for 15–20% of acute leukaemias in children.

### Presentation

The presentation is the same as for acute lymphoblastic leukaemia, with more likelihood of tissue infiltration:

- gum hypertrophy: monocytic leukaemia

- skin involvement: myeloblastic leukaemia
- disseminated intravascular coagulation: promyelocytic leukaemia.

### Diagnosis

See above section on acute lymphoblastic leukaemia.

### Treatment

**This is less successful than for acute lymphoblastic leukaemia.** *Induction therapy is based on 8–10 days of intensive chemotherapy with drugs such as daunorubicin, etoposide, thioguanine and cytosine. Remission rates of over 80% can be achieved, but these regimens are associated with severe and prolonged myelosuppression, with a significant risk of toxic death. This risk should be carefully considered before curative therapy is attempted. Consolidation therapy is again based on intensive and life-threatening chemotherapy. The risk of CNS relapse is less than with acute lymphoblastic leukaemia. Lumbar puncture with triple intrathecal chemotherapy (methotrexate, hydrocortisone and cytosine) should be given with each course of chemotherapy.*

### Prognosis

Less than 50% of these children will be expected to survive long term, with a high risk of toxic death following intensive chemotherapy.

### Non-Hodgkin's lymphoma (NHL)

Childhood NHLs are a heterogeneous group of usually diffuse lymphocytic or lymphoblastic neoplasms arising from both B and T cells. Burkitt's lymphoma, a B-lineage NHL, is the most common childhood malignancy reported from tropical Africa, and is also prevalent in South America and in parts of South-East Asia.

### Presentation

Lymphomas can arise in any area of lymphoid tissue, and therefore the presenting features are protean. Patients often have marrow involvement and sometimes CNS disease.

- Burkitt's lymphoma is an aggressive tumour, usually affecting the head and neck, but also arising from several abdominal organs. **Progression in size of Burkitt's lymphoma can be rapid, given its 48-hour doubling time.** Head tumours usually present with extensive involvement, with swelling of the jaw and tooth loosening, gum expansion, bleeding, ulceration and exophthalmos.
- The majority of non-Burkitt B-cell lymphomas are disseminated at diagnosis, often with diffuse abdominal disease.
- T-cell NHL presents with thymic and/or nodal involvement, often with signs of airway or superior vena cava obstruction.

### Diagnosis

The diagnosis is frequently suggested on clinical examination (e.g. classical features of Burkitt's or T-cell lymphoma). The diagnosis is supported by appropriate imaging (X-ray, ultrasound). Bone-marrow aspiration and lumbar puncture should be performed. Biopsy is necessary if the diagnosis cannot be made on a bone-marrow aspiration.

**Treatment****Burkitt's lymphoma**

This is an extremely chemosensitive tumour, and a high remission rate can be achieved with a single course of cyclophosphamide. **Repeated courses of cyclophosphamide may be successful in some early-stage patients, but the success of therapy is further improved, particularly for patients with advanced disease, by the use of multi-agent chemotherapy using combinations such as COMP (cyclophosphamide, vincristine, methotrexate and prednisolone), for example, given over a 6-month period. This should be accompanied by administration of intrathecal methotrexate and hydrocortisone.** As with acute lymphoblastic leukaemia, biochemical disturbance as a result of rapid tumour lysis is a major risk, and intravenous fluids, allopurinol and close monitoring of renal function are required.

**Non-Burkitt B-cell NHL**

**Repeated courses of multi-agent chemotherapy with COMP or CHOP (cyclophosphamide, Adriamycin, vincristine and prednisolone) are often successful, especially for early-stage disease. For advanced disease, more intensive regimens such as the French LMB protocols may result in a high success rate, although the toxicity of these regimens is potentially high.**

**T-cell NHL**

**In contrast to B-cell NHL, therapy for T-cell disease is usually based on leukaemia-type therapy (with intensification modules and continuing chemotherapy). CNS-directed therapy with cranial irradiation or moderate-dose methotrexate with ongoing intrathecal methotrexate should be used.**

**Prognosis****Burkitt's lymphoma**

The prognosis varies according to the stage of disease, although overall at least 85–90% of patients will be cured with modern therapy in well-resourced countries. Where ability to give chemotherapy is restricted, simpler therapy can yield 50–60% survival rates. However, CNS disease is associated with a poor outcome.

**Non-Burkitt B-cell NHL**

The prognosis is poorer than with Burkitt's lymphoma, and depends on the stage of disease and the intensity of treatment. In low-stage disease a survival of at least 75% is expected. The prognosis is worse with extensive disease, particularly with bone-marrow or CNS involvement.

**T-cell NHL**

With modern leukaemia-type therapy, survival rates are around 65–70% or higher.

**Hodgkin's lymphoma****Presentation**

Unlike NHL, Hodgkin's lymphoma tends to be confined to the lymph nodes or spleen, although spread to other sites, such as the lungs, liver and bone, may occur. Most children present with a primary painless neck mass, although any nodal group may be involved. Patients are staged according to the Ann Arbor system, which incorporates an A and B

designation for the absence or presence, respectively, of fever, night sweats and weight loss.

**Diagnosis**

Diagnosis is generally made by lymph-node biopsy. Essential staging investigations include chest X-ray and abdominal ultrasound. Bone-marrow aspirate and trephine should be performed on patients with evidence of advanced disease.

**Treatment**

*In the past, radiotherapy was widely utilised, often using extensive radiation fields (e.g. the 'mantle' or 'inverted Y' techniques) to cover all known sites of disease. Radiation is still used in localised disease, but generally chemotherapy is preferred for most patients, using regimens such as ChlVPP (chlorambucil, vinblastine, procarbazine and prednisolone) or MVPP (with nitrogen mustard replacing chlorambucil). Six to eight courses are given every month. Such chemotherapy may be given on an outpatient basis, and is relatively non-toxic, although the risk of infertility in boys is high. Some of the toxicity can be avoided by alternating ChlVPP or MVPP with ABVD (doxorubicin, bleomycin, vinblastine and dacarbazine), although this may have the potential to cause cardiotoxicity.*

**Prognosis**

Hodgkin's lymphoma generally carries a good prognosis. For patients with stage I and II tumours, over 80% are expected to be cured. Even with advanced disease, over 50% of patients would be expected to survive.

**Brain tumours**

These are a heterogeneous collection of several tumours that together represent around 25% of all childhood cancer patients in Europe and North America. The proportion in resource-limited countries is much lower, at least partly due to under-diagnosis as a result of limited availability of neuroimaging (CT and MRI), neurosurgery and neuropathology.

**Presentation**

About 60% of childhood brain tumours arise in the posterior fossa, and usually present with signs and symptoms of raised intracranial pressure due to obstruction of CSF pathways. A variety of other presenting features may occur, depending on the site and rate of progression of the tumour. These include irritability, behavioural disturbance, cranial nerve palsies, long tract signs (particularly truncal ataxia), endocrine abnormalities, visual disturbance and seizures.

**Diagnosis**

Modern imaging with **CT scanning, or preferably MRI (if available)** has revolutionised the management of brain tumours, and should be performed if CNS tumours are suspected. Some tumours have characteristic appearances on imaging (e.g. diffuse brainstem glioma and optic nerve glioma), although most tumours require histological confirmation. Imaging of the spine and examination of the spinal fluid is required to assess for CNS spread in high-grade bone tumours (e.g. medulloblastomas, high-grade gliomas).

**Treatment**

For most tumours, modern neurosurgery (see Section 5.16.K) is vital to management. Prompt relief of raised intracranial pressure is often required, and may be

life-saving. This is achieved with dexamethasone, which when used peri-operatively has also been shown to significantly reduce operative mortality.

Surgery may also be required to relieve hydrocephalus (e.g. with ventricular peritoneal shunting). The aim of definitive surgery is to provide a histological diagnosis and usually to shrink the tumour as much as possible. Tumour resection is required for most tumours, including all posterior fossa tumours (except the brainstem), tumours of the cerebral hemispheres and craniopharyngiomas. Some tumour types may be cured with surgery alone (e.g. cerebellar low-grade astrocytoma), although others (e.g. medulloblastoma) require **adjuvant radiotherapy**.

*Generally a large dose of radiotherapy is given to the tumour bed, while some tumours (e.g. medulloblastoma) require whole CNS radiotherapy due to the high risk of CSF dissemination. To date chemotherapy has had relatively little impact on the treatment of brain tumours, although it can be used to try to delay radiotherapy in the very young.*

Radiotherapy to the whole brain and spine has a very high risk of sequelae, particularly in young children. These include neuropsychological disability, growth failure (growth hormone deficiency and poor spinal growth) and hypothyroidism.

The following is a brief guide to the management and prognosis of individual tumour types.

### **Medulloblastoma**

#### **Prognosis**

The prognosis is around 60% for children with non-metastatic disease and 30% for those with disseminated disease. Children with medulloblastoma aged less than 3 years have a much worse prognosis than older children. Radiotherapy may be curative, but most centres do not advocate this, as radiation therapy to the developing brain is associated with a very high incidence of severe handicap. Prolonged chemotherapy can be used to try to delay radiotherapy, but even then survival is only around 20%.

### **Cerebellar low-grade astrocytoma**

#### **Treatment**

Surgical resection is performed, and post-operative radiotherapy is not required if the resection has been complete.

#### **Prognosis**

The prognosis is at least 80% following total resection.

### **Supratentorial low-grade astrocytoma**

#### **Treatment**

Surgical resection is performed for accessible lesions, although many of these tumours (e.g. those involving the hypothalamus and optic pathways) are not fully resectable. In these cases, focal radiotherapy should generally be given, particularly in patients with progressive disease.

#### **Prognosis**

The prognosis is variable, mainly depending on the site of the tumour.

### **High-grade glioma**

#### **Treatment**

Surgical resection (as complete as possible) is performed, and post-operative focal radiotherapy is required.

#### **Prognosis**

Overall, the prognosis is very poor, at around 15%. Patients who undergo complete resection and have Grade 3 (anaplastic astrocytoma) tumours have a much better chance of survival than those who undergo subtotal resection and have Grade 4 tumours (glioblastoma multiforme).

### **Ependymoma**

#### **Treatment**

Surgical resection (as complete as possible) is performed, and post-operative focal radiotherapy is required.

#### **Prognosis**

The prognosis is around 30–50%, mainly depending on the degree of tumour resection.

### **Brainstem glioma**

#### **Treatment**

Focal exophytic tumours are treated with surgery followed by focal radiotherapy.

#### **Prognosis**

The prognosis is around 30–50%, mainly depending on the degree of tumour resection.

### **Diffuse (malignant) brainstem gliomas**

#### **Treatment**

Palliative radiotherapy may possibly be used.

#### **Prognosis**

These tumours are fatal (less than 5% survival).

### **Craniopharyngioma**

#### **Treatment**

Surgical resection is performed, although there is a high peri-operative mortality rate. *Radiotherapy is sometimes used for recurrent tumours.*

#### **Prognosis**

The prognosis is variable. All patients suffer from pan-hypopituitarism, which requires hormone replacement therapy.

### **Neuroblastoma**

This biologically unusual tumour can arise from any part of the sympathetic nervous system, although around 60% originate from the adrenal gland. Localised stage I and stage II disease and the unique stage IV S disease of infancy have a good outlook, although for the 80% of patients who present with advanced tumours the prognosis is very poor.

#### **Presentation**

A large proportion of patients present with an abdominal (adrenal) or pelvic mass, often extending across the midline. Para-spinal masses that extend into the spinal canal causing cord compression, and thoracic primaries that cause airway obstruction, also occur. Most patients (65%) present with metastatic disease that often causes bone pain and limp, with marrow infiltration mimicking leukaemia, skin infiltration or orbital masses causing proptosis or peri-orbital bruising.

#### **Diagnosis**

Ultrasound of the abdomen *(or CT of the abdomen, if*

available), chest X-ray (or CT of the chest for thoracic tumours, if available), abdominal X-ray (calcification is often a feature of primary tumours), 24-hour urine collection or spot urine sample for catecholamine metabolites (secreted in 85% of cases), bone-marrow aspirate and trephine (bilateral) are all helpful. **MIBG scan and technetium bone scan are performed to investigate metastasis to the bones.** Although the diagnosis can be made without tumour biopsy for patients with classic features of stage IV disease, histological confirmation is required for localised tumours and for advanced disease where the diagnosis is in doubt.

#### Treatment and prognosis

Patients with stage I and II disease should be treated with surgical excision, which if complete is associated with an 80% or higher survival rate. *For stage III patients, the prognosis is around 40%, with treatment including multi-agent chemotherapy with drugs such as cyclophosphamide, vincristine, Adriamycin, etoposide and platinum, followed by surgical excision of the tumour.* Stage IV disease has a very poor prognosis, and it is essential to provide palliative care to reduce the suffering of these patients.

#### Retinoblastoma

Although rare in many countries, retinoblastoma is a common paediatric cancer in many areas, including sub-Saharan Africa, Pakistan and India. Two forms are identified, namely an autosomal-dominant heritable form that may affect one or both eyes, and a sporadic (non-heritable) form that is always unilateral.

#### Presentation

Most children present within the first few years of life with a white mass in the pupil or with a squint. In patients with a family history, routine surveillance may detect an early lesion. Delayed presentation may result in a protruding fungating orbital mass.

#### Treatment and prognosis

Enucleation of the involved eye is the standard therapy, and is curative in about 75% of patients with localised disease.

*Very small tumours may also be effectively treated with a cobalt plaque, local irradiation, light coagulation or cryotherapy. External beam radiotherapy may be curative in early cases, but cataract formation usually results. Extensive spread outside the orbit is usually fatal. Relatively simple chemotherapy (e.g. with carboplatin, vincristine and etoposide) appears to be effective in reducing large tumours, sometimes facilitating preservation of vision and possibly preventing metastatic spread.*

#### Wilms' tumour (nephroblastoma)

This tumour occurs in nearly all parts of the world, and is one of the most curable of all childhood cancers. Approximately three out of four cases occur in children under 5 years of age.

#### Presentation

Most patients present with a large and generally painless flank mass with or without haematuria and hypertension. The diagnosis may be confused with the abdominal distension associated with malnutrition and with other flank

masses, such as neuroblastoma and splenomegaly associated with malaria or haemoglobinopathy.

#### Diagnosis

The presence of a renal tumour can be confirmed by ultrasonography, which should also assess the presence of inferior vena cava involvement. Alternatively, intravenous urogram (with injection into the feet to perform a cavagram) can be used, as can **CT scan (with contrast) (if available).** The diagnosis can be made on the basis of clinical presentation and imaging findings. Histopathological confirmation is not mandatory, but is advisable, particularly in those under 6 months of age. A chest X-ray should look for evidence of lung metastases.

#### Treatment

The SIOP approach of up-front chemotherapy (4 weeks of vincristine and actinomycin D for non-metastatic tumours, and 6 weeks of the two drugs plus Adriamycin for metastatic tumours) followed by surgery is more suited to resource-limited countries. The duration and type of further chemotherapy after surgery depend on the local staging of the tumour and the response to initial treatment. For stage I tumours, further vincristine and actinomycin may be given for 4 weeks or 6 months depending on the histological response. For stage II disease, vincristine and actinomycin should be given for 6 months, a regimen which may also be used for stage III tumours with the possible addition of radiotherapy. *For stage IV tumours and for so-called 'unfavourable (anaplastic)' histology groups, all three drugs should be given for 6–12 months. Radiotherapy to the abdomen should only be given if residual bulky disease is present after surgery. Patients with pulmonary metastases at diagnosis should receive lung irradiation (20 Gy), particularly if the lung metastases persist after pre-nephrectomy chemotherapy.*

#### Prognosis

For patients with stage I and II tumours (favourable histology), at least 80% should be cured. Stage III and IV tumours have survival rates of around 60–70% and 50–60%, respectively. However, the prognosis is poor for patients with unfavourable histology.

#### Liver tumours

The two main types of liver tumour are hepatoblastoma and hepatocellular carcinoma (HCC). Although both are rare in Europe and North America, in several parts of the world, such as East Africa and New Guinea, HCC is a relatively frequent childhood malignancy. In children with HCC, as in adults, there is a clear and possibly causative association with hepatitis B infection both in the presence and in the absence of coexisting cirrhosis.

#### Presentation

Hepatoblastoma generally presents in children under 3 years of age, whereas HCC is seen in older children and adolescents. The presentation in both hepatoblastoma and HCC is similar, with most patients presenting with abdominal distension and a right upper quadrant mass. Additional features, particularly for HCC, include abdominal pain, nausea, weight loss, anorexia and jaundice. Features of underlying chronic liver disease may be present with HCC.

### Diagnosis

The liver mass may be seen on ultrasound examination of the abdomen and **CT scan (if available)**. The diagnosis should be confirmed by biopsy. *Alpha-fetoprotein levels are elevated* in nearly all cases of hepatoblastoma and in about 65% of cases of HCC. *In these patients, the alpha-fetoprotein level may be used as a tumour marker to monitor progress*. A chest X-ray should be taken to look for evidence of lung metastases.

### Treatment and prognosis

Surgical excision is the definitive treatment for both tumours. *Hepatoblastoma is a chemosensitive tumour, and pre-operative chemotherapy significantly improves the prognosis, facilitating surgical excision and the control of distant metastases. The most active agents are doxorubicin and cisplatin. Cisplatin monotherapy along with surgery is recommended for localised and non-metastatic tumours.* The prognosis for patients with these tumours is around 50%, although the surgery is difficult and carries significant risks.

The overall prognosis for HCC is very poor. This disease is much less responsive to chemotherapy than hepatoblastoma, and unfortunately these tumours are often multi-centric or extensively invasive, making resection possible in less than 30% of patients. Of these cases, only one-third survive long term.

### Soft-tissue sarcomas

These tumours arise from undifferentiated embryonic tissue. The most common of these is rhabdomyosarcoma, a tumour of striated muscle. Rhabdomyosarcomas can arise anywhere where there is such striated muscle or embryonic remnants thereof, but the most common sites include the orbit, head and neck (including the nasopharynx), the genito-urinary tract in both boys and girls, and the extremities. Two main histological types are recognised, namely the more common embryonal type, and the less common alveolar type, which generally carries a much poorer prognosis.

### Presentation

Most rhabdomyosarcomas present as diffuse masses, but orbital lesions generally present with proptosis and diplopia, and nasopharyngeal lesions often present with nasal obstruction, epistaxis and pain. At least 25% of sarcomas will have metastases at diagnosis, most commonly to the lungs and lymph nodes.

### Diagnosis

Histological confirmation is required by biopsy or excision of the primary tumour. Initial radical surgery should not be performed. Primary tumours should be defined by **CT scan (if available)** (this is particularly important for head and neck and orbital tumours), although other techniques such as tomography and ultrasound examination may be useful. For head and neck lesions, lumbar puncture with careful CSF examination is required. Parameningeal tumours are those in which CSF invasion is demonstrated or possible due to the proximity of the tumour to the meninges based on **CT scanning (if available)**. Metastatic surveillance includes chest X-ray, abdominal ultrasound examination **or CT scanning (if available)**, and bilateral bone-marrow aspiration.

### Treatment

In view of the high rate of local and distal dissemination, chemotherapy is required for all patients. The VAC regimen (vincristine, actinomycin D and cyclophosphamide, four to nine courses), is most commonly used. In more recently devised regimens, ifosfamide has replaced cyclophosphamide (IVA ifosfamide, actinomycin D and vincristine), although ifosfamide carries a far greater risk of side effects, including haemorrhagic cystitis and nephropathy. Unless the tumour can be completely excised, local therapy should generally be performed after cytoreductive chemotherapy (e.g. after three to six courses). Surgery is the usual local therapy for sites such as the extremities and genito-urinary system. For head and neck tumours, surgical excision of the primary tumour is usually extremely difficult, and **radiotherapy should be considered**.

*Radiotherapy is the treatment of choice following chemotherapy for orbital tumours.*

*For parameningeal tumours, whole CNS radiotherapy and intrathecal methotrexate is advised.*

### Prognosis

For completely resected tumours, the prognosis is good, with at least 70% survival. For those with regional disease the prognosis is less good, with about 40–50% survival. Survival is particularly poor for patients with metastatic disease (less than 20%) and for parameningeal tumours, so careful consideration is needed before embarking on a curative treatment for these categories. Alveolar histology confers a significantly worse prognosis for all stages and sites.

### Kaposi's sarcoma

This tumour has become a major healthcare problem in areas affected by the HIV pandemic. Younger children tend to present with disseminated suppurative lymphadenopathy and conjunctival disease, whereas in older children, skin nodules predominate.

### Treatment

*Radiotherapy may control locally aggressive tumours. Kaposi's sarcoma may also respond to chemotherapy, including agents such as vincristine, actinomycin D and DTIC.*

### Bone sarcomas

About 50% of all sarcomas occur in the bone, the predominant types being osteosarcoma and Ewing's sarcoma.

### Presentation

A bone sarcoma usually presents as a painful mass which may be hot and tender, mimicking osteomyelitis. Around 95% of osteosarcomas arise in long bones, and about 50% occur in the upper tibia or lower femur. Around 50% of Ewing's sarcomas occur in long bones, usually in the shaft, with the remainder occurring in the pelvis, shoulder, skull and vertebrae. About 20% of patients with Ewing's sarcoma and 10–20% of those with osteosarcoma have metastatic disease at diagnosis.

### Diagnosis

The diagnosis is suggested on plain X-ray with osteosarcoma showing bony expansion with osteoblastic and/or lytic activity. Ewing's sarcoma generally appears as an

ill-defined lytic lesion. Diagnosis is confirmed with biopsy, preferably using an open technique under direct vision. Chest X-ray or *CT of the chest (if available)* is used to detect lung metastases, the lung being the most common metastatic site for both tumours.

#### Treatment and prognosis for Ewing's sarcoma

*Chemotherapy using vincristine, actinomycin D, Adriamycin and cyclophosphamide should be given to control both local and metastatic disease.* Local therapy with wide surgical excision should be performed. **If this is not possible, high-dose radiotherapy (e.g. 45–50 Gy) should be given**, although for long bone sites amputation may be more appropriate.

The overall prognosis is around 40%, but depends on the site and the adequacy of local tumour control. The prognosis for patients with metastatic disease is very poor.

#### Treatment and prognosis for osteosarcoma

Amputation of the long bone containing the primary tumour only gives a cure rate of about 20%. *Chemotherapy either before or after local therapy has increased survival to around 50% for non-metastatic patients. Six courses of cisplatin and doxorubicin (three pre- and three post-surgery) may be feasible in many resource-limited countries. The current American and European protocols use a combination of cisplatin, doxorubicin and high-dose methotrexate.*

Local control is either with amputation or (if available) with tumour resection and **endoprosthetic bone replacement or rotation plasty**.

#### Germ-cell tumours (GCTs)

Around 3% of tumours in children are GCTs, which are seen mainly in infants and adolescents. They include benign (mature and immature teratoma) and malignant (e.g. yolk sac tumour, germinoma) subtypes.

#### Presentation

In infancy, the usual presentation is a pelvic or sacrococcygeal mass often noticed after birth (or sometimes prior to birth on antenatal scans). In adolescents, GCTs present either as an enlarged mass in the gonads (testicular enlargement or a pelvic mass arising from the ovary) or in the mediastinum with signs of airway or superior vena cava obstruction.

#### Diagnosis

Initial assessment is by X-ray and CT (if available) for mediastinal masses, and ultrasound examination for abdominal and pelvic masses. Assessment of serum alpha-fetoprotein and  $\beta$ -human chorionic gonadotrophin levels can assist in diagnosis and monitoring of the disease.

#### Treatment and prognosis

For mature and immature teratoma as well as malignant GCTs Stage I, surgery alone can be sufficient, with a survival of more than 90%. For more advanced malignant GCTs, four to six cycles of platinum-compound-based chemotherapy in addition to surgery can achieve a survival of around 70%.

#### Palliative chemotherapy and radiotherapy

As stated above, if curative treatment is not possible or has failed, the focus must then be on providing palliative care,

particularly symptom control, including adequate pain relief (see Section 1.15 and Section 1.16). Occasionally, palliative chemotherapy may be appropriate, such as the use of steroids with or without vincristine in relapse or incurable acute lymphoblastic leukaemia and lymphomas. Steroids are also used in the control of symptoms such as headache due to certain brain tumours. Palliative radiotherapy may be useful for treating bone pain caused by tumour infiltration (e.g. in neuroblastoma) and by bone tumours themselves, and may be helpful in controlling symptoms caused by compression of nerves (including the spinal cord) or other vital organs.

#### Conclusion

Although in many resource-limited countries the curative treatment of children with cancer may not be achievable currently, children will present with often distressing symptoms, which we must strive to alleviate and palliate. As infections in particular become more controllable in resource-limited settings, cancer starts to emerge as a major cause of morbidity and mortality. Some allocation of resources becomes inevitable, and as paediatric oncology requires a multidisciplinary approach, thinking about and acting on the problems faced by children with cancer can lead to improvement of care for all children in hospital.

#### Organisations working to advance paediatric oncology around the world

World Child Cancer ([www.worldchildcancer.org](http://www.worldchildcancer.org)): currently working in Mexico, Colombia, Cameroon, Ghana, Malawi, Mozambique, Bangladesh, the Philippines and the Pacific Islands.

International Confederation of Child Cancer Parent Organisations (ICCCPO) (<http://icccpo.org/index.cfm>): **an international network of parent support groups and survivor networks that provide psychosocial care for children and their families.**

Maternal Childhealth Advocacy International – Cameroon ([www.mcai.org.uk](http://www.mcai.org.uk)).

St Jude Children's Research Hospital based in the USA ([www.stjude.org](http://www.stjude.org)): a paediatric treatment and research facility. It develops advanced cures for and means of prevention of paediatric cancer through research and treatment. It is involved worldwide in supporting projects through its International Outreach programme, including twinning. It includes the following:

- Cure4kids ([www.cure4kids.org](http://www.cure4kids.org)): a free online education and collaboration resource dedicated to supporting the care of children with cancer and other catastrophic diseases worldwide.
- Pond4kids ([www.pond4kids.org](http://www.pond4kids.org)): provides a free database collecting epidemiological data and including a cancer registry.

International Society of Pediatric Oncology (SIOP) (Société Internationale d'Oncologie Pédiatrique) ([www.siop-online.org](http://www.siop-online.org)): this organisation has a special focus on paediatric oncology in developing countries (PODC). Some of the relevant working groups include the following:

- twinning, collaboration and support
- graduated-intensity treatment guidelines
- providing advice and support to low-income countries on the most appropriate protocols to use based on the resources available, including financial resources,

training, supportive care, monitoring and investigations, and infection control

- abandonment of treatment
- palliative care
- essential drugs.

International Network for Cancer Treatment and Research (INCTR) ([www.inctr.org](http://www.inctr.org)): this organisation is dedicated to helping to build capacity for cancer research and treatment in developing countries, and it focuses on palliative care, cancer registration, research, training, nursing and pathology services.

Union for International Cancer Control (UICC) World Cancer Congress ([www.uicc.org](http://www.uicc.org)): this organisation focuses

on raising awareness, education, and developing a global network of influence.

Franco-African Pediatric Oncology Group (GFAOP) ([www.gfaop.org](http://www.gfaop.org)): this runs projects for children with cancer in Africa, including a recent Wilms' tumour protocol trial.

## 5.15 Eye disorders

### BOX 5.15.1 Minimum standards

- Vitamin A.
- Ocular antibiotics.
- Fluorescein.
- Ocular steroids.
- Aciclovir.
- Occlusive pads.
- Glasses and other visual aids.

### Introduction

Two of the most important eye disorders in children in resource-limited countries are vitamin A deficiency (xerophthalmia) and trachoma. Both of these can be prevented by appropriate action in the community, which is cheap and very effective for both disorders.

### Eye examination and diagnosis: basic equipment

- Vision-testing chart. Show only one letter at a time and get the child to match the letter on a chart (see Figure 5.15.1).
- A bright torch light which can give a focused beam of light.
- An ophthalmoscope:
  - The ophthalmoscope is mainly used for examination of the ocular fundus (i.e. the retina, choroid and optic nerve).
  - It can also be used for examination of the ocular media (i.e. the cornea, lens, and aqueous and vitreous humour). Dial a small positive lens (about +2 or +3) in the ophthalmoscope, and hold it about 20 cm from the patient's eye. In the healthy eye with a dilated pupil, there will be a clear red glow of light reflected from the retina, called the red reflex, and any opacity in the cornea, lens or aqueous or vitreous

humour will appear as a black shadow against this red reflex.

- The ophthalmoscope can also be used to act like a magnifying lens to examine in detail the conjunctiva, sclera, iris, etc. To do this a very strong positive lens (about +20) is dialled in the ophthalmoscope, which is then held very close to the patient's eye.

An ultra-low-cost ophthalmoscope, otoscope and loupe which is solar powered is now available ([www.arclightscope.com](http://www.arclightscope.com)).

- Mydriatic drops:
  - **Cyclopentolate 1%, or cyclopentolate 0.5%** in children less than 6 months old. **Atropine 0.5%**

FIGURE 5.15.1 Eye testing.

ointment is very long-acting. It can be given to parents to put into the eyes for 2 days prior to a clinic appointment, especially if an initial attempt at refraction and fundus examination has been unsuccessful because of the child becoming distressed when drops were used in the clinic.

- Local anaesthetic drops:
  - **Proxymetacaine 0.5% is ideal for children because it stings less than other topical anaesthetic drops. Tetracaine 0.5% or 1% is an alternative which is less quickly degraded when not stored in the refrigerator.**
- Sterile **fluorescein** paper strips.
- Binocular telescopic magnifying glasses (loupes) are very useful but not essential. Some magnification will be achieved by using a strong pair of reading glasses (+3.00–4.00 DS) perched as far down your nose as possible.
- More sophisticated equipment, such as a tonometer for measuring intra-ocular pressure, a slit lamp and a binocular indirect ophthalmoscope, may only be available in a specialist clinic. However, if available, they greatly add to the diagnosis and treatment that can be offered.

Gaining the confidence and trust of the child is the most important step in a successful eye examination, which should not be painful or unpleasant, except possibly unavoidably when drops are put in the child's eye. If the child finds it hard to cooperate, examine the parents' or older siblings' eyes first to gain the child's confidence. A general anaesthetic may sometimes be required in small children where a serious eye problem (e.g. retinoblastoma) is suspected.

**FIGURE 5.15.2** Position in which to examine the eye of a young child.

### Three ways of examining the eyes of young children

Examining the eyes of babies and young children is often difficult. Patience and encouragement are required to gain the confidence of the child. If it is still difficult to get a good view, the following techniques may be helpful:

- 1 Let the parent cuddle the child as he or she faces backwards over the parent's shoulder (see Figure 5.15.2), especially if the parent's anxiety and sense of obligation to restrain the child is adding to the child's fears. You may then be able to attract the child's interest in participating in the examination from this secure position.
- 2 In the case of infants, wrap the baby in a sheet or blanket, with their head on the examiner's lap, and their body on their mother's lap (see Figure 5.15.3). Gently hold open their lids with the fingers and thumb of one hand. The other hand is then free to instil any eye drops, or hold a torch or condensing lens. This is probably the best way

**FIGURE 5.15.3** Supine posture for eye examination.

to get a satisfactory view of the eye, but it also provokes the greatest resentment from the baby.

- 3 If it is difficult to get drops into the child's eye, try lying the child flat on their back, create a puddle of drops at the inner canthus, and wait while the child is held facing upwards (see Figure 5.15.4). The child will eventually open their eye, and the medication in the puddle of drops at the inner canthus will then go into the eye.
- 4 In difficult cases, where a serious eye condition is suspected, it may be necessary to instil a drop of local anaesthetic, and use a speculum to hold open the eyelids. However, this should only be done by an experienced professional in controlled circumstances, and must not be attempted in the face of determined resistance from any but the smallest child.

### Presenting symptoms of eye disease

These include the following:

- red, sore, irritable or discharging eyes
- impairment or loss of vision
- squint.

#### Red, sore, irritable or discharging eyes

- A sticky discharge with no redness, normal cornea and apparently normal vision in a child up to the age of 18 months (and occasionally older) is commonly caused by a blocked tear duct. Teach the mother to express the lacrimal sac with firm pressure to the side of the nose at the inner canthus.
- Bilateral sore red irritable eyes are usually caused by conjunctivitis. If the symptom is **unilateral** the usual cause is an ulcer or injury to the cornea or iritis. Evert the upper eyelid to inspect the upper tarsal conjunctiva. Apply fluorescein stain to the cornea to diagnose an ulcer or identify a foreign body. The green fluorescein dye will stain the ulcer. A foreign body, especially if lodged under the upper lid, may be associated with staining of the cornea.

FIGURE 5.15.4 Seated posture for eye examination.

FIGURE 5.15.5 Expressing the lacrimal duct. © [www.medscape.com](http://www.medscape.com)

### Conjunctivitis

- **Acute** bacterial conjunctivitis causes a mucopurulent discharge from the conjunctiva and is usually self-limiting, resolving after a few days. Give topical antibiotics as drops or ointment to speed recovery.
- Acute bacterial conjunctivitis is **dangerous in neonates** when caused by sexually transmitted disease. The cornea in a neonate is at much greater risk, and neonates produce less tears to wash away bacteria. **Treatment is urgent.**
- The WHO-recommended treatment for severe neonatal conjunctivitis is a single IM injection of either **ceftriaxone** 50 mg/kg (maximum 125 mg) or **kanamycin** 25 mg/kg (maximum 75 mg) and hourly **tetracycline ointment** or **chloramphenicol drops or ointment**.

- In presumed gonococcal infection, empirical treatment for possible co-infection with chlamydia – that is, ceftriaxone **and** erythromycin to prevent chlamydial pneumonia in the baby – should be strongly considered.

In addition, we recommend diagnosis and treatment of the mother for uro-genital disease due to gonococcus and/or chlamydia in order to prevent salpingitis.

- **Acute viral conjunctivitis** is a self-limiting disease that usually lasts for a week or so. Tear secretions are watery rather than mucopurulent. There is no specific treatment, but it is customary to give antibiotic drops.
- **Vernal conjunctivitis** is a chronic allergic conjunctivitis which is very common and causes recurrent severe itching of the eyes. Affected children are usually atopic (i.e. suffer from asthma and eczema). In addition to itchy eyes, there may be redness, watering, lid swelling and a mucus discharge. Typically there are papillae of the conjunctiva under the upper lid. In some cases these can be massive in size and may be associated with corneal ulceration in the upper third of the cornea. There may be nodular swelling and opacity at the corneo-scleral junction (i.e. the limbus). Anti-inflammatory drops such as cromoglycate relieve the symptoms, but in severe cases use topical steroids (e.g. hydrocortisone 1%, betamethasone 0.1%, or dexamethasone 0.1% eye drops). However, prolonged use of topical steroids has a high risk of causing steroid-induced glaucoma.

### Trachoma

See Section 6.1.M.

### Corneal ulcers

- Corneal ulcers are usually **unilateral**. There is usually pain and photophobia. Staining the eye with fluorescein will show the outline of the ulcer.
- **Herpes simplex** ulcers are typically branched and irregular. Treat by applying **aciclovir ointment 3%** every 2 hours until the epithelium has healed.
- **Bacterial corneal ulcers** are more serious and can rapidly progress to destroy the cornea and the eye. They must be treated as an emergency. If possible, first perform a Gram stain and microscopy of tissue scraped with great care from the edge of the ulcer with a scalpel blade. This will often give helpful information about the cause of the ulcer and so make the treatment more specific. Antibiotic drops should be given hourly or 2-hourly for 48 hours and then four times a day. The choice of antibiotic depends on the availability and also the results of the Gram stain. Ofloxacin (0.3%) or ciprofloxacin (0.3%) both have a good spectrum of activity against Gram-positive and Gram-negative bacteria. **In most circumstances one of these is the first choice.** Concentrated locally made antibiotic drops are very helpful if pre-prepared drops are not available. These can be made up by diluting antibiotic powder for injection in 5 mL of sterile water or 0.9% saline. These home-made eye drops should only be used for 48 hours, and should then be discarded. The following are the recommended strengths: gentamicin 15 mg/mL or amikacin 50 mg/mL for Gram-negative organisms; cefuroxime, ceftazidime or cefazolin 50 mg/mL for Gram-positive organisms. If a Gram stain is not possible, two types of drops can be given alternately every hour. Chloramphenicol (0.5%

drops and 1% ointment) is a cheap and readily available alternative if none of the above are available.

- **Fungal corneal ulcers** are very common in hot humid climates. The branching filaments of the fungus can be identified on a Gram stain. The treatment is unfortunately very difficult because topical antifungal drugs are hard to obtain and the response to treatment is slow. Natamycin is sometimes available as an eye ointment. Econazole, clotrimazole and ketoconazole are all available as skin creams, and it may be necessary to use either these or systemic antifungal agents in difficult cases.

### Iritis

Iritis is a less common cause of acute red eye. The pupil is constricted and irregular and there are often deposits known as keratic precipitates on the posterior surface of the cornea. Give intensive topical steroids hourly (prednisolone, betamethasone or dexamethasone drops) and keep the pupil dilated with mydriatics (atropine 0.5–1% twice daily).

### Vitamin A deficiency (xerophthalmia)

Xerophthalmia usually only affects malnourished children (see Section 5.10.A on vitamin A deficiency).

- In the early stages, the conjunctiva appears dry and wrinkled, but this is not easy to detect.
- As the disease progresses, the cornea also appears dry and then shows signs of corneal ulceration. Ulcers may progress very rapidly to destroy the entire cornea. Eventually the whole eye shrinks or the child may be left with a dense corneal scar.
- In communities where vitamin A deficiency is common, older children are frequently found with corneal scars dating from early childhood. In most cases malnutrition is a chronic problem, and the disease is precipitated by an acute infective illness, which is nearly always measles. Xerophthalmia and measles are particularly important because these ulcers are very frequently bilateral, whereas most other causes of corneal ulceration and scarring usually only affect one eye.

There are three other factors which may precipitate corneal destruction in xerophthalmia:

- **Herpes simplex:** severe and often bilateral herpes simplex ulcers may develop.
- **Traditional eye medicines:** application of toxic substances may cause damage and chemical burns to the conjunctiva and cornea.
- **Exposure:** sick and malnourished children may lie with their eyes open and exposed, so the cornea is not protected by the eyelid.

### Management

- Apply topical antibiotics and ensure adequate closure of the eyelids. Give **local aciclovir** if **herpes simplex** is suspected. Give **topical steroids** (hydrocortisone 1% or betamethasone 0.1% eye drops or ointment) if a clear history of toxic traditional eye medication is obtained.
- Give vitamin A capsules (200 000 IU/day in children over 1 year of age, 100 000 IU/day for those aged 6–12 months, and 50 000/day for those under 6 months, for 2 days, then another dose in 2 weeks). Systemic antibiotics and rehydration may also be indicated.

## The child who cannot see or who cannot see well

If only one eye is affected, the child and their family may not be aware of the problem. However, a child with poor vision in one eye only will often develop a squint in that eye (see below).

### Cornea

Bilateral corneal scarring that is severe enough to cause serious visual impairment is most commonly a consequence of xerophthalmia and measles (both of which are preventable, by giving vitamin A and immunisation). Careful refraction may improve the sight. An optical iridectomy or a corneal graft may also help.

### Cataract

Cataract is the most common congenital ocular abnormality. It may be present at birth, or may develop in early childhood. It may be complete, presenting as a dense white opacity in the pupil, or be incomplete and less obvious. There will be a normal pupillary light reflex, so that the pupil constricts when a light is shone into the eye. In other causes of a white appearance of the pupil, including retinoblastoma, the reaction of the pupil to a light shone in the affected eye is usually lost.

Congenital cataracts require **early expert surgical treatment**, otherwise the child will develop nystagmus, which will prevent the development of good vision.

### Congenital glaucoma

Congenital glaucoma usually presents with photophobia, a hazy cornea and often enlargement of the eye called buphthalmos. Urgent specialist surgery is required to control intra-ocular pressure and save what sight is available, otherwise the child will become irreversibly blind.

### Retinal diseases

- **Retinopathy of prematurity** is the commonest cause of acquired retinal disease. It is associated with excessive oxygen given to premature babies (see Section 3.4). It is now particularly common in middle-income countries, such as Latin America, Eastern Europe, the Middle East and Asia. In countries with highly developed intensive neonatal care services it is uncommon, and in resource-limited countries most very premature babies do not survive.
- **Retinitis pigmentosa** is the most common congenital disorder of the retina. It affects the peripheral retina and causes night blindness.
- **Vitamin A deficiency** also causes night blindness by affecting rod photoreceptors in the peripheral retina.
- **Retinoblastoma** is important because **it is one of the few eye diseases that can be fatal in a child if not properly treated**. The tumour can present in one eye or in both eyes as a white mass in the pupil, a squint, a painful inflamed eye or a mass in the orbit. If the eye is removed before the tumour has spread, the child's life may be saved.

### Optic nerve

Optic nerve hypoplasia or optic atrophy may be congenital. It may also be acquired following meningitis, or rarely following an infection such as typhoid or measles. There is no effective treatment.

**Cortical blindness**

Cortical blindness occurs following severe brain insults such as meningitis or cerebral malaria. The pupillary light reflex is normal, but the child cannot see. In some cases the vision gradually improves with time.

**Management of blindness**

- In the majority of cases, management is with rehabilitation and education rather than medical treatment.
- Cataracts and glaucoma in particular must be recognised and diagnosed early to preserve and save as much sight as possible.
- Most blind children have some sight and should have an opportunity to use low-cost visual aids. Simple aids, manufactured locally, may enable children to read and so transform their opportunities for education. These aids may consist of a strongly positive lens worn as spectacles or used as a stand magnifier.

**Squint**

Squint, or misalignment of the eyes (also known as strabismus), is common in children. When assessing a child for squint, consider the following:

- **Does the child really have a squint?** Look at the corneal light reflexes. If the reflection of light is in the same position in each eye, there is no squint, but if one is asymmetrical then that eye is squinting.
- **Does the squint alternate?** Cover the non-squinting

eye. If the squinting eye moves to look at the light or object being held, and if the child can use either eye to fixate, then the squint alternates. This means that the vision is fairly good in each eye, and the treatment of the squint is purely cosmetic.

- **If the squint does not alternate, is there any disease in the squinting eye?** Test the pupillary light reflex and then dilate the pupils with mydriatic eye drops. Look for diseases such as cataract, retinal scar and in particular retinoblastoma. Refer the child for treatment if you find cataract or an abnormality in the retina. Treatment for retinoblastoma is urgent enucleation.
- **Is there a refractive error, such as hypermetropia (long sight) or myopia (short sight)?** This requires refraction tests.
- **Is the squinting eye amblyopic (i.e. is there poor vision in the squinting eye)?** At first, squints cause double vision (diplopia), which the child finds confusing. As time passes, the visual acuity in the squinting eye becomes permanently suppressed. The treatment for amblyopia is to force the child to use the squinting eye by wearing an occlusive patch over the healthy eye for about 1 hour a day for several weeks.

**Amblyopia only develops in young children, and it can only be treated in children under 5 years of age.** Surgery may be required, but should not be considered until eye disease and refractive errors have been excluded and amblyopia has been treated.

## 5.16 Neurological disorders

### 5.16.A Coma

#### **BOX 5.16.1 Minimum standards**

- ABC and high-dependency care.
- Clinical chemistry.
- Haematology, including blood film for malaria.
- Toxicology, chest X-ray, cultures and lumbar puncture.
- Neuroimaging: CT and MRI (if available).

**Introduction**

Coma is a state of unresponsiveness, in which the child is unable to be aroused by external stimuli (physical, verbal or sensory) or inner needs. It results from a process either diffusely affecting the cerebral hemispheres or directly impairing the function of the reticular activating system in the brainstem.

It may be caused by:

- systemic disorders (e.g. metabolic encephalopathies)
- intracranial diseases which are either diffuse or focal.

**Primary assessment and resuscitation**

**Coma is a medical emergency that requires immediate assessment and detection of reversible causes. Initial quick resuscitative measures are paramount, before undertaking a full clinical assessment of the child.**

**History**

A detailed history should be taken from the parent or carer, with a focus on the following:

- possible cause of coma
- onset and progression of unconsciousness
- extent of injury
- signs of deterioration or recovery
- past medical history.

**Examination**

Clinical examination is directed towards identifying signs suggesting the following:

- cause or causes
- extent of injury
- level of consciousness.

A general examination should be undertaken guided by the history and presumptive cause of coma. Identify immediate

reversible causes of coma, such as hypoglycaemia, hyperglycaemia, trauma and seizures, and treat them accordingly (see Table 5.16.A.1). Look for rashes (e.g. purpura of meningococcaemia), tick bites, signs of trauma, evidence of ingestion of drugs or chemicals, and evidence of organ failure.

**TABLE 5.16.A.1** Causes of coma

<i>Trauma</i>	<b>Head injury</b> (consider child abuse)
<i>Seizure</i>	Overt <b>seizures</b> , status epilepticus, subclinical seizures, post-ictal state
<i>Infections</i>	<b>Bacterial (meningitis):</b> <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Neisseria meningitidis</i> , streptococci (group B), <i>Pseudomonas</i> species, tuberculosis Consider cerebral abscess
	<b>Viruses:</b> herpes simplex, Japanese B virus (JVB), herpes zoster
	<b>Acute spirochaetaemia:</b> syphilis, Lyme disease, leptospirosis
	<b>Parasitic:</b> malaria, rickettsial
	<b>Fungal:</b> <i>Cryptococcus neoformans</i>
<i>Metabolic</i>	<b>Hypoglycaemia:</b> Excess insulin or metabolic disorders
	<b>Hyperglycaemia:</b> Diabetic ketoacidosis
	<b>Hypoxaemia</b>
	<b>Electrolyte imbalance:</b> hyponatraemia or hypernatraemia
	<b>Severe dehydration</b>
	<b>Severe malnutrition</b>
	<b>Organ failure:</b> Liver failure, renal failure, Addison's disease, respiratory failure
	<b>Drugs:</b> Opiates, salicylates, organophosphates, benzodiazepines, thiazines, aluminium in patients undergoing dialysis, barbiturates, antidepressants
<b>Other:</b> Porphyrias, Reye's syndrome	
<i>Poisoning</i>	Alcohol, recreational drugs, accidental/deliberate poisoning
<i>Tumours</i>	<b>Primary:</b> medulloblastoma, astrocytoma
	<b>Secondary:</b> leukaemias, sarcomas
<i>Vascular</i>	Haemorrhage (subdural/subarachnoid), hypertension, hypotension, thrombosis, aortic stenosis, cardiac asystole, vacuities and collagen vascular syndromes
<i>Shock syndromes</i>	Sepsis, trauma, burns, peritonitis

### Causes of coma

The following features found on examination may be indicative of specific causes.

- **Pulse:** bradycardia may indicate raised intracranial pressure (RICP) or reflect the effects of poisons or drug overdose.
- **Blood pressure:** hypertension may indicate hypertensive encephalopathy or signs of RICP; hypotension occurs in shock.
- **Temperature:** this may indicate sepsis.
- **Respiratory pattern:** this may be irregular due to brainstem lesion or RICP, rapid due to acidosis or aspirin ingestion, or slow due to opiate ingestion.
- **Pupil size and reactivity:** pupil may be small due to opiate ingestion, or large due to amphetamine ingestion or RICP; pupils may be unequal and/or unreactive due to RICP.
- **Skin rashes:** these may be due to infections (e.g. meningococcal septicaemia, dengue fever).
- **Breath odour:** this may be caused by diabetic ketoacidosis, alcohol ingestion, or inborn errors of metabolism.
- **Hepatomegaly:** this may indicate Reye's syndrome or other metabolic disorders.

- **Fundi:** Papilloedema may indicate RICP; dilated veins may indicate RICP; retinal haemorrhages may indicate trauma or malaria; and exudates, retinal whitening and orange coloration of vessels may indicate other signs of malaria retinopathy
- **Posture/oculocephalic reflexes** (see Figure 5.16.A.2): these are abnormal in RICP.

### Neurological examination

The purpose of the neurological examination is not only to identify features of raised intracranial pressure (including herniation syndromes), focal deficits (e.g. space-occupying lesions) and lateralising signs (hemiplegic syndromes), but also to establish a baseline for comparison on subsequent evaluations. Examination may also help to provide prognostic information.

### Level of consciousness

Many methods exist for establishing the level of consciousness. Two that are commonly used are the AVPU system, and coma scales.

**FIGURE 5.16.A.1** Sites for the application of a painful stimulus to elicit a response.

**AVPU system**

**A = Alert**

**V = Response to Voice command**

**P = Response to Pain**

**U = Unresponsive**

In this test:

- 'A' means that the patient is awake, alert and interacting with the environment.
- 'V' means that the patient appears to be asleep, but when spoken to opens their eyes.
- 'P' indicates that there is no response to a voice, but a painful stimulus will produce some response (e.g. a withdrawal).
- 'U' indicates that the patient is completely unresponsive to any stimulus.

Figure 5.16.A.1 shows sites for the application of a painful stimulus in order to elicit a response.

**TABLE 5.16.A.2 Glasgow Coma Scale**

Activity	Best response	Score
<i>Eye opening</i>	Spontaneous	4
	To verbal stimuli	3
	To pain	2
	None	1
<i>Verbal</i>	Orientated	5
	Confused	4
	Inappropriate words	3
	Incomprehensible sounds	2
	None to pain	1
<i>Motor</i>	Follows commands	6
	Localises pain	5
	Withdraws in response to pain	4
	Abnormal flexion in response to pain (decorticate)	3
	Abnormal extension in response to pain (decerebrate)	2
	No response to pain	1

**TABLE 5.16.A.3 Adelaide Coma Scale**

Activity	Best response	Score
<i>Eye opening</i>	Eyes open spontaneously	4
	To request	3
	To pain	2
	No response to pain	1
<i>Verbal</i>	Orientated, alert	5
	Recognisable and relevant words but less than usual, spontaneous cry	4
	Cries only to pain	3
	Moans only to pain	2
	No response to pain	1
<i>Motor</i>	Obeys commands	6
	Localises painful stimulus	5
	Withdrawal from pain	4
	Abnormal flexion to pain (decorticate)	3
	Abnormal extension to pain (decerebrate)	2
	No response to pain	1

**Coma scales**

These have been devised to measure the depth of coma and improve agreement between clinicians. Coma scales can also be used to monitor progression or regression of the depth of coma. Although many different versions exist, the most widely used ones are the paediatric modification of the Glasgow Coma Scale (for children between the ages of 4 years and 15 years) and the Adelaide Coma Scale (for children under 4 years of age).

**Pupillary reactions**

Use a bright torch and from the side shine the light on the cornea of each eye in turn. Observe for pupillary size

(constricted or dilated) and the reaction to light (normal, sluggish or non-reactive). While doing this test consider the effect of drugs used in treatment (e.g. benzodiazepines).

### Ocular movements

- Eyelid response.
- Corneal response.

### Oculocephalic reflexes (doll's head manoeuvre)

In the normal state while turning the head sharply to one side, the eyes move to the opposite side. In the abnormal state the eyes only partly deviate or remain fixed (see Figure 5.16.A.2).

**Before performing this test it is important to check that there is no cervical injury.**

### Oculo-vestibular or caloric response

Tilt the head forward at 30 degrees, and instil ice cold water in the ear. In the normal state the eyes turn to the side of the stimulus (see Figure 5.16.A.2). This manoeuvre tests brainstem function.

**Before doing this test it is important to ascertain that the tympanic membrane is intact and there is no wax in the external meatus.**

### Motor function and activity

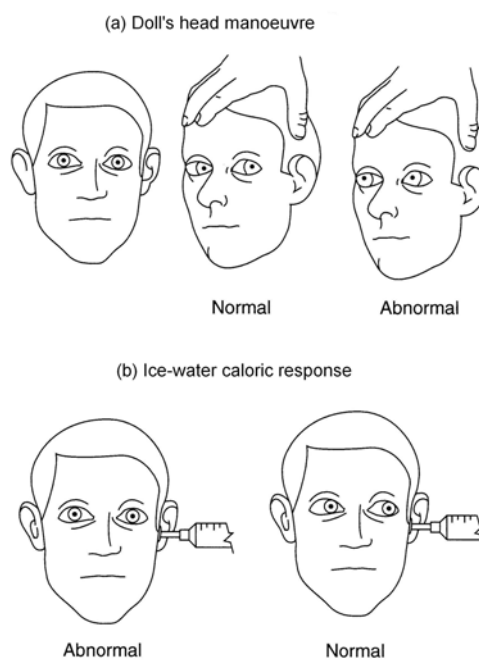

Observe for tremors, abnormal movements and tone. The presence of hypertonia or hypotonia indicates a neuromuscular problem. Exaggerated deep tendon reflexes and clonus may indicate an upper motor neuron type lesion, whereas their absence may indicate a lower motor neuron type problem.

Abnormal postures in an unconscious patient (e.g. decerebrate or decorticate rigidity) may indicate brain damage at cerebral or cortical level (see Figure 5.16.A.3).

### Respiratory pattern

Abnormal variations in breathing pattern may be difficult to identify in children. The following may be sought for:

- **irregular:** consider seizures
- **Cheyne–Stokes:** raised intracranial pressure, cardiac failure
- **Kussmaul breathing:** acidosis, central neurogenic hyperventilation, midbrain injury, tumour or stroke

**FIGURE 5.16.A.2** Oculocephalic reflex (doll's head manoeuvre) and oculo-vestibular response (ice-water caloric response).

- **apneustic (periodic) breathing:** pontine damage, central herniation.

### Signs and symptoms of raised intracranial pressure

- Preceding history of headache.
- Recurrent vomiting.
- Sixth (abducens nerve) cranial nerve palsy.
- Sluggish or no pupillary reaction.
- Dilated retinal veins with reduced pulsations.
- Papilloedema.
- Subhyaloid retinal haemorrhages.
- Bradycardia.
- Raised blood pressure.
- Irregular respiration.

**FIGURE 5.16.A.3** Abnormal postures elicited in an unconscious patient by a painful stimulus. (a) No response. (b) Decorticate. (c) Mixed decorticate/decerebrate. (d) Decerebrate.

## Investigations

These are guided by the presumptive clinical diagnosis. Essential tests may include the following:

- **Clinical chemistry** for blood glucose, electrolytes, creatinine, urea, blood gases and liver function tests (including clotting profile).
- **Blood film** for malarial parasites.
- **Haematological parameters** such as full blood count and peripheral blood film. Toxicological tests for salicylates, organophosphates, opiates, alcohol and paracetamol.
- **Blood cultures.**
- **Lumbar puncture** if there is a high index of suspicion of central nervous system infection. This should be delayed if there are features suggestive of raised intracranial pressure, the child is too sick, there is infection at the puncture site, there is a bleeding tendency or there is rash of meningococcal septicaemia. The child should be given antibiotics to cover the possibility of bacterial meningitis, and lumbar puncture should be deferred until a later date.
- **Chest X-ray** if there is suspicion of tuberculosis or severe pneumonia.

If facilities are available, consider the following:

- Computerised tomography (CT) scan or preferably magnetic resonance imaging (MRI) scan. These are particularly useful for detecting space-occupying lesions and traumatic injury. Contrast dye should be given if an infection or a tumour is suspected.
- Plasma ammonia level and plasma and CSF lactate levels.
- Urine and plasma for organic and amino acids.

## Other investigations (if available)

These will depend on the cause of the coma, and include the following:

- **Hormonal assays:** thyroid hormones, cortisol, ketosteroids (adrenal insufficiency).
- **Electroencephalography (EEG):** this may be helpful in detecting seizures or encephalitis. It may also be useful in establishing the prognosis.
- **Evoked potential responses:** these may help to detect brainstem lesions.
- **Neuroimaging:** magnetic resonance angiography or MRI or CT scan.

## Differential diagnosis

A simple way to establish a cause would be to determine whether it is primarily intra- or extracranial. Intracranial conditions may be subdivided into those with or without focal signs. Extracranial causes include encephalopathies arising from metabolic derangements or exogenous toxins. The common causes are listed in Table 5.16.A.1.

## Management

The prognosis depends on the aetiology, age of the patient, and level of consciousness at presentation. The presumptive cause of coma guides the treatment and the initial response to appropriate interventions.

See subsequent subsections and disease-specific sections (e.g. meningitis (Section 5.16.B), malaria (Section 6.3.A.d), tuberculosis (Section 6.1.N)). Consider the following interventions for general coma management.

## Immediate general management: overview – see relevant sections for detail

ABC support of vital functions (see Section 1.11)

- **Support respiration** if respiratory effort is not adequate to maintain the desired oxygen saturation and/or carbon dioxide excretion.
- **Support circulation** to maintain adequate cerebral perfusion (aim to keep systolic blood pressure at normal values for age, and avoid hypotension).
- Assess for and treat **hypoglycaemia** (see Section 5.8.B)
- **Maintain normoglycaemic state:** be cautious about administering insulin to hyperglycaemic patients, as hyperglycaemia may be stress induced.
- **Assess and maintain electrolyte balance:** avoid hyponatremia: use Ringer-lactate or Hartmann's solution, both with added glucose (50 mL of 50% glucose in 500 mL of crystalloid gives a 5% solution, 100 mL gives a 10% solution). If possible keep serum sodium levels in the normal range (135–145 mmol/litre).
- **Treat seizures** if present and give prophylactic anti-convulsants if the child has repeated seizures (see Section 5.16.E and 5.16.D).
- Treat for meningitis if this is an acute illness (see Section 5.16.B).
- Treat for cerebral malaria if history and test confirm (see Section 6.3.A.d).
- Insert a nasogastric tube to **aspirate the stomach contents**. Perform gastric lavage in circumstances such as drug or chemical ingestion.
- Assess for and treat hypoglycaemia (see Section 5.8.B)
- **Regulate the body temperature** (avoid hyperthermia, i.e. temperature > 37.5°C).
- Undertake appropriate **medical management of raised intracranial pressure.**
- **Support ventilation** (maintain a  $p\text{CO}_2$  of 3.5–5.0 kPa).
- **Reduce raised intracranial pressure** by using the following:
  - **Mannitol:** 250–500 mg/kg, i.e. 1.25–2.5 mL/kg of 20% IV over 15 minutes; repeat as required based on response and clinical signs (maximum total dose 2 grams/kg).
  - **Hypertonic saline:** 3 mL/kg of 3% sodium chloride as required, to a maximum increase of plasma sodium level of 10 mmol/litre.
- **Dexamethasone** (for life threatening cerebral oedema surrounding a space-occupying lesion):
  - Child under 35 kg; 20 mg initially then 4 mg 3 hourly for 3 days, then 4 mg every 6 hours for 1 day, then 2 mg every 6 hours for 4 days then decrease by 1 mg daily.
  - Child over 35 kg; 25 mg initially, then 4 mg 2 hourly for 3 days, then 4 mg 4 hourly for 1 day, then 4 mg 6 hourly for 4 days then decrease by 2 mg daily.
- **Catheterisation** for bladder care and urine-output monitoring.
- Plan for continued **regular clinical assessment**, mainly nursing observations of pulse, respiration, blood pressure and level of consciousness.

## Intermediate general management

- Prevent the child from falling out of the bed.
- Nutritional support: give enteral nutrients to prevent malnutrition during periods of unconsciousness.
- Skin care: prevent bed sores by turning the patient.
- Use eye padding to avoid xerophthalmia.

- Family counselling, support and consent in the case of invasive procedures.
- Chest physiotherapy is needed to avoid hypostatic pneumonia.
- Restrict fluids to 80% of maintenance if evidence of water retention is seen.
- Prevent deep vein thrombosis by physiotherapy and/or use of anti-embolism stockings.
- Maintain oral and dental hygiene.
- To avoid infection, provide appropriate care for central and peripheral venous or arterial access by maintaining sterility when handling the sites.
- Be alert for hospital-acquired infection.

### Long-term management

Provide rehabilitation, family education and support for disabilities that may arise. Seizures need to be looked for and treated.

### Cerebral malaria (see Section 6.3.A.d)

In endemic areas, malaria is by far the commonest cause of coma. The majority of children affected are in the second year of life. Onset of coma is dramatic: the child may be well in the morning and comatose by the evening. The fatality rate is high even after prompt administration of antimalarial drugs. Neurological sequelae (i.e. hemiplegia, spasticity, blindness, deafness) may occur.

## 5.16.B Bacterial meningitis

### BOX 5.16.B.1 Minimum standards

- Lumbar puncture.
- Early parenteral antibiotics.
- Antituberculous drugs (if indicated).
- Dexamethasone (if indicated).
- Anticonvulsants.
- Monitoring of vital signs, fluid balance, blood glucose and electrolytes.
- Immunisation and/or prophylaxis for contacts.
- Follow-up for neurological sequelae.

The incidence of bacterial meningitis is about ten times higher in resource-limited than in well-resourced countries, and the outcome is worse. Mortality is reported to be 12–44% in resource-limited countries, and less than 5% in well-resourced countries. In the former, sequelae are under-reported and frequent (20%), including significant neurological impairment and hearing loss.

### Pathogens that cause meningitis

- Worldwide, the commonest pathogens are *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Neisseria meningitidis*. **Local incidence varies, and in many countries has been altered by vaccine availability.**
- Neonatal meningitis is most commonly caused by group B streptococcus (*Streptococcus agalactiae*) and *E. coli*. Other coliforms and streptococci, as well as *Neisseria meningitidis* and *Listeria monocytogenes*, may also occur. *Listeria monocytogenes* and Group B streptococci cause both early and late neonatal infections, and may have a better prognosis than infections caused by coliforms. Neonatal meningitis has a poorer prognosis than most community-acquired meningitis of later childhood.

### Diagnosis of meningitis

#### Clinical

- **In infants and children:** fever, neck stiffness, bulging fontanelle (in infants), vomiting, headache, altered consciousness and possibly convulsions. In meningococcal

meningitis there may be a maculopapular or petechial rash.

- **In neonates:** signs are more subtle and non-specific and include poor feeding, hyper- or hypothermia, convulsions, apnoea, irritability and a bulging fontanelle.

#### Laboratory

- Contraindications to lumbar puncture include evidence of raised intracranial pressure (especially coma or focal neurological signs), the child being too sick to tolerate a flexed position, infection at the puncture site, bleeding tendency (blood clotting or platelet disorder), or a widespread petechial rash suggesting meningococcal disease. In these situations, antibiotics should be started and lumbar puncture delayed until it is safe to undertake.
- Gram stain of CSF may identify bacteria in about two-thirds of cases, and provides a guide to choice of antibiotic therapy in the absence of culture facilities.
- Other laboratory tests of use include blood culture and polymerase chain reaction (PCR) of CSF, and for general management, full blood count, serum electrolytes and glucose levels, and urine specific gravity. In malarial areas, undertake a blood smear and treat appropriately. Both meningitis and malaria may coexist in a patient and be difficult to distinguish from each other.

#### Other pathogens

Consider tuberculous meningitis in children who do not respond to the initial antibiotics, particularly if two or more of the following are present: history more than 7 days, HIV known or suspected, patient remains unconscious, CSF has a moderately high white blood cell count (typically > 300–500/mL, mostly lymphocytes), elevated protein levels (0.8–4 grams/litre) and low glucose levels (< 1.5 mmol/litre), Chest X-ray suggests tuberculosis, optic atrophy, focal neurological deficit or extrapyramidal movements (see Section 6.1.N).

Children with HIV are more prone to meningitis and septicaemia caused by *Streptococcus pneumoniae* and *Salmonella* species, and relapse is more frequent. Non-typhoidal *Salmonella* (NTS) meningitis is common in post-malarial anaemia and malnutrition, and requires lengthy antibiotic treatment (at least 1 month).

Fungal infections (e.g. *Cryptococcus neoformans*),

**TABLE 5.16.B.1 Bacterial meningitis: typical findings in cerebrospinal fluid**

Condition	White cell count ( $\times 10^6/L$ )	Cell differential	Protein (g/litre)	Glucose (mmol/litre)
Normal	0.5 < 22 in full term, < 30 in premature neonates	PMN $\leq$ 2 but < 15 in neonate	< 0.5	Two-thirds blood glucose
Acute bacterial meningitis*	100 to > 300 000	Mostly PMN. Monocytes in <i>Listeria</i> infection	> 1.0	< 2.5
Tuberculous meningitis	50–500 sometimes higher	Lymphocytes early but also PMN	> 1.0	< 2.5, Usually 0
Herpes encephalitis	usually < 500	Mostly lymphocytes PMN early in the disease	> 0.5	Normal
Cerebral abscess	10–200	PMN or lymphocytes	> 1.0	Normal
Traumatic tap	WBC and RBC	RBC/WBC =500/1	Increases by 0.001 g/L per 1000 RBC	

\*Bacterial meningitis can occur without a pleocytosis. Partial treatment will alter these findings. PMN, polymorphonuclear granulocytosis; WBC, white blood cell count; RBC, red blood cell count.

mostly in children with HIV, often cause severe headache without neck stiffness. Lumbar puncture may improve symptoms.

## Therapy

Antibiotic choices depend upon activity against the infecting organism, CSF penetration, cost and availability of the antibiotic, route of administration, and local patterns of antibiotic resistance (see Tables 5.16.B.2, 5.16.B.3 and 5.16.B.4). If national guidelines are available they should be followed. The degree of diagnostic certainty is also important, especially in the case of meningitis with minimal rash, as treatment should be given for all the common causes of bacterial meningitis according to the child's age group.

It is important to know the antimicrobial sensitivities in the local area. Antimicrobial resistance has emerged among the three major bacterial pathogens that cause meningitis outside the neonatal period. In the meningococcus, intermediate penicillin resistance may occur and chloramphenicol resistance is emerging. *Haemophilus influenzae* infections are also frequently beta-lactamase resistant, and chloramphenicol resistance has been described. Third-generation cephalosporins are therefore the drugs of choice for both organisms, although if they are precluded on the basis of cost, chloramphenicol (plus penicillin or ampicillin) is an alternative. Pneumococci resistant to penicillin and to chloramphenicol are widespread in Asia and some parts of Africa, and third-generation cephalosporins are again the drugs of choice. However, pneumococcal resistance to third-generation cephalosporins may occur. Treatment of these strains requires the addition of vancomycin or rifampicin to therapy with third-generation cephalosporins.

Third-generation cephalosporins (ceftriaxone or cefotaxime) may be necessary first-choice antibiotics in some areas. In neonates, ceftazidime, which is also active against *Pseudomonas* infections, may be the most suitable drug.

The antibiotic regimen should be rationalised once culture and sensitivity results for the infecting organism become available.

During confirmed epidemics of meningococcal meningitis and where there are other signs such as petechial rash, lumbar punctures are unnecessary. If resources are very limited, oily chloramphenicol (100 mg/kg IM) as a single

dose of up to 3 grams can be curative. If the oily dose is too large for one buttock, divide it into two doses. Alternatively, single-dose IM ceftriaxone, 100 mg/kg up to 4 grams, may be recommended.

## Duration of therapy

Neonates require 14–21 days of treatment. In infants and children, a 10-day course is usually adequate for pneumococcal and *Haemophilus* infections, and a 7-day course for meningococcal infections. Seven days of ceftriaxone treatment is usually sufficient. Where antibiotic availability is very limited, some authors have used 5- to 7-day courses of ceftriaxone for uncomplicated meningococcal, pneumococcal or *Haemophilus* meningitis in infants and children.

## Corticosteroids

Dexamethasone may reduce the incidence of neurological sequelae and deafness in bacterial meningitis, **although studies in resource-limited countries have been inconclusive. The usually recommended dose of dexamethasone is 0.15 mg/kg four times daily for 4 days (or if this is not available, prednisolone 2 mg/kg per day for 4 days).** The first dose should be given concurrently with, or a maximum of 4 hours after, first antibiotic administration.

There is **no** evidence that corticosteroids are helpful in bacterial meningitis where there is delay in presentation and antibiotics have already been given some hours earlier. Steroids are generally not indicated in meningococcal disease.

**Do not use steroids in the newborn or in children younger than 3 months,** or in patients with suspected cerebral malaria or viral encephalitis.

## Nursing and ongoing care

### Monitoring

- Careful observation is essential.
- Raised ICP and shock are the most severe complications. Early recognition and treatment are essential.
- Daily weights and urine specific gravity aid the assessment of fluid requirement.
- Temperature, pulse, blood pressure, capillary refill time (normal value is less than 3 seconds), respiratory rate

and effort, conscious level and pupillary responses should be monitored frequently after admission (4- to 6-hourly), particularly in patients with meningococcal disease (see Section 6.1.G). Pulse oximetry is valuable (if available) for monitoring oxygenation and for identifying early evidence of respiratory compromise.

- A critical care pathway is an ideal way of incorporating observations, treatment and laboratory findings on one chart. Doses and treatments can be standardised and incorporated on the chart.
- Ideally, if available, monitor electrolytes (sodium, potassium, calcium and magnesium, urea and/or creatinine) and replacement of fluid deficits (hyponatraemia due to excessive IV administration of hypo-osmolar solutions is common, and can predispose to seizures). Monitoring of full blood count and coagulation screen should be undertaken regularly if these are initially abnormal.

### Supportive care

#### Fluids

Maintenance fluids should be given once any shock or dehydration has been corrected, initially by the IV route but later by nasogastric tube or orally. The degree of dehydration may be underestimated, and deep breathing may be a sign of acidosis. Low serum sodium levels often occur in meningitis. Avoid over-hydration by maintaining careful fluid balance, and in particular avoid IV fluids with low sodium levels such as 5% glucose. Use Hartmann's solution with added glucose (5–10%) or a similar proprietary fluid. If electrolytes are being measured, maintain serum Na<sup>+</sup> in the high normal range and above 135 mmol/litre.

#### Fluid balance

**Urine output** should be monitored, particularly in the unconscious child. Weighing nappies can be useful in the infant or young child. Catheterisation, unless undertaken in an aseptic way, can lead to urinary tract infection and is unwise if resources are limited.

#### Cerebral support

**Seizures** must be controlled with anticonvulsants, but there are no data to support routine use of prophylactic anticonvulsants (see Section 5.16.D and Section 5.16.A on seizures and coma).

If there is a high **fever** (> 39°C), apply temperature reduction methods, including paracetamol.

**Blood glucose levels** must be monitored every 4 hours, particularly in the infant and young child. Hypoglycaemia must be considered in any child with seizures or altered consciousness and corrected as follows: give 2–5 mL/kg of 10% glucose IV and recheck blood glucose levels 30 minutes later. If they remain low (less than 2.5 mmol/litre), repeat the IV glucose dose (5 mL/kg) and ensure that glucose is included in any infusion.

#### Gastric and airway protection

A **nasogastric tube** may be helpful in unconscious children or in those who are vomiting, in order to protect the airway. A small amount of milk (1 mL/kg/hour) passed down this nasogastric tube may prevent gastric erosions. Gastric protection may also be provided by using drugs such as ranitidine or omeprazole (if available).

#### Nutritional support

A **nasogastric tube** should be inserted if the child is unable to feed orally after 24 hours. Continue expressed breast milk if the child is breastfed, or give milk feeds 15 mL/kg every 3 hours.

#### Bedside care

Turn an unconscious child 2-hourly, keeping them dry, and prevent overheating. Insert a nasogastric tube if there is persistent vomiting.

Include the mother or family members in progress reports, and make them part of the caring team.

### Complications

- Convulsions with or without hypoglycaemia (see Sections 5.16.D and E for management of convulsions).
- If fever does not settle within 48 hours and if the child's condition deteriorates or is not improving, repeat lumbar puncture and review the CSF findings, and consider drug resistance and tuberculous meningitis.
- If the fontanelle is patent, monitor the head circumference daily to detect hydrocephalus. Consider a head ultrasound scan to look for ventriculitis, ventricular dilatation, subdural effusion or brain abscess. In older children, computed tomography or magnetic resonance imaging may be helpful for assessing the size and position of any intracranial lesion (if available and if intervention is possible).
- Aspiration pneumonia may occur in the unconscious child.
- Hydrocephalus, deafness, visual loss, epilepsy and neurological deficits may develop and be evident either early in disease or at follow-up. Around 20% of cases worldwide will develop serious sequelae.

### Follow-up

- Undertake hearing tests in all children, and neurological assessments and head circumference measurements (in infants) on discharge from hospital and at post-discharge visits 1 month and 6 months after recovery. In the absence of effective treatment, a deaf child will require training in lip-reading and sign language, and they and their family will need significant support.
- New sequelae are unlikely to develop after discharge, but may have been missed.
- Physiotherapy may be required if neurological sequelae have resulted in contractures.

### Immunisation to prevent meningitis

Highly effective protein-conjugated polysaccharide vaccines are available against *Haemophilus influenzae* and several serogroups of *Streptococcus pneumoniae* and *Neisseria meningitidis*. They are effective in young infants as well as in older children and adults. If they are unavailable, plain polysaccharide vaccines against *Neisseria meningitidis* and *Streptococcus pneumoniae* may be provided. Vaccine availability may be limited in low-income countries.

**TABLE 5.16.B.2 Antibiotic choices by age group for immediate treatment and where the infecting organism is not known**

Age group	Probable pathogen	Antibiotics of choice	Alternative antibiotics
Neonates	Gram-negative bacteria Group B streptococci <i>Listeria</i> <i>Neisseria meningitidis</i> <i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i>	Ampicillin <b>plus</b> third-generation cephalosporin: cefotaxime/ceftriaxone	Penicillin (but use ampicillin if <i>Listeria</i> is suspected) <b>plus</b> gentamicin or ceftazidime
1 month to 5 years	<i>Neisseria meningitidis</i> <i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i>	Third-generation cephalosporin: cefotaxime/ceftriaxone Add vancomycin or rifampicin if there is <i>S. pneumoniae</i> resistance	Chloramphenicol <b>plus</b> ampicillin Add vancomycin or rifampicin if there is <i>S. pneumoniae</i> resistance
Children over 5 years	<i>Neisseria meningitidis</i> <i>Streptococcus pneumoniae</i>	Third-generation cephalosporin: cefotaxime/ceftriaxone Add vancomycin or rifampicin if there is <i>S. pneumoniae</i> resistance	Chloramphenicol <b>plus</b> ampicillin Add vancomycin or rifampicin if there is <i>S. pneumoniae</i> resistance

For all age groups, if there is no improvement after the third day, look for evidence of cerebral abscess or subdural effusions, where relevant. These would manifest as continuing fever, localising neurological signs or decreased consciousness. Ultrasound or CT (if available) would be helpful. Seek neurosurgical advice (if available). Repeat the lumbar puncture, looking for evidence of improvement such as a reduced white cell count or increased CSF glucose levels. Add in a third antibiotic. Consider other sites of infection, such as cellulitis, pneumonia with empyema, arthritis or osteomyelitis.

Give all antibiotics parenterally (IV or IM) for at least 3 days. Chloramphenicol can then be given orally if the child is significantly improved.

The IM route may be used if the IV route cannot be accessed. High oral doses of chloramphenicol can be used if there is no alternative, but are not recommended for infants under 3 months of age.

**TABLE 5.16.B.3 Antibiotic therapy in bacterial meningitis where the infecting organism is known**

Organism	Antibiotics of choice	Alternative antibiotics	Duration
<i>Haemophilus influenzae</i>	Ceftriaxone/cefotaxime	Ampicillin <b>plus</b> chloramphenicol*	10–14 days
<i>Streptococcus pneumoniae</i> †	Ceftriaxone/cefotaxime	Ampicillin/benzylpenicillin <b>plus</b> chloramphenicol*	10–14 days
<i>Neisseria meningitidis</i>	Ceftriaxone/cefotaxime	Benzylpenicillin <b>plus</b> chloramphenicol*	7 days
Gram-negative bacilli (including <i>E. coli</i> )	Ceftriaxone/cefotaxime with or without gentamicin	Ampicillin <b>plus</b> gentamicin or chloramphenicol*	At least 21 days‡
<i>Salmonella enteritidis</i>	Ceftriaxone/cefotaxime <b>plus</b> IV ciprofloxacin (if available)	Meropenem or chloramphenicol* <b>plus</b> ampicillin (may be incomplete cover and excess mortality compared with cephalosporins)	At least 21 days‡
<i>Listeria monocytogenes</i>	Ampicillin <b>plus</b> gentamicin		10–14 days
Group B streptococcus	Benzylpenicillin <b>plus</b> gentamicin or ceftriaxone/cefotaxime		10–14 days
<i>Staphylococcus</i> species	Flucloxacillin <b>plus</b> gentamicin	Flucloxacillin <b>plus</b> chloramphenicol*	10–14 days

\* Chloramphenicol should be used with caution in children under 3 months of age. Monitoring of serum levels is advisable in this group.

† *Streptococcus pneumoniae* infections that are resistant to penicillins and cephalosporins are increasingly prevalent. If resistance is suspected, add either rifampicin or vancomycin (see doses below).

‡ Gram-negative infections are difficult to treat and have a high rate of sequelae. A repeat lumbar puncture to ensure response to antibiotics may be indicated if the clinical picture is not improving.

The choice of antibiotic depends on local antibiotic resistance patterns, national guidelines and drug availability.

Give all antibiotics parenterally for at least 3 days.

Once culture and sensitivity results are available, empirical antibiotics should be changed accordingly.

Do not delay antibiotic therapy if cephalosporins are unavailable; use the next most appropriate antibiotic combination.

### Bacterial meningitis: prophylaxis for contacts

#### *Neisseria meningitidis*

Give rifampicin to all household contacts for 2 days as follows: adults, 600mg twice daily; children aged 1 month to 12 years, 10mg/kg twice daily; neonates, 5mg/kg twice daily (see Section 6.1.G for alternative antibiotics and vaccination regimes).

In many countries, rifampicin is protected from use in

any disease other than TB. In this case consider giving ciprofloxacin orally as a single dose as follows: adults, 500mg; children aged 5–12 years, 250mg; children aged 1 month to 5 years, 125mg.

#### *Haemophilus influenzae*

Give rifampicin to all non-vaccinated household contacts for 4 days at the doses stated above.

TABLE 5.16.B.4 Bacterial meningitis: antibiotic doses

Antibiotic	Route	Dose
Ampicillin	IV	100mg/kg/4–6 hourly (max. single dose 2g every 4 hours)
Benzylpenicillin	IV	50mg/kg/4 hourly (max. single dose 2.4g)
Cefotaxime	IV	50mg/kg/6 hourly (max. daily dose 12g)
Ceftriaxone	IV or IM	80mg/kg/24 hours once daily* (max. single dose 4g) large doses preferably IV
Chloramphenicol	IV	25mg/kg 6 hourly <sup>†</sup> (after loading dose of 50mg/kg)
	Oral	25mg/kg 6 hourly <sup>†</sup>
	IM	An oily preparation of chloramphenicol is available and is usually used in a single dose of 50–100mg/kg with a maximum dose of 3g. The dose may be repeated after 24 hours. It is recommended only if more suitable alternatives are unavailable
Flucloxacillin or cloxacillin	IV	50mg/kg 6 hourly (max. dose 8g/day)
Gentamicin	IV or IM	1 month–12 years 2.5mg/kg 8 hourly <sup>‡</sup> (see Section 3.4 for neonatal doses)
Ciprofloxacin	IV	10mg/kg 8 hourly (10mg/kg/12 hourly in the neonate)
Meropenem	IV	1 month to 12 years body weight < 50kg; 40mg/kg 8 hourly; body weight > 50kg; 2g every 8 hours (maximum single dose 2g) by slow IV injection over 5 minutes 12–18 years 2g every 8 hours
Vancomycin	IV	15mg/kg loading dose and then 10mg/kg 6 hourly <sup>‡</sup> (total daily dose should not exceed 2g)

\* Ideally, 80mg/kg 12-hourly should be given for the first two doses, followed by 80mg/kg/24 hours.

<sup>†</sup> Although not recommended in children under 3 months old or in malnourished children, the evidence for this is slight.

<sup>‡</sup> Monitoring of drug levels is strongly advised if at all possible, with adjustment of doses.

For doses in the neonatal period, see Section 3.4

## 5.16.C Encephalitis

### BOX 5.16.C.1 Minimum standards

- ABCD and intensive care.
- Lumbar puncture, basic clinical chemistry and haematology.
- Temperature control.
- Anticonvulsants.
- Antiviral and antibiotic drugs.

### Introduction

Encephalopathy refers to a clinical syndrome of reduced consciousness for which there may be a variety of causes. Encephalitis is an inflammatory process involving primarily the brain parenchyma, but sometimes also the meninges (meningoencephalitis) or spinal cord (encephalomyelitis). Primary encephalitis refers to cases in which the causative agent invades and replicates within the nervous system, whereas in post-infectious encephalitis the clinical manifestations appear to be caused by an immunological response to the agent. In practice it can be difficult to differentiate

between the two entities. This subsection focuses on primary infectious encephalitis.

### Aetiology

- In many instances no specific aetiological agent can be identified.
- Geographical location and seasonal variation influence the frequency of infection with specific organisms.
- Viruses are the responsible pathogen in the majority of cases (see Table 5.16.C.1).
- Arboviruses are an important cause of encephalitis worldwide, but the major contributor within the arbovirus group, the Japanese encephalitis virus (JEV), is limited to Asia and the Pacific Rim.
- Enteroviruses are a common seasonal cause of encephalitis in Europe and the USA. In the last decade there have been periodic large outbreaks of enterovirus 71 infections in Asia, and the overall incidence of enterovirus 71 is increasing in this region.

**TABLE 5.16.C.1 Causes of viral encephalitis according to geographical region**

America	Europe and the Middle East	Africa	Asia	Australasia
<ul style="list-style-type: none"> <li>West Nile Virus</li> <li>La Crosse</li> <li>St Louis</li> <li>Dengue</li> <li>Rabies</li> </ul>	<ul style="list-style-type: none"> <li>Tick-borne encephalitis</li> <li>West Nile virus</li> <li>Rabies</li> </ul>	<ul style="list-style-type: none"> <li>West Nile virus</li> <li>Rift Valley fever virus</li> <li>Congo-Crimean haemorrhagic fever</li> <li>Dengue</li> <li>Rabies</li> </ul>	<ul style="list-style-type: none"> <li>Enterovirus 71</li> <li>Japanese encephalitis</li> <li>West Nile virus</li> <li>Dengue</li> <li>Murray Valley encephalitis</li> <li>Rabies</li> <li>Nipah</li> </ul>	<ul style="list-style-type: none"> <li>Murray Valley Encephalitis</li> <li>Japanese Encephalitis</li> </ul>
<ul style="list-style-type: none"> <li>Sporadic causes</li> </ul>	<ul style="list-style-type: none"> <li>Herpes simplex 1 and 2</li> <li>Varicella zoster virus</li> <li>Epstein–Barr virus</li> <li>Cytomegalovirus</li> <li>Human herpes virus 6 and 7</li> <li>Coxsackieviruses</li> <li>Echoviruses</li> <li>Enteroviruses 70 and 71</li> <li>Parechovirus</li> <li>Poliovirus</li> <li>Measles</li> <li>Mumps</li> <li>Rubella</li> </ul>			

**TABLE 5.16.C.2 Suggested investigations in children with acute encephalitis, with reference to differential diagnosis**

Investigation	Relevance
Blood glucose levels	Hypoglycaemia (common in infants and children with severe infections and poor oral intake/vomiting)
	Hyperglycaemia (diabetes)
	Metabolic encephalopathies, inborn errors of metabolism
Full blood count, blood film	Cerebral malaria (in endemic regions, returning travellers, etc.)
Urea and electrolytes	Hyponatraemia, syndrome of inappropriate secretion of antidiuretic hormone
Liver function tests	Reye's syndrome, metabolic encephalopathies
	Liver failure
Arterial blood gas	Metabolic encephalopathies
	To assess severity, particularly in individuals with brainstem compromise
Ammonia	Reye's syndrome, metabolic encephalopathies
Blood culture and Widal test	Typhoid and other septicaemias may have encephalopathic features
Acute and convalescent serology	To include locally relevant pathogens (e.g. Japanese encephalitis serology in Asia) and those suggested by history and examination (e.g. measles, mumps, varicella, HSV, <i>Mycoplasma</i> , <i>Legionella</i> )
Toxicology	Heavy metals, pesticides
Erythrocyte sedimentation rate	Collagen vascular disorders
Autoantibodies	Collagen vascular disorders
Cerebrospinal fluid (CSF) <ul style="list-style-type: none"> <li>Examination and culture</li> <li>CSF PCR</li> </ul>	Bacterial meningitis Tuberculous meningitis Intracranial haemorrhage HSV Enterovirus 71
Electroencephalography (EEG)	Status epilepticus
Neuroimaging (with contrast enhancement)	Space-occupying lesion (malignancy, brain abscess) Tuberculous meningitis Intracranial haemorrhage

- Herpes simplex type 1 (HSV-1) causes sporadic encephalitis worldwide.
- The common childhood viral infections such as measles, mumps, rubella and chickenpox (varicella zoster virus, VZV) may all involve the nervous system.
- Spirochaetal infections including syphilis, leptospirosis and Lyme disease are a well-recognised cause of meningoencephalitis. Other organisms such as *Brucella* are occasionally implicated. *Mycoplasma pneumoniae* is an important and treatable cause. Neurological

involvement may occur in chlamydial and rickettsial infections, and both fungi (e.g. *Cryptococcus*) and parasites (e.g. *Angiostrongylus cantonensis*) may cause meningoencephalitis.

- Immunocompromised individuals are at particular risk of developing parasitic and fungal infections.
- Encephalitis has been noted to occur following a wide variety of immunisations. Fortunately, improvements in vaccine technology in recent years have meant that such complications are now rare.

## Clinical features

### Presentation

The following clinical manifestations commonly occur, whatever the aetiological agent:

- An acute systemic illness with fever, headache, nausea and vomiting.
- Generalised seizures, less commonly focal.
- Behavioural or personality changes.
- Deteriorating conscious level, confusion and drowsiness, lapsing into coma.
- Neck stiffness is common but not invariable.
- Signs of involvement of any part of the nervous system may be present (e.g. hemiparesis, ataxia, myelitis, movement disorder, brainstem abnormalities).
- A rash may point to a specific diagnosis (e.g. measles, VZV, enteroviruses).
- Presentation may be subtle and/or subacute in immunocompromised individuals.
- Signs of raised intracranial pressure (ICP) may be present. The possible contribution of raised ICP to the

clinical picture should always be considered, as this may be amenable to treatment.

Severity ranges from a mild illness with fever, a single brief seizure and confusion lasting for 2–3 days, to a more prolonged illness with a fluctuating level of consciousness and evolution of neurological signs over several weeks. Occasionally the course may be fulminating, with death occurring within a few days.

### Diagnosis

The following investigations (see Table 5.16.C.2) should be considered in all cases but may be constrained by lack of resources. Efforts should be directed towards identifying those diseases that are treatable, common locally, or indicated by specific details in the history.

CSF examination and culture provide valuable diagnostic information, but if the child shows evidence of raised ICP, has signs suggestive of a space-occupying lesion or has cardiovascular compromise, lumbar puncture may be contraindicated. Lumbar puncture should be deferred until considered clinically safe, and antimicrobial therapy should be prescribed empirically, directed towards the common pathogens and antibiotic sensitivity patterns in the region.

Typical findings in the CSF in viral encephalitis are documented in Table 5.16.C.3, together with characteristic features on EEG and neuroimaging. In general it is possible to differentiate between viral and bacterial CNS infections on the basis of the CSF picture. If there is doubt, however, empirical antibiotic therapy should be given pending CSF culture results (see Section 5.16.B). Alternatively, if the child is stable, the lumbar puncture should be repeated after 24–48 hours while observing the clinical condition closely.

**TABLE 5.16.C.3 Typical findings in viral encephalitis**

Investigation	Findings
CSF microscopy and biochemistry	<ul style="list-style-type: none"> <li>● Rarely may be normal</li> <li>● Usually lymphocyte-predominant pleocytosis (from a few to several thousand white blood cells/mm<sup>3</sup>)</li> <li>● In early disease, polymorphonuclear cells may predominate</li> <li>● Mildly elevated or normal protein levels</li> <li>● Normal CSF/plasma glucose ratio</li> <li>● Absence of microorganisms on Gram stain</li> <li>● Eosinophilia suggests parasitic infection</li> <li>● India-ink stain: cryptococcus</li> <li>● Normal CSF opening pressure (&lt; 25 cmH<sub>2</sub>O)</li> </ul>
Electroencephalography (EEG)	<ul style="list-style-type: none"> <li>● Virtually always abnormal</li> <li>● Diffuse slow waves; occasionally unilateral patterns may suggest particular causative agents, such as HSV (see below) or subacute sclerosing panencephalitis</li> </ul>
Neuroimaging: CT or MRI	<ul style="list-style-type: none"> <li>● May be normal</li> <li>● Cerebral oedema is common</li> <li>● Features may suggest particular causative agents (e.g. HSV, Japanese encephalitis virus)</li> </ul>

### Management

In the majority of cases no specific treatment is available, and management is primarily supportive.

- Provide bed rest, and analgesia for headaches. Care is needed with sedation, as a deterioration in conscious level may be obscured and/or respiratory depression may occur.
- Antipyretics may be used to alleviate distress, but are no longer recommended solely to reduce the temperature.
- Ensure adequate oxygenation (SaO<sub>2</sub> > 94%).
- Regularly monitor electrolytes and review fluid balance.

**Fluid restriction may not be appropriate if the cardiac output is low.** Aim to keep the serum sodium level (and other electrolytes) within the normal range. Consider the possible causes of hyponatraemia (e.g. vomiting/gastrointestinal losses, excessive hypotonic intravenous fluids, over-hydration, syndrome of inappropriate secretion of antidiuretic hormone) and act accordingly.

- Critically ill children, particularly those with evidence of brainstem involvement or raised ICP, should be managed in an intensive-care unit if possible. Assisted ventilation and cardiovascular support should be

instituted early if there is evidence of compromise. Children should be nursed with the head in the midline and tilted 20 degrees up. If they are ventilated, normocapnia should be maintained.

- Control of seizures (see Section 5.16.D and E). Caution is required when using anticonvulsant drugs with the potential to cause respiratory depression. EEG monitoring may reveal subclinical seizure activity.
- Intermittent use of mannitol (250–500 mg/kg per dose, which may be repeated after 1 hour) or hypertonic saline may be helpful if there is evidence of raised intracranial pressure (ICP), but remember that electrolyte and fluid balance monitoring are critical (hypernatraemia is as dangerous as hyponatraemia). ICP monitoring should only be undertaken in centres that are experienced in this technique.
- If there are pointers in the history, examination and/or preliminary investigations that suggest a specific diagnosis such as HSV, *Mycoplasma* or Lyme disease, the relevant treatment should be given (see below).
- If bacterial or tuberculous meningitis cannot be excluded, and the child is severely ill, consider providing cover with appropriate drugs until these diagnoses can be definitively ruled out (see Section 5.16.B and Section 6.1.N). A second lumbar puncture performed 24–48 hours after admission may aid this decision (provided that raised ICP is not present).

### Long-term prognosis

The illness may be prolonged, and survivors may be left with significant neurological sequelae. Physiotherapy and rehabilitation should be commenced once the acute stage of the illness is over and the child is stable. Some children remain in hospital for many months, and relatives require considerable support to cope with the often devastating effects on the family. A number of children without overt neurological sequelae are left with subtle problems, including visual and hearing impairments, learning difficulties and behavioural problems. Long-term follow-up is needed to detect and manage these problems.

## Features of specific viral infections that cause encephalitis

### Enterovirus 71

- There have been recurrent outbreaks in Asia since the 1990s, and a rising prevalence in the region.
- Children under 5 years of age are most commonly affected.
- These infections can be associated with hand, foot and mouth disease (HFMD) (with vesicular lesions on the hands, feet or mouth) or herpangina (mouth ulcers)
- Neurological involvement includes aseptic meningitis, acute flaccid paralysis, Guillain-Barré-type illness and brainstem encephalitis (cranial nerve involvement, myoclonic jerks and autonomic disturbance). The onset of neurological problems is commonly within the first 3 days of illness.
- Diagnosis is primarily clinical, but viral culture on throat, rectal or vesicle swabs provides supportive evidence. If available, PCR is advisable to identify the specific serotype of enterovirus.
- Children affected with brainstem encephalitis are at risk of cardiopulmonary complications such as shock,

pulmonary oedema and/or haemorrhage. They should be managed in a paediatric intensive care unit if possible.

- Polyclonal IgG (2 grams/kg in 24 hours) may be given when there is neurological involvement, although there is no direct evidence to support this therapy at present. There are potential adverse effects, such as anaphylaxis, and IVIG should only be administered with cardiac monitoring facilities.
- High-level supportive care is necessary for patients with cardiopulmonary compromise, but there is a high case fatality and morbidity in this group.

### Japanese encephalitis virus

- This is the most common cause of encephalitis worldwide. There are an estimated 50 000 cases and 15 000 deaths each year.
- It is currently limited to Asia and the Pacific Rim, but there is evidence that previously non-endemic regions such as Tibet have cases.
- The virus is transmitted by *Culex* mosquitoes, with an enzootic cycle involving pigs and birds.
- Most infections are asymptomatic (200–300 asymptomatic cases for every case of encephalitis).
- Extrapyramidal and brainstem involvement is common in patients with encephalitis. Patients may have Parkinsonian features acutely, with some later developing choreoathetoid movement disorders. Gradual improvement over several months is usual in survivors.
- Myelitis may occur, usually accompanied by some encephalitic features. The prognosis for recovery from myelitis is poor.
- Diagnosis rests on IgM/IgG capture ELISA in serum and CSF. Viral isolation is difficult, as the viraemia is short-lived.
- Thalamic, basal ganglia and brainstem lesions are often apparent on CT or MRI imaging (if available).
- There are no specific features on EEG.
- Treatment is supportive only, but effective vaccines are available.
- The prognosis is poor. Up to 30% of patients with encephalitis die in the acute stage. Neurological sequelae are common in survivors, but do tend to improve with time.

### Herpes simplex virus

- This causes sporadic encephalitis worldwide.
- Encephalitis is more frequently a manifestation of recurrent than primary infection. There is no correlation between the presence of herpetic skin lesions and the diagnosis of HSV encephalitis.
- Seizures (both focal and generalised) are a prominent feature.
- Personality changes, temporal lobe phenomena, and dysphasia are also common.
- CSF findings:
  - Lymphocytic pleocytosis: < 50 to 2000/mm<sup>3</sup>.
  - Red blood cells are present in CSF in more than 80% of cases, reflecting haemorrhagic necrosis.
  - Protein levels are usually moderately elevated, but may reach very high levels as the disease progresses (3–5 grams/litre).
  - Up to 25% of cases may have a relatively low CSF glucose concentration.

- Occasionally the CSF is entirely normal in early disease.
- Diagnosis is by polymerase chain reaction (PCR) or serology on CSF. Viral isolation is difficult.
- If the initial CSF PCR is negative but there are ongoing clinical features suggestive of HSV infection (e.g. deteriorating level of consciousness, focal seizures), a repeat lumbar puncture more than 72 hours after the onset of neurology is advisable. Early CSF for PCR may be falsely negative.
- EEG may show a typical pattern of multifocal periodic lateralising episodic discharges (PLEDs) on a slow background, often with a temporal lobe focus.
- CT and MRI (if available) may show lesions (often haemorrhagic) in the temporal lobes. In early disease, scans may be normal.
- **Treatment is with high-dose IV aciclovir for 21 days as an infusion over one hour** (neonate to 3 months 20mg/kg; 3 months–12 years 500mg/m<sup>2</sup> (see Section 9 for chart on surface area); 12–18 years 10mg/kg. All doses given 8 hourly: in older child use ideal weight for height if obese).
- Treatment may be stopped if the patient is diagnosed with a clear alternative cause of the encephalitis.
- In those with a definitive diagnosis, it is advisable to have a negative CSF PCR at the end of the treatment course.
- Early diagnosis and treatment improve the outcome significantly. HSV is a possibility in all patients with encephalitis, although in areas of the world where other pathologies such as enterovirus 71 encephalitis are endemic, HSV is responsible for only a very small minority of the total number of cases. **If resources permit, start aciclovir (at the dosage stated above) in all cases without a definitive diagnosis and continue until HSV has been excluded, or an alternative diagnosis has been reached.**
- Mortality can still be up to 20%, with around 15% of cases left with severe sequelae. Relapses occur occasionally, but these are less likely to occur if treatment is continued for 21 days.

#### Varicella zoster virus (VZV)

- VZV infection usually only results in mild encephalitis, with acute cerebellar ataxia as the main feature. Seizures and coma are rare, and the prognosis is good.

#### Measles (see Section 6.2.E)

- Acute encephalitis may occur 6–8 days after the onset of the rash, and may be severe, with up to 10% mortality and frequent sequelae.
- Delayed chronic encephalitis may also occur in the form of subacute sclerosing panencephalitis (SSPE), presenting with cognitive deterioration and myoclonic jerks. In such cases the EEG shows stereotypic polyphasic complexes on a background of excess slow activity.

#### Rabies (see Section 6.2.H)

- Saliva (plus virus) from an infected mammal enters via a bite, skin abrasion, or rarely through intact skin or mucous membranes.
- The incubation period varies from a few days to many months. A history of animal bite may not be elicited at the time of presentation.
- There is an initial prodrome of fever and malaise lasting

a few days, followed by a second phase of excitement, hyperacusis, hydrophobia and pharyngeal spasms.

- Lastly, a paralytic phase occurs (rarely this may be the only manifestation).
- Death is inevitable once neurological signs are apparent.
- Effective prevention is available with the human diploid cell vaccine, and should be combined with passive immunisation if exposure has occurred.

### Other organisms

#### Mycoplasma

- Neurological involvement occurs in up to 7% of infections.
- Both direct invasion of CNS and immune-mediated disease occur.
- Aseptic meningitis, transverse myelitis and Guillain-Barré syndrome are the most common manifestations.
- Diagnosis is by complement fixation titres (if available).
- If the diagnosis is suspected, treat intravenously or enterally if tolerated, with erythromycin, 12.5mg/kg/dose 6-hourly for 10 days. However, this is not effective for the immune-mediated disease.

#### Cryptococcus

- This can cause acute fulminant meningoencephalitis in immunocompromised children.
- It may present more subtly in an immunocompetent child.
- Consider when there is prolonged headache, fever, vomiting and focal neurology.
- It is important to have a baseline CSF opening pressure (provided that there are no contraindications).
- There may be normal CSF biochemistry and cell count.
- Diagnosis is based on India ink smear or CSF culture or rapid antigen assay in CSF or serum.
- Start with a 2-week induction treatment phase of an IV infusion over 4–6 hours of amphotericin 250 micrograms/kg once daily increasing as tolerated to 1.5mg/kg once daily (after a test dose of 100 micrograms/kg to be included in the first calculated dose) plus flucytosine 25mg/kg/every 6 hours, or fluconazole 6–12mg/kg/day up to a maximum of 800mg/day.
- Children with HIV may require higher doses of amphotericin (up to 5mg/kg/day)
- Amphotericin therapy requires pre-hydration and close supervision for toxicity, including hepatic and renal function tests, electrolyte monitoring and regular full blood counts.
- In settings where amphotericin is not available, fluconazole 12mg/kg/day up to 1200mg/day with or without flucytosine 100mg/kg/day or fluconazole 12mg/kg/day up to 1200mg/day alone may be used.
- Initial treatment should be followed by an 8-week consolidation phase using fluconazole 6–12mg/kg/day, up to a maximum of 400–800mg/day.
- For the maintenance treatment phase, fluconazole 6mg/kg/day up to a maximum of 200mg/day is used.
- Raised intracranial pressure may develop during treatment, and prompt recognition is important. If identified, repeated therapeutic lumbar punctures can be helpful in controlling headache and limiting the development of ventricular dilatation, blindness and cranial nerve palsies.
- In HIV-infected individuals, consider antiretroviral therapy

once antifungal treatment is established, but there is a risk of immune reconstitution syndrome.

### Human angiostrongylus

- This is predominantly found in the Pacific Islands and Asia, where it is the most common cause of eosinophilic meningoencephalitis.
- The main mode of infection is via consumption of raw snails or other molluscs, freshwater prawns, frogs and contaminated vegetables.
- The hands may become contaminated with larvae that are then directly carried to the mouth by small children.
- Presentation is commonly with acute severe headache, low-grade fever, cranial nerve involvement, visual disturbances, paraesthesia or hyperaesthesia, and raised intracranial pressure.
- Peripheral blood eosinophilia may be very marked.
- Eosinophils are also seen in the CSF. Organisms may

invade both the meninges and the brain parenchyma, especially involving the posterior fossa.

- Diagnosis is primarily clinical, relying on a history of likely ingestion of contaminated food, with typical clinical findings and an eosinophilic CSF picture. Serological tests are available, but may be normal in the early stages, and are also difficult to interpret because there is great cross-reactivity with other parasites.
- MRI (if available) may show multiple micronodular enhancing lesions.
- In many cases the symptoms spontaneously resolve within several weeks (mean period of 20 days).
- It is rarely fatal, and sequelae are usually minimal. A minority of patients have persistent paraesthesia and weakness associated with chronic infection.
- Provide analgesia for headache: consider giving a 2-week course of albendazole and prednisolone orally, but the evidence for treatment regimes in children is lacking, and most cases resolve with time.

## 5.16.D Epilepsy

### BOX 5.16.D.1 Minimum standards

- Anticonvulsants: phenobarbitone, phenytoin, sodium valproate, carbamazepine, ethosuximide.
- Temperature control.
- Prednisolone.
- EEG and neuroimaging with CT and MRI (if available).

### Introduction

Epilepsy is a symptom caused by a central nervous system (CNS) disorder, and is usually defined as the occurrence of two unprovoked seizures. In over 70% of cases a cause cannot be identified (idiopathic epilepsy), although genetic causes may be important, as there is often a family history. Most children with epilepsy live in disadvantaged communities where the incidence rates are estimated to be twice those in western countries, and where more than 70% of affected individuals are untreated.

The impact of epilepsy on children and families is wide-ranging. To reduce disability, management is best shared with other healthcare workers who can visit the family closer to home, such as community doctors, and healthcare or disability workers.

### Confirming the diagnosis of epilepsy

There is no justification for a trial of anti-epileptic drugs if the diagnosis is unclear. The diagnosis of epilepsy is purely a clinical one, and is usually based on a good history or eyewitness account or ideally a video (often taken with a mobile phone) of an event.

Important features of the seizures include the following:

- timing and duration
- provocation factors
- the early phase of the attack; look for localising features
- movements
- sensory symptoms

- level of responsiveness
- nature of offset.

In early childhood, breath-holding attacks, reflex anoxic seizures and febrile syncope may be commonly mistaken for epileptic seizures. Syncope, hypoglycaemia and non-epileptic attacks such as extensor spasms also enter the differential diagnosis.

### Role of investigations

The history and sometimes the examination will usually indicate the cause. Children can be managed without the need for an electroencephalogram (EEG) or neuroimaging. EEG and neuroimaging (preferably an MRI scan, but sometimes a CT scan may be informative) should be reserved for intractable cases or those with neurological signs suggesting a space-occupying lesion. Such problems, and the imaging needed to identify them, will usually require the support of a specialised neurosurgical centre, at least one of which should exist in every country.

### Prognostic features of epilepsy

When a syndrome cannot be identified precisely, the features in Table 5.16.D.2 can serve as a guide to the prognosis.

Once the diagnosis and prognosis have been assessed, draw up a problem list as follows:

- What effect does the epilepsy have on the development of the child?
- Are learning or motor problems present?
- Is the child attending school and getting opportunities to play with other children?
- Are there any behavioural problems?

### Selecting appropriate anti-epilepsy drugs

Phenobarbitone, phenytoin, carbamazepine and sodium valproate should be available.

Convulsive status epilepticus (see Section 5.16.E).

**TABLE 5.16.D.1 Clinical classification: most common syndromes of epilepsy in children**

Syndrome	Features	Treatment
<i>Generalised</i>		
Tonic or tonic–clonic (grand mal)	Loss of consciousness Stiffening, convulsive movements Incontinence Post-ictal drowsiness, headache	Phenobarbitone Phenytoin Sodium valproate Carbamazepine
Absences	Vacant stare, with decrease in awareness, responsiveness and memory Precipitated by hyperventilation	Ethosuximide (may not be affordable) Sodium valproate <b>Avoid</b> carbamazepine and phenytoin
Myoclonic	Head nodding or jerks of limbs	Ethosuximide (may not be affordable) Sodium valproate <b>Avoid</b> carbamazepine and phenytoin
Infantile spasms	Sudden flexion of head, trunk and limbs; sometimes extensor spasms Associated with hypsarrhythmia on the EEG and developmental delay	Steroids (these require careful monitoring; <b>avoid</b> using them if this is not feasible) Sodium valproate
Lennox–Gastaut syndrome	Multiple seizure types: tonic (especially night), atonic, absences, generalised tonic–clonic. Associated with slow spike and wave on EEG and developmental delay	Sodium valproate Carbamazepine Phenytoin Combinations of the above
Secondary generalised seizures	Seizures starting as partial, and developing (sometimes rapidly) into generalised tonic–clonic seizures	Carbamazepine Sodium valproate Phenytoin Phenobarbitone
<i>Partial</i>		
Simple	Convulsive movements involving the eyes, face and parts of limbs. May have sensory symptoms	Carbamazepine Sodium valproate
Complex	Aura of abdominal discomfort, vacant stare, loss of contact with surroundings, lip smacking, chewing, swallowing, facial flush, hallucinations Post-ictal tiredness and headaches May produce apnoea	Carbamazepine Sodium valproate Phenobarbitone
Benign epilepsy of childhood with Rolandic spikes	Most common, usually starts at 3–10 years of age Predominantly simple partial seizures involving oropharyngeal muscles (gurgling), face or limbs, mostly during sleep Characteristic EEG, normal intelligence	Often do not need treatment Carbamazepine Sodium valproate Phenobarbitone

**TABLE 5.16.D.2 Prognosis in epilepsy**

Good outcome	Adverse outcome
Single seizure type	Multiple seizure types
No additional impairment	Additional neurological impairment (especially cognitive)
Late age of onset (for the syndrome)	Early age of onset (for the syndrome)
Provoked by illness, stress, flashing lights	Unprovoked
Short seizures	Status epilepticus
Low frequency of seizures	High frequency of seizures
Good initial response to anti-epileptic drugs	Poor initial response to anti-epileptic drugs, requiring polytherapy

**How to start treatment**

- Monotherapy is the aim, to reduce the side effects and interactions.
- Try to avoid using drugs that impair development (e.g. phenobarbitone, except in infancy).
- If possible, always prescribe the same brand, as there may be pharmacodynamic differences.
- Always start in low doses to minimise side effects and increase the likelihood of compliance.
- Remember to warn the child and their family about any likely side effects, especially if they are temporary, such as drowsiness.
- Increase the drug dose gradually (every 2–4 weeks) until the seizures stop or are significantly reduced, or side effects become significant (see Table 5.16.D.3).

**How to monitor treatment**

- Case notes should record the diagnosis, problem list, dates and types of seizures, indication for treatment,

past treatment with response and side effects of treatment, and information that has been given to the child and their parents or carers.

- Hand out medical cards to be kept as a seizure diary, reminder of prescription and clinic dates. Graphic symbols can be used for the illiterate.
- Regularly review the child to check on their progress. Review them more often if seizure control has not been achieved, or if are side effects or drug changes.

#### **When to change treatment**

- Consider changing treatment if side effects are troublesome.
- Introduce the second anti-epileptic drug in the normal way, first checking for possible drug interactions. Once established, begin to withdraw the first anti-epileptic gradually. If seizure control is not achieved with monotherapy, seek a specialist referral.

#### **When and how to stop treatment**

In children with a good prognosis, 12–24 months of freedom from seizures is associated with a 70% risk of continuing seizure remission. Withdrawal must be a gradual and closely monitored process. If seizures recur after a decrease in drug dose, they usually remit once the last decrease has been reversed. The withdrawal period depends on the drug (e.g. phenobarbitone over 4–6 months, carbamazepine over 2–3 months).

#### **Whom to refer**

This depends upon local facilities. One-third of patients will be intractable to treatment with first-line anti-epileptic drugs. Some of them may not have epilepsy, and others may have syndromes with a poor prognosis. They will require specialist assessment and treatment advice. Epilepsy may also be a part of complex developmental disorders involving the CNS, and these children may also benefit from specialist input.

**TABLE 5.16.D.3 Doses of common anti-epileptic drugs**

Drug	Usual dose	Side effects and toxicity
Carbamazepine	1 month–12 years initially 5 mg/kg at night or 2.5 mg/kg twice daily increasing to 5 mg/kg three times a day Maximum dose 20 mg/kg per day 12–18 years Initially 100–200 mg 1–2 times daily increasing to 200–400 mg two or three times daily. Maximum up to 1.8 g daily	Ataxia, diplopia, aplastic anaemia (bruising, mouth ulcers)
Phenobarbitone	One month to 12 years initial dose 1.5 mg/kg twice daily increasing to 2.5–4 mg/kg/day once or twice daily 12–18 years 60–180 mg once daily	Drowsiness, agitation, rashes, developmental impairment
Phenytoin	1 month–12 years initial dose 1.5–2.5 mg/kg twice daily then increasing to 2.5–5 mg/kg twice daily 12–18 years initial dose 75–150 mg twice daily increasing to 150–200 mg twice daily (maximum 300 mg twice daily)	Gum hypertrophy, hirsutism, acne, ataxia, diplopia, nystagmus, neuropathy, choreoathetosis, encephalopathy, lymphoma, megaloblastic anaemia
Sodium valproate	1 month–12 years initial dose 5–7.5 mg/kg twice daily increasing to 12.5–15 mg/kg twice daily 12–18 years initial dose 300 mg twice daily increasing to 0.5–1 g twice daily	Nausea, epigastric pain, alopecia, weight gain, tremor, hepatitis, pancreatitis, encephalopathy

#### **Social issues**

##### **Promoting social integration**

Children need to participate as fully as possible in the normal activities of their peers, at school, at play, in the home and preparing for employment. Community workers should be involved in the wider management, and parents' fears and anxieties discussed.

##### **Supporting parents**

Parents often tend to overprotect their children who have epilepsy, and may lack confidence in dealing with seizures. In many societies epilepsy carries a stigma. Opportunities to discuss first aid, behaviour and other concerns are vital, and can be provided by healthcare workers or parent groups.

##### **First-aid advice**

The general theme to be emphasised is that children with epilepsy should be encouraged to live as full and normal a life as possible. There are very few absolute restrictions, but these include climbing trees or riding bikes or motorcycles. Children should be accompanied when swimming or when

near to hazards such as stoves and fires. During a convulsion, place the child in the recovery position, protect them from hard or sharp objects in the vicinity, and cushion their head. Do not put anything in their mouth or try to restrain their limbs. Let them recover by themselves. They may need to rest or sleep, but keep them under observation because they may start convulsing again. As a rough guide, a convulsion that does not stop spontaneously within about 10 minutes is likely to continue for longer, and may need intervention with anti-epileptic drugs given IV, rectally or buccally. The use of rectal diazepam at home by parents and carers is described later in this subsection.

#### **Febrile seizures**

A febrile seizure is a seizure that occurs in children aged between 6 months and 7 years with febrile illness not caused by an intracranial disease. The commonest age of onset is 14–18 months. Febrile seizures are common, occur in 2–5% of all these children, and account for about one-third of all childhood seizures.

### Clinical presentation

Febrile seizures are usually brief, generalised, clonic or tonic-clonic convulsions lasting less than 10 minutes with minimal post-ictal confusion or weakness. About 20% of febrile seizures are complex (i.e. focal), or last longer than 15 minutes, or occur more often than once in 24 hours. Complex febrile seizures may suggest an underlying central nervous system cause and are associated with a poorer outcome (cognitive impairment or epilepsy).

Febrile seizures occur while the child has a recognisable infection, most commonly an upper airway infection or a viral illness such as gastroenteritis. Other causes include pneumonia, urinary tract infections and after vaccinations. Shigellosis, roseola infantum and malaria have an unusually high incidence of seizures. Most children have a core temperature of 38–41 °C, but it may occur at the onset of the febrile illness, and the child may have a normal temperature at the time of seizure.

An increased frequency of febrile seizures occurs in the children of parents and siblings who have had febrile seizures, and siblings with epilepsy.

### Identify the cause

Check blood glucose levels (by finger-prick test if available), take a careful history and examine the patient thoroughly, especially with regard to alertness and ability to play, looking for common and serious sites of infection. Where relevant, look at rapid test or film for malaria parasites, and full blood count. Consider urinalysis, lumbar puncture, cultures of blood, urine, pharyngeal swab and cerebrospinal fluid, and relevant X-rays in children whose history and examination offer clues to serious infection. A lumbar puncture is mandatory if meningitis is thought to be a possibility (unless there is evidence of raised intracranial pressure, when IV antibiotics should be given until meningitis can be excluded; see Section 5.16.A and Section 5.16.B).

### Differential diagnosis

Exclude the following:

- meningitis
- encephalitis
- acute encephalopathies of metabolic or toxic origin
- cerebral malaria
- electrolyte disorders
- hypoglycaemia
- anoxia
- trauma
- haemorrhage
- tumour.

Other entities that can be confused with febrile seizures include the following:

- febrile delirium (in which the patient is speaking but not making sense)
- febrile rigors (in which the patient is shaking with a fine tremor).

### Treatment

No treatment is necessary in simple self-limiting febrile seizures provoked by a minor febrile illness. Advice to parents should consist of the following:

- Reassurance that the condition is almost always benign and that the large majority of children stop having seizures after 5 or 6 years of age, while many have only one seizure.
- Practical demonstration of the recovery position for use if a further seizure occurs (see Section 5.16.E).
- Advice to seek medical help if a further seizure occurs, both in case it is prolonged (less than 5% of cases, but see below) and, importantly, so that the source of the provoking infection can be identified.

### Sequelae

- About one-third of children with febrile seizures will have another febrile seizure.
- Around 3% will have at least one afebrile seizure.
- Around 2% may develop epilepsy (recurrent afebrile seizures).
- Approximately 65% of children with simple febrile seizures will have had no further seizures by 7 years of age.
- Recurrent seizures tend to re-occur, particularly in children aged less than 1 year at the onset of the febrile convulsions or those with a positive family history.

### Risk of later epilepsy

The risk factors for the development of epilepsy are as follows:

- complex febrile seizures
- previous abnormal neurological function
- multiple febrile seizures
- family history of epilepsy
- age less than 1 year at the first seizure.

### Long-term care: home treatment

- Rectal diazepam for parents to administer if there are prolonged seizures (2.5 mg for children under 1 year, 5 mg for those aged 1–3 years, 10 mg for those aged over 3 years). **The parents must also be taught what to do if their child stops breathing (i.e. they should be equipped with a bag and mask and shown how to use it).**
- Oral or rectal paracetamol to prevent or treat febrile seizures.
- Advice to parents as described above.

## 5.16.E Convulsive status epilepticus

### BOX 5.16.E Minimum standards

- ABC and high-dependency care.
- Anticonvulsants:
  - lorazepam
  - phenobarbitone
  - phenytoin
  - paraldehyde
  - diazepam
  - midazolam
  - thiopentone.
- Temperature control.
- Mannitol.
- Dexamethasone.

### Introduction

Convulsive status epilepticus (CSE) is a life-threatening condition in which the brain is in a state of prolonged electrical discharge. It is defined as a generalised convulsion lasting for more than 30 minutes, or recurrent convulsions which occur very frequently over a 30-minute period, where the patient does not regain consciousness between seizures.

The duration of the convulsion is highly relevant, as the longer the duration of the episode, the more difficult it becomes to control it. Convulsions that persist for longer than 10 minutes are much less likely to stop spontaneously. Therefore it is usual practice to institute anticonvulsive treatment when the episode has lasted for 5 minutes or more.

### Common causes of convulsions in children

These include the following:

- fever with a predisposition to febrile convulsions (usually between the ages of 6 months and 6 years)
- meningitis
- epilepsy
- hypoxia
- metabolic abnormalities
- abrupt withdrawal of anti-seizure medication, especially phenobarbitone
- an acute cerebral event or injury (e.g. haemorrhage, trauma)
- ingestion of medication.

Tonic-clonic status occurs in approximately 5% of patients with epilepsy. Up to 5% of children with febrile seizures will present with status epilepticus. The mortality rate of status epilepticus can be high (up to 20% in adults), especially if treatment is not initiated quickly. However, with optimal management and adherence to a structured and standardised management plan, the mortality in children is much lower and patients can survive with minimal or no brain damage.

### Evaluation and immediate management of status epilepticus

During a seizure:

- Turn the child on their side.
- **Adopt an ABC approach. It is vital to ensure satisfactory**

### respiration and circulation and to exclude or treat hypoglycaemia before giving anti-epileptic drugs.

- Ensure that the airway is patent and that there is adequate respiratory effort and circulatory volume. Institute corrective measures immediately if these are required.
- If available, administer oxygen via a mask.
- Check glucose levels and treat if they are low (< 2.5 mmol/litre or 45 mg/dL). If in doubt or unable to check the levels, it is safer to treat as if hypoglycaemia is present and give 10% dextrose IV 2–5 mL/kg as an initial bolus and, if safe to do so, follow this with an infusion containing a glucose-containing fluid to avoid the risk of rebound hypoglycaemia.
- If the seizure has lasted more than 5 minutes (or if the duration is not known), prepare for anticonvulsant treatment. Short recurrent seizures lasting less than 5 minutes should also be treated (see Figure 5.16.E.1).
- **A self-inflating bag with non-return valve (e.g. Ambubag) and a suitably sized face mask must be available in case excessive respiratory depression is caused by benzodiazepines** (see Section 1.12).
- Treat the fever (if present) with exposure, tepid sponging and rectal paracetamol (40 mg/kg loading dose, 20 mg/kg if less than 3 months of age).

### Drugs

#### Lorazepam (intravenous or intra-osseous route)

Lorazepam is a benzodiazepine with a fast onset of action and a longer duration of effect (12 hours) compared with diazepam (which is less than 1 hour). It produces less respiratory depression than other benzodiazepines, and is less likely to require additional anticonvulsants to stop the seizure. However, absorption from the rectal route is poor. Lorazepam is not available in every country, but is no more expensive than diazepam.

Dose: 50–100 micrograms/kg/dose by IV or intra-osseous route (the dose can be repeated after 10 minutes if necessary).

#### Midazolam (buccal application)

Midazolam is an effective fast-acting anticonvulsant that has an onset of action within minutes but has a shorter lasting effect (15–20 minutes). Most children do not convulse again once the seizure has been terminated.

Buccal midazolam is twice as effective as rectal diazepam, but both drugs produce the same degree of respiratory depression. This occurs only in about 5% of patients, is short-lived, and is usually easily managed with bag-valve-mask ventilatory support.

Midazolam can be given by the buccal or IV route. However, the ready-made buccal midazolam may not be available in some countries. In such situations the standard IV preparation can be used instead via the buccal route. Simply draw the required dose in a syringe using a needle so as to filter off any glass fragments, and after removing the needle apply the drug on the buccal mucosa between the lower lip and the gum.

Dose:

- 500 micrograms/kg/dose (maximum 10 mg) with buccal application (the dose may be repeated).

### **Diazepam**

Diazepam is an effective, commonly used, readily available and fast-acting anticonvulsant with similar characteristics to midazolam. It is widely used, but may now be superseded by the more effective lorazepam or buccal midazolam where the latter is available. The rectal dose is well absorbed.

Dose:

- 500 micrograms/kg/dose rectally
- 200–300 micrograms/kg/dose by the IV or intra-osseous route (the dose may be repeated).

### **Lorazepam (intranasal route)**

This has been found to be safer than IM paraldehyde, and is also less expensive and easier to access. It is directly instilled into one nostril, with the patient in a supine position, drop by drop over 30–60 seconds.

Dose: 50–100 micrograms/kg/dose intranasally.

### **Paraldehyde**

Paraldehyde is an effective and cheap anticonvulsant with a sustained level of effect and a good safety profile. However, it may be difficult to find in some countries. Paraldehyde takes 10–15 minutes to start to take effect, and its action is sustained for 2–4 hours.

It is generally given by the rectal route after mixing the required dose with an equal amount of any edible oil (e.g. olive oil). This mixture is then quickly pushed up the rectum using a simple feeding tube attached to a syringe.

**Do not leave paraldehyde standing in a plastic syringe for longer than a few minutes, as the drug dissolves plastic.** The IM route can also be used, but is very painful and can lead to abscess formation, so is better avoided. Paraldehyde causes little respiratory depression, but should not be used in patients with liver disease.

Dose: 0.4 mL/kg rectally (0.4 grams/kg).

### **Phenytoin**

Phenytoin is a readily available anticonvulsant that can give very good results with little effect on respiration. It has a peak action within 1 hour, and a long half-life. Its action is therefore more sustained than that of diazepam.

It is administered as an IV infusion mixed with 0.9% sodium chloride solution made up to a concentration of 10 mg/mL, given over a 20-minute period. Phenytoin can cause dysrhythmias and hypotension (especially if given rapidly), so it is important to monitor the electrocardiogram (ECG) and blood pressure if these are available. In addition, local irritation, phlebitis and dizziness may accompany IV administration.

If the child is known to be on oral phenytoin it is better to either avoid using phenytoin (use phenobarbitone instead) or use a lower loading dose (i.e. 10 mg/kg).

Dose: 20 mg/kg IV infusion given over 20 minutes (only use normal (0.9%) saline for dilution).

### **Phenobarbitone**

Phenobarbitone is a time-tested anticonvulsant and readily available in many countries; the parenteral preparation is on the WHO essential drug list. It can be used to good effect in all age groups, and causes little respiratory depression.

It is given by the IV route as a slow injection over 5–15 minutes, and can also be given by the IM route, although the absorption is variable. It has a sustained effect that lasts over 12–24 hours.

There is now evidence to suggest that phenytoin and phenobarbitone may have some synergistic effect when used sequentially. It is thought that one primes the brain in readiness for the other, thus producing a beneficial effect. However, there is controversy about which drug should be used first.

Dose: 20 mg/kg IV infusion over 5–10 minutes.

### **Thiopental**

Thiopental (thiopentone) sodium is a drug better used by experienced staff who are familiar with it (usually anaesthetists: see Section 1.24) and who are capable of intubating difficult cases. It is a general anaesthetic agent with no analgesic properties but with marked cardiorespiratory effects. It is usually given after paralysis and intubation in induction of anaesthesia. Other anti-epileptic medication must be continued. The child should not remain paralysed, as continued seizure activity cannot otherwise be monitored. A paediatric neurologist should continue to give clinical advice and support.

### **General measures once seizures are controlled**

- **Maintain a normoglycaemic state** using 5% glucose-containing solutions (10% in young infants). Often children may show a hyperglycaemic pattern following seizures as a stress-induced response. This does not require correction with insulin.
- **Normal maintenance fluid volume** can be given to avoid hypoglycaemia and to maintain electrolyte balance. However, evidence of raised intracranial pressure or increased antidiuretic hormone secretion should necessitate fluid restriction.
- **Assess and maintain electrolyte balance**, maintaining serum sodium levels within the normal range (135–145 mmol/litre). Avoid hyponatraemia by using Ringer-lactate or Hartmann's solution.
- **Aspirate the stomach contents** by inserting a gastric tube, and perform gastric lavage or give charcoal (1 gram per year of the child's age) if appropriate for specific drug ingestion.
- **Regulate the temperature**, ensuring that temperatures above 37.5°C are avoided.
- **Treat raised intracranial pressure**, if clinically present (see Section 5.16.K), as follows:
  - Support ventilation (maintain a  $p\text{CO}_2$  of 4.5–5.5 kPa).
  - Maintain a 20-degree head-up position.
  - Give 20% mannitol, 250–500 mg/kg (1.25–2.5 mL/kg) IV over 15 minutes. This may be repeated on a 2-hourly basis as required.
  - Alternatively, hypertonic saline can be used (2.7% or 3% at a dose of 3 mL/kg). This may not be associated with a 'rebound' rise in pressure or induce a diuresis like mannitol but rather augments plasma volume.
  - Give dexamethasone, 500 micrograms/kg twice daily (for oedema surrounding a space-occupying lesion).
- **Catheterise the bladder**, as distension may aggravate raised intracranial pressure.
- **Frequent reassessment of ABC** is mandatory, as

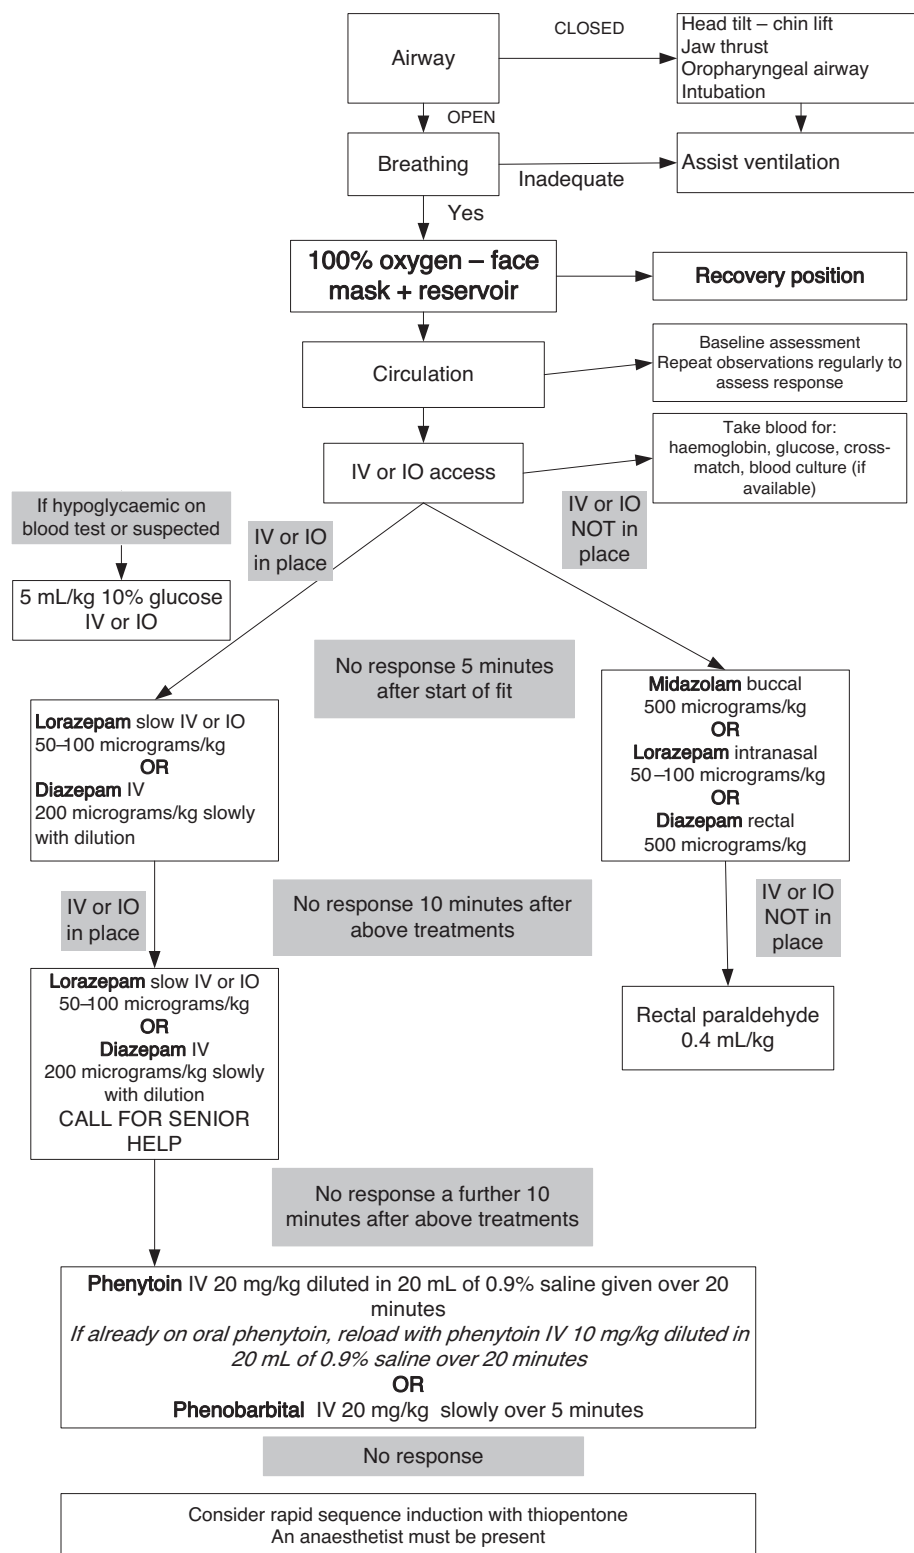

FIGURE 5.16.E.1 Algorithm for the treatment of status epilepticus in children.

therapy may cause depression of ventilation or hypotension, especially if benzodiazepines or barbiturates have been used.

- If available, a standard EEG can be done to establish cessation of electrical seizure activity.

- **Identify and treat the underlying cause** of the convulsion.
- Following seizure control there are several regimes for continued drug control of the convulsions, but they are beyond the scope of this text.

## 5.16.F Neuropathies

### BOX 5.16.F Minimum standards

- Muscle biopsy.
- Prevention of scoliosis.
- Prevention of muscle contractures.

### Introduction

Neuropathies are diseases that affect the anterior horn cells and/or the peripheral nerves.

### Anterior horn cell disease

The most common neuropathies are:

- poliomyelitis (see Section 6.2.G)
  - spinal muscular atrophy.

### Spinal muscular atrophy

This is a motor neuron disease of the spinal cord and brainstem, inherited as an autosomal-recessive disorder and associated with deletions of the survival motor neuron (SMN) and neuronal apoptosis inhibitory protein (NAIP) genes. It is the second commonest autosomal-recessive disorder after cystic fibrosis.

### Clinical features

These children have delayed motor development but normal social, language and intellectual development. They are floppy and weak. The weakness is proximal more than distal, and affects the lower limbs more than the upper ones. The children are areflexic, and fasciculation of the tongue is

diagnostic (observed with the tongue at rest in the mouth). There are three clinical subtypes based on severity.

- **Severe infantile type:** These infants never sit, crawl or walk. The onset is before or soon after birth. They have severe intercostal and bulbar weakness but the diaphragm is spared. Most die from respiratory failure before their second birthday.
- **Intermediate type:** These infants can sit but are unable to walk. They may or may not have respiratory and bulbar weakness, and this factor determines their prognosis. If it is absent, these children can survive into adulthood.
- **Mild type** (also known as Kugelberg–Welander type). The onset is later and these children can walk, but they do so late and with difficulty. Respiratory and bulbar weakness is not usually present. A coarse tremor of the hands is frequently seen in this and the intermediate form. This is a useful sign for distinguishing this type from muscular dystrophy, with which it is often confused (see Table 5.16.F.1).

### Diagnosis

Since the discovery of the gene defect, muscle biopsy is rarely needed. Deletion of the *SMN* gene is found in almost all cases of spinal muscular atrophy of all three types. It can be detected rapidly by the polymerase chain reaction (PCR). Blood (2–5 mL in an EDTA tube), or DNA extracted from it, can be sent by post to a laboratory that will perform the test and confirm the diagnosis within a few days.

TABLE 5.16.F.1 Comparison of spinal muscular atrophy (mild type) and Duchenne muscular dystrophy

Feature	Spinal muscular atrophy	Duchenne muscular dystrophy
Motor milestones	Delayed	Normal or delayed
Hypotonia	+++	+/-
Pseudohypertrophy	+/-	+++
Hand tremor	+++	-
Tongue fasciculation	+	-
IQ	Normal	Normal or low
ECG	Baseline tremor	R- and Q-wave changes
Creatine kinase	Normal or slightly raised ( $\times 2$ )	Very high ( $\times 100$ )
EMG	Chronic denervation	Myopathic
Muscle biopsy	Denervation	Dystrophic

### Management

Management is supportive. The most important complication in the intermediate form is the development of scoliosis. This can be delayed by getting the child to stand with support of lightweight callipers for as long as possible. If the child is confined to a wheelchair, a brace may be needed to control the scoliosis. Surgery (fusion of the spine) may be necessary. Children with symptoms of nocturnal hypoventilation (disturbed sleep, headaches, daytime drowsiness and poor concentration) may benefit from assisted non-invasive night-time ventilation with a nasal mask (see Section 8.2).

### Peripheral neuropathy

The two commonest causes of peripheral neuropathy in children are Guillain–Barré syndrome (see Section 5.16.G) and hereditary motor and sensory neuropathy.

### Hereditary motor and sensory neuropathy

This is the commonest chronic peripheral neuropathy in children. It is progressive, and there are several types, but the commonest is type I (peroneal muscular atrophy). It is dominantly inherited, and most children are asymptomatic until late childhood, when unsteady clumsy gait with frequent falls develops. There is weakness and wasting of the muscles of the anterior compartment of the leg. The parents

are often asymptomatic. The diagnosis is confirmed by the finding of very low motor conduction velocities in both the child and one of the parents, indicating demyelination. Type II is similar, but rare, and shows axonal rather than demyelinating changes in nerve conduction studies. There are no treatments for these diseases other than special boots and ankle orthoses to stabilise the ankle.

### Other peripheral neuropathies

These include leukodystrophies (where peripheral nerve demyelination occurs as part of CNS demyelination), toxic neuropathy (due to glue or benzene sniffing, lead, or drugs) and diphtheria (see Section 6.1.C).

## 5.16.G Guillain-Barré syndrome

### BOX 5.16.G Minimum standards

- ABC resuscitation and emergency care.
- Lumbar puncture.

### Introduction

This is the commonest peripheral neuropathy seen in childhood. It is a demyelinating neuropathy induced by an autoimmune process that is precipitated by a preceding viral or other infection. It has a peak incidence at around 8 to 9 years of age in well-resourced countries and 3 to 4 years of age in resource-limited ones, possibly due to overcrowding. Rarely, an acute axonal form occurs, especially in some countries, such as China.

### Clinical features

The onset is usually acute. There is often a history of a preceding upper respiratory or gastrointestinal tract infection and insidious sensory symptoms (e.g. muscle tenderness, occasionally an unsteady gait, and frequent falls). The weakness starts in the lower limbs and ascends to affect the trunk, upper limbs, and the respiratory (intercostal and diaphragm), bulbar and facial muscles. It is usually symmetrical and affects both proximal and distal muscles, and may take 10–30 days to reach its maximum. Cranial nerve involvement often precedes respiratory difficulties. Reflexes are frequently absent. Sensory loss is minimal and of the 'glove-and-stocking' distribution. Ophthalmoplegia, papilloedema and bladder involvement rarely occur. Autonomic dysfunction occurs in many children, resulting in hypertension, hypotension and cardiac arrhythmias. In some patients the paralysis occurs rapidly with quadriplegia and respiratory paralysis within 2–5 days.

### Chronic inflammatory demyelinating polyradiculoneuropathy

The disease may evolve into chronic inflammatory demyelinating polyradiculoneuropathy. This disease is similar to Guillain-Barré syndrome, consists of progressive or relapsing motor and sensory dysfunction, and lasts at least 2 months, with hyporeflexia of all four limbs. The importance of identifying this condition is that it responds to steroids (prednisolone 2 mg/kg/day).

### Diagnosis

The diagnosis is confirmed by an abnormal nerve conduction stimulation, but a high CSF protein level and almost normal cell count are very suggestive. These findings are

usually present after the first week of onset. Other causes of acute flaccid paralysis such as poliomyelitis in endemic countries need to be considered (see Table 5.16.G.1).

### Management

Supportive care is the cornerstone of successful management of the acute patient. Of greatest concern is respiratory failure due to paralysis of the diaphragm (the muscle that is most important for breathing). **Intubation** may be needed if there is evidence of impending respiratory failure. The following steps in management should be taken:

- Admit the child to hospital to monitor for impending respiratory and bulbar paralysis and autonomic dysfunction.
- Measure the respiratory rate, heart rate and blood pressure, perform pulse oximetry and if possible measure vital capacity (or peak flow), and check airway protection frequently. Blood gas analysis may be helpful.
- If the vital capacity is less than 50% of normal for age **and/or there is significant respiratory failure with hypoxaemia and hypercapnia**, ventilate the child if possible.
- If bulbar and respiratory paralysis occurs, airway protection, tube feeding and ventilatory support will be necessary. Airway protection can be achieved by intubation or tracheostomy.
- Plasma exchange (also called plasmapheresis) and high-dose immunoglobulin therapy may lessen the severity of the illness and accelerate recovery in some patients, but are not widely available. These two treatments are equally effective, and a combination of the two is not significantly better than either alone. However, immunoglobulin is easier to administer.
- Children who require ventilation can be given high-dose human immune globulin if available (0.4 grams/kg IV over 6 hours daily for 5 days). This can be repeated if there is no response, if deterioration occurs or if there is a relapse.

### Prognosis

Recovery is usually complete within 4–6 months in most children, but may take up to 2 years. About 5% of children will have minor motor sequelae, and around 2–3% will die from respiratory failure or autonomic dysfunction. Poor prognostic factors include onset of weakness within 8 days of preceding infection, rapid progression, cranial nerve involvement and a CSF protein level of > 800 mg/litre in the first week of the disease. The prognosis is generally better in children than in adults.

TABLE 5.16.G.1 Other causes and features of acute flaccid paralysis

Cause	Features
<i>Spinal cord</i>	
Poliomyelitis	Preceding fever, headache and meningeal irritation, asymmetrical weakness, CSF pleocytosis
Enterovirus: Japanese B encephalitis	Similar to poliomyelitis
Trauma	History and evidence of trauma
Myelitis	Paraplegia, segmental sensory loss Bladder and bowel sphincter disturbance
Epidural abscess	Fever, vertebral tenderness
<i>Neuropathies</i>	
Guillain-Barré syndrome	Symmetrical, areflexia, ascending weakness
Diphtheria	Preceding history of diphtheric pharyngitis, cardiac involvement, deep sensation impaired
Botulism	Bulbar symptoms before onset of weakness, ophthalmoplegia
Tick paralysis	Rapid progressive paralysis, no sensory loss, normal CSF protein levels Resolves quickly once tick has been removed
<i>Metabolic</i>	
Acute intermittent porphyria Hereditary tyrosinaemia	Family history, other symptoms
<i>Muscle</i>	
Myasthenia gravis (rare but treatable)	Fluctuating weakness that is worsened by activity and better after rest Tensilon test is positive
Acute viral myositis	Tender muscles, limp, fever, elevated muscle enzymes (creatine phosphokinase or aldolase)
<i>Other causes</i>	
Organophosphate poisoning	History of exposure, excessive salivation, twitching of muscles, meiosis, tachycardia

## 5.16.H Muscular dystrophy

### BOX 5.16.H.1 Minimum standards

- Creatine kinase measurement.
- Prevention of scoliosis and contractures.
- Prednisolone.

### Introduction

The muscular dystrophies are a group of inherited disorders that cause progressive muscle weakness and share a common pathological process of muscle fibre degeneration and fibrosis.

### Duchenne muscular dystrophy

This is the most common muscular dystrophy, caused by deficiency of dystrophin, a structural protein found on the inner side of the sarcolemmal membrane. The deficiency is caused by deletions or point mutations of the dystrophin gene, which is located on the short arm of chromosome Xp21.

### Clinical features

Duchenne muscular dystrophy is X-linked; it affects boys

and is transmitted by females. Affected infants are normal in the first 2 years but will have very high serum creatine kinase levels. They usually present between 2 and 5 years of age with delayed walking, frequent falls, and difficulty in climbing stairs and in getting up from the floor. The weakness affects proximal more than distal muscles, and the pelvic girdle more than the shoulder girdle. The facial muscles are unaffected. Prominent calves and thighs are characteristic. With time, these children walk on their toes with marked lumbar lordosis and a waddling gait. The arm reflexes are lost early but ankle jerks are preserved. Once confined to a wheelchair, they rapidly develop contractures of the knees, hips and ankles and scoliosis. Intellectual impairment may occur or develop in some patients, often related to the onset of respiratory failure. The ECG shows dominant R waves in right-sided leads, deep Q waves in left-sided leads, and inverted T waves in most patients.

### Diagnosis

The serum creatine kinase activity is very high (100 times normal). The electromyogram (EMG) is myopathic, and muscle biopsy shows dystrophic changes and absent

dystrophin. Deletions in the dystrophin gene can be identified by the polymerase chain reaction (PCR) in DNA extracted from blood in 60–80% of patients.

### Management

There is no effective drug treatment. A course of oral prednisolone (0.75 mg/kg/day) for 3–6 months can produce a small but significant improvement in muscle strength, but has many side effects, and these must be weighed against the slight benefit. Night splints to keep the ankles at 90 degrees may delay shortening of the tendo-achilles. When walking is becoming difficult, the fitting of lightweight callipers and intensive physiotherapy may keep the child ambulant for a few more years. Once the child is wheelchair-bound, a rigid seat and adequate postural support of the spine may prevent scoliosis.

### Prognosis

The weakness is progressive, and by 10–12 years of age a wheelchair will be needed. Later, as respiratory muscle weakness develops, nocturnal hypoventilation may cause disturbed sleep and morning headaches (due to hypoventilation and carbon dioxide retention). Assisted non-invasive ventilation (using a nasal mask) at night will improve the child's quality of life (see Section 8.2). Death occurs in the twenties from respiratory or cardiac failure.

### Genetic counselling

An elevated creatine kinase activity (on three separate occasions) in female relatives indicates carrier status. Some will also have an abnormal muscle biopsy, with some fibres showing normal and others absent dystrophin. Normal creatine kinase and muscle biopsy does not exclude the carrier state. Prenatal diagnosis is possible in some but not all families, but requires specialised molecular genetic techniques.

### Becker muscular dystrophy

This is a milder variant of Duchenne muscular dystrophy, and is rare. Onset is between 5 and 10 years of age, and ambulation is maintained beyond 15 years and often into adulthood. This disorder is caused by partial deficiency of dystrophin.

### Limb girdle muscular dystrophies

These are rare and vary in severity. A severe form is prevalent in North Africa. It has a clinical picture similar to Duchenne muscular dystrophy, but affects boys and girls and has more prominent involvement of the shoulder girdle muscles, with winging of the scapulae. It is associated with deficiency of one of the sarcoglycans, a group of sarcolemmal proteins intimately linked to dystrophin. This can be demonstrated in muscle biopsy specimens. The intelligence remains normal and the heart is unaffected. Genetic tests for diagnosis are available in specialised laboratories.

### Congenital muscular dystrophy

Infants with congenital muscular dystrophy are born floppy and weak and have contractures. They have delayed motor milestones, and most are unable to walk. They develop a characteristic long thin expressionless face with an open mouth. There is no ophthalmoplegia. There are several subgroups, some with eye or brain abnormalities and demyelination. Merosin is deficient in one subgroup. Inheritance is autosomal recessive and the gene defect is known for most of them. The creatine kinase may be elevated or normal, and the diagnosis is made by muscle biopsy or genetic testing. Management is supportive. Congenital muscular dystrophy must be distinguished from other causes of hypotonia (i.e. other congenital myopathies, infantile spinal muscular atrophy and organic acidaemias).

## 5.16.1 Breath-holding episodes

### BOX 5.16.1.1 Minimum standards

- Haemoglobin measurement.
- Oxygenation measurement.

### Introduction

Breath-holding episodes occur in about 4% of children under the age of 5 years. They typically start between the ages of 6–18 months, and usually cease before the age of 5 years. They are infrequent, usually occurring less than once a month, but occasionally occur more often. There are two types of episodes, which are differentiated by the presence of **cyanosis** or **pallor**. The underlying mechanism of the two types is different.

### Type of episodes

#### Cyanotic breath-holding episodes

These are provoked by anger, frustration, fright or pain. The infant cries vigorously, holds their breath in expiration, goes blue, loses consciousness and becomes limp. Rarely this is followed by a brief stiffening of the body. The infant

then starts breathing again and the attack ends. These attacks may be due to cerebral ischaemia from a sudden rise in intrathoracic pressure that impedes venous return. Intrapulmonary right–left shunting also plays a part.

#### Pallid asystolic spells

These are less common than the cyanotic type (about 20% of all cases), and may occur in the context of a minor illness. The attack is provoked by pain, usually from a mild injury on the head. The child cries, loses consciousness, develops marked pallor and goes stiff. Occasionally the child loses consciousness immediately after the injury without crying. A few clonic jerks (reflex anoxic seizures) may occur. These pallid spells are caused by vagal asystole, and can be induced by pressure on the eyeballs (oculo-cardiac reflex), although it is not necessary to elicit this reflex, and if thought to be important, this should only be done under controlled conditions with EEG and ECG monitoring. **There is also a risk of damaging the eyeballs when pressing on them.**

### Diagnosis

The diagnosis is based on a careful history of the sequence of events. These attacks are frequently confused with epilepsy. In epilepsy, the cyanosis occurs after the tonic-clonic phase of the seizure. In breath-holding spells cyanosis occurs before but, more importantly, the diagnosis rests on the fact that the attacks are always precipitated by an appropriate stimulus. An EEG is not necessary except when the diagnosis is in doubt and epilepsy is suspected. **An ECG must be done in pallid asystolic spells to exclude long QT interval syndromes. Always exclude anaemia, which is a well-documented cause of breath-holding episodes. Also exclude chronic hypoxaemia, which is also a cause from unrecognised cardiac or respiratory disease.**

### Prognosis

These attacks are frightening for the parents, but are harmless. They eventually cease with time, and if there is no underlying pathology they do not have any long-term effects. There is no risk of subsequent epilepsy. Some infants with the pallid type go on to develop faints in later childhood.

### Management

The parents need to be given an explanation of these attacks and reassured about their harmless nature. There is no effective drug and no need for drug treatment. Treat anaemia and hypoxaemia if these are present.

## 5.16.J Migraine

### BOX 5.16.J.1 Minimum standards

- Paracetamol and ibuprofen.
- Anti-emetics.
- Propranolol, clonidine and pizotifen.

### Introduction

Migraine is a common cause of recurrent headaches in children. Its prevalence increases with age. It may be preceded by a history of recurrent abdominal pain and vomiting at a younger age (abdominal migraine, cyclical vomiting). The headache is typically throbbing in nature, temporal or frontal in location, more often bilateral than unilateral (in contrast to adult migraine), and commonly associated with nausea, vomiting, pallor and sometimes photophobia. It usually lasts for 1–3 hours, but sometimes persists for 24 hours, and it is relieved by sleep. Migraine is precipitated by stress (e.g. school examinations, family pressure, unrealistic expectations) and sometimes by hunger, fatigue, lack of sleep, exposure to sun, and some foods (e.g. chocolates, Coca-Cola, caffeinated drinks, nuts, cheese). A positive family history of migraine, especially on the maternal side, is found in over 90% of patients, and the diagnosis of migraine must be questioned in the absence of such a history. Between the attacks the child is well.

### Classification of migraine

Migraine is classified into three types.

- **Common migraine:** There is no aura in this type. It is the commonest form in children, accounting for over 80% of children with migraine.
- **Classical migraine:** An aura precedes the headache, which is rare in children (about 10%). Visual aura include hemianopia (loss of half of the visual field), scotoma (small areas of visual loss), fortification spectra (brilliant white zigzag lines), blurred vision and flashes of lights. Occasionally sensory auras occur, consisting of paraesthesia round the mouth and numbness of the hands and feet.
- **Complicated migraine:** Rarely neurological signs occur during the headache and persist for varying periods after it. Ophthalmoplegic migraine (third cranial nerve palsy) is rare, and must be distinguished from a berry aneurysm

or other space-occupying lesion compressing the third cranial nerve.

- **Hemiplegic migraine** is the occurrence of hemisyn-drome (weakness or numbness down one side of the body) with the headache. Recurrent attacks of hemiplegic migraine are rare in children, but occasionally, starting in infancy, a child may have alternating hemiplegia as a manifestation of migraine.
- **Basilar migraine** results from vasoconstriction of the basilar and posterior cerebral arteries. Symptoms include vertigo, tinnitus, diplopia, blurred vision, ataxia and occipital headaches. There is complete recovery after the attack. Minor head trauma may precipitate basilar migraine.

### Management

A careful history and examination is essential to confirm the diagnosis of migraine. Investigations are rarely needed. Explanation of the attacks and the relatively benign nature and good prognosis will reassure the parents and the child, and by itself will lead to a reduction in frequency and severity of the headaches in over 50% of these children. Where possible, precipitating factors need to be identified and eliminated or reduced. In particular, dietary factors such as chocolate, Coca-Cola, caffeinated drinks and cheese should be avoided.

### Acute attack

Rest and sleep in a quiet darkened room is usually preferred by patients. A simple analgesic alone or in combination with a non-steroidal anti-inflammatory agent is often all that is required, and if given at the onset will abort or reduce the severity of the headaches. Paracetamol (20 mg/kg per dose, repeated every 6 hours as necessary) and ibuprofen (5 mg/kg per dose) are useful agents.

If nausea and vomiting are troublesome, an anti-emetic may be prescribed, such as metoclopramide. Aged 5–9 years 2.5 mg and 9–18 years 5 mg three times daily orally or 100–150 microgram/kg slowly (over 2 minutes) by IV injection (maximum 1 mg). Children weighing over 60 kg can have metoclopramide orally 10 mg three times daily

Prochlorperazine is also useful, 200 micrograms/

kg (maximum 12.5mg) orally IM or IV immediately, then 100 micrograms/kg per dose 6- to 8-hourly, orally or rectally. Prochlorperazine is not licensed for use in children who weigh less than 10kg. Extrapyramidal side effects may occur.

The triptans (sumatriptan, zolmitriptan and rizatriptan) are serotonin-receptor agonists and are highly effective for the acute attack, but their use in children under 12 years of age awaits further evaluation. The dose of sumatriptan for adults is 50–100mg orally as soon as possible after onset. It must not be used for basilar or hemiplegic migraine.

### Prophylactic treatment

If the headaches are frequent (at least three to five per month) and troublesome, continuous prophylaxis is required, usually for a period of 1 year. If the headaches recur, the course of treatment is repeated. The drug of choice for children is propranolol, but pizotifen and clonidine have both been tried in children, with varying degrees of success.

- Propranolol is a beta-blocker, and can be given to children over 2 years of age (the dose for children aged 2–12 years is 200–500micrograms/kg three times daily

orally; for children over 12 years it is 20–40mg two to three times daily). **Propranolol must not be given to children with asthma or diabetes, and it may cause depression.**

- Clonidine can be given at a dose of 2 micrograms/kg every 8 hours (maximum dose 200 micrograms/day).
- Pizotifen is given for children aged 5–10 years at an initial dose of 500 micrograms, increasing to 1 mg at night or 500 micrograms 8-hourly. For children aged 10–12 years give 1 mg at night or 500 micrograms 8-hourly. For children aged 12–18 years give 1.5 mg at night, increasing to 1.5 mg 8-hourly. It may cause weight gain.

### Prognosis of migraine

The prognosis is generally good. About 50% of children with migraine will undergo spontaneous prolonged remission after the age of 10 years. In most children the headaches are infrequent and rarely interfere with schooling or daily activities. In some the headaches are frequent and troublesome, and these will require prophylactic treatment.

## 5.16.K Neurosurgical disorders

### BOX 5.16.K.1 Minimum standards

- Maternal folic acid before and during pregnancy.
- Dexamethasone and mannitol.
- High-dependency care.
- Antibiotics.
- Anticonvulsants.
- Shunts.
- Regional/national centre (with CT and MRI scanning facility).

### Introduction

Every country needs at least one hospital equipped to manage children with neurosurgical problems. The central and essential component of accurate assessment of the most frequently encountered intracranial neurosurgical emergencies is the prompt identification of the presence of raised intracranial pressure (ICP). Once this is recognised and controlled, the precise diagnosis of the site and cause can await sophisticated neuroimaging by ultrasound examination, computed tomography (CT) or magnetic resonance imaging (MRI).

### Raised intracranial pressure

The signs and symptoms are different for pre-speech and younger infants compared with older children.

### Babies and children under 2 years

The signs and symptoms are as follows:

- abnormally rapid head growth
- separation of cranial sutures
- bulging of the anterior fontanelle (note that the anterior fontanelle usually closes by 18 months of age)
- dilatation of scalp veins

- irritability
- vomiting
- loss of truncal tone
- fluctuating level of responsiveness
- irregular rate and rhythm of breathing, usually with slowing of the respiratory rate
- irregular heart rate, usually with bradycardia, but occasionally with tachycardia
- decerebrate attacks.

It is important to note that features may be non-specific (as in irritability and vomiting), that there may be marked fluctuations in the younger child's condition from minute to minute and from hour to hour, and that frank unconsciousness occurs relatively late, often being preceded by apnoea. Decerebrate attacks can be mistaken for epileptic seizures; in the former, the child extends all four limbs and trunk, whereas in the latter, flexion of the upper limbs is more usual and there are clear tonic-clonic phases.

### Older children

The signs and symptoms are as follows:

- headaches
- vomiting
- loss of postural control of the trunk
- **failing vision**
- diplopia
- **neck pain and extension**
- **decerebrate attacks**
- irregular rate and rhythm of breathing, usually with **slowing of the respiratory rate**
- irregular heart rate, usually with bradycardia, but occasionally with tachycardia, and mounting hypertension with widening pulse pressure
- **diminishing level of consciousness.**

The most urgent features are failing vision, neck pain and extension, decerebrate attacks, diminishing level of consciousness and cardiorespiratory failure, as they all indicate incipient terminal events. Failing visual acuity is also urgent, as it indicates severe papilloedema and a danger of permanent visual loss. The absence of papilloedema does not exclude raised intracranial pressure; its presence does indicate that there is a risk of permanent visual loss.

Accurate cerebral localisation on a clinical basis is difficult in children and virtually impossible in babies and young children, but the following can be fairly dependable features of a supra-tentorial mass lesion:

- dysphasia
- visual field defects
- epileptic seizures.

Unilateral pupillary dilatation indicates a mass ipsilateral to the dilated pupil, or on the side of the pupil that dilated first in the case of bilateral pupillary dilatation.

### Management

Although the definitive solution is removal of the causative lesion, this will often have to await the availability of imaging by computed tomography and transfer to a neurosurgical facility. The emergency relief of raised intracranial pressure can be achieved by one or more of the following medical measures:

- dexamethasone by slow IV injection (500 micrograms/kg immediately and then 100 micrograms/kg every 6 hours)
- 20% mannitol by IV infusion (250–500 mg/kg and repeated as required based on response and clinical signs; maximum total dose 2 grams/kg infusion over 20 minutes).
- alternatively, hypertonic saline can be used (2.7% or 3% at a dose of 3 mL/kg). This may not be associated with a rebound rise in pressure as may occur with mannitol and does not induce a diuresis like mannitol but rather augments plasma volume.
- intubation and artificial ventilation to PaCO<sub>2</sub> of about 4 kPa (if available).

**In an extreme emergency**, and faced with a rapidly deteriorating child with no immediate prospects of evacuation for neuroimaging and specialist neurosurgical care, the following measures can be employed if there is no history of head injury.

### Babies

Trans-fontanelle needle tapping of the subdural space is undertaken, and if there is no subdural effusion, the needle is then advanced into the cerebral ventricle in the hope of finding and relieving hydrocephalus.

### Infants and children

Right frontal burr-hole and ventricular drainage is undertaken (see below).

If there is a history of head injury, the procedure for 'blind' burr-holes is followed (see below).

Head injuries (see Section 7.3.C).

### Intracranial abscesses

Spontaneous extradural, subdural or intracerebral abscesses most commonly arise in children as a complication of an

acute, or very occasionally chronic, episode of infection in the paranasal sinuses or middle ear. The cardinal clinical features are as follows:

- raised intracranial pressure
- signs of focal neurological disturbance, including epileptic seizures
  - systemic signs of sepsis; these may be absent.

The diagnosis can be confirmed by CT scan with IV contrast enhancement (if available).

- Evacuation of pus is important both to relieve raised intracranial pressure and mass effect, and to provide material for accurate microbiological diagnosis. Intracerebral abscesses can often be drained satisfactorily by burr-hole aspiration, which may have to be repeated. Extradural and subdural collections will usually require a major craniotomy.
- Raised intracranial pressure will usually be very severe, and may require the use of mannitol.
- Pending microbiological diagnosis, or in the absence of such support, the most useful antibiotics are a combination of cefuroxime (IV 60 mg/kg 6-hourly for 3 days, then 25 mg/kg 6-hourly) and metronidazole (7.5 mg/kg by IV infusion over 20 minutes every 8 hours) for a minimum of 3 weeks. A further 6 weeks of an appropriate oral antibiotic, such as amoxicillin, is usually necessary.
- Amoxicillin route: oral
  - Dose: 1 month to 18 years of age, 40 mg/kg daily in 3 divided doses maximum dose 1.5 g daily in 3 divided doses.
- An ENT surgeon may need to drain fronto-ethmoid sinuses or mastoids to prevent recurrence.

### Hydrocephalus

Hydrocephalus can be diagnosed by trans-fontanelle ultrasound in infants with an open anterior fontanelle, and by CT (if available) in older infants and children. CT will also demonstrate the likely cause.

- The emergency relief of hydrocephalus, or suspected hydrocephalus, is by trans-fontanelle needle drainage in babies, or by burr-hole drainage and insertion of an external ventricular drain in older children.
- The best site for burr-hole drainage is on the right coronal suture in the mid-orbital line. The landmarks for trans-fontanelle puncture are the same as for subdural puncture (see above), but the needle is angled more steeply. Most babies will tolerate venting of up to 50 mL of CSF. Following withdrawal of the needle, the skin puncture is closed with a suture to prevent external leakage of CSF.
- It is important to have the CSF examined by a microbiology laboratory, remembering that sub-acute, partially treated, 'neglected' pyogenic meningitis and tuberculous meningitis can present with hydrocephalus.
- Definitive treatment may involve removal of the obstructing lesion in the case of a tumour or other mass, or establishment of a permanent CSF diversion by inserting an implanted ventriculo-peritoneal shunt.
- Shunt blockage is common and must be diagnosed quickly. The symptoms of shunt blockage are essentially those of raised intracranial pressure, and require urgent attention if death or disability is to be avoided. **The most reliable eye sign is loss of upward gaze.** Blockages

usually affect the ventricular end of the catheter rather than the peritoneal end. Many children develop abdominal distension after shunting. This is due to the unusual load of CSF. In the absence of vomiting and constipation, it should be treated conservatively.

- Shunt infections can present acutely with features of cerebral irritation, fever and seizures if there is major ventriculitis occurring within a few days of insertion; however, this is relatively rare. **The only method that is guaranteed to eliminate shunt infection is removal of all components, including any loose or retained fragments from earlier procedures, interval external drainage, appropriate antibiotics and shunt reinsertion through fresh incisions. As with all serious infections, success is dependent upon accurate microbiological diagnosis.** The most frequently encountered organisms are *Staphylococcus epidermidis* and *Staphylococcus aureus*. The most useful antibiotic is vancomycin by IV injection children 1 month to 18 years 15 mg/kg every 8 hours to a maximum daily dose of 2 grams. The duration of treatment depends on how rapidly the CSF becomes sterile, but a minimum of 7 days is recommended.

### Myelomeningocele

Myelomeningocele is the commonest major congenital malformation compatible with survival. Its incidence has been progressively falling for 20 years. Although there are regional variations, the overall frequency is 0.7–0.8 per 1000 live births. The objective of management in the immediate postnatal period is the prevention of infection

of the central nervous system. This is achieved by early closure of the lesion.

- The level of the open lesion is noted and an assessment made of the sensorimotor level, the state of the sphincters, any orthopaedic deformity, and the presence of major hydrocephalus, as evidenced by signs of raised intracranial pressure (see above).
- **The ideal is to achieve closure within 24 hours of birth. The majority of lesions have adequate skin in the wall of the sac, as long as this is not unnecessarily sacrificed by a wide incision. The technique employed involves mobilisation of the neural placode, watertight dural repair and closure of the skin.** While awaiting closure, the lesion should be protected with a dressing of moist sterile 0.9% saline, which must be replaced every few hours to prevent desiccation.
- Most babies will require surgical treatment for hydrocephalus in the first few weeks of postnatal life.

In children who are paralysed and without urinary or bowel control, the commitment is a lifelong one, and this is a challenge to families and healthcare systems. Before offering treatment to these children, it is important that their future prognosis and quality of life is discussed with the parents.

The aim should be to prevent as many as possible of these anomalies by adequate maternal nutrition prior to conception and during pregnancy.

**Folic acid taken prior to conception and for the first trimester of pregnancy abolishes 75% of cases of myelomeningocele and anencephaly.**

See Section 5.10.A.

## 5.17 Orthopaedic problems

### BOX 5.17.1 Minimum standards

- Antibiotics.
- X-rays.
- Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).
- Antituberculous drugs.
- Orthopaedic procedures.

### Introduction

Injuries are by no means the only paediatric orthopaedic problems in resource-limited countries. There is a great burden of orthopaedic infective conditions which, if treated suboptimally, can lead to considerable handicap. Furthermore, there is the same spectrum of non-infective conditions as is seen in well-resourced countries which, due to the limited resources available in under-resourced healthcare systems, represents a considerable diagnostic and therapeutic challenge.

### Infections

Paediatric musculoskeletal infections are a common presentation in resource-limited countries. Morbidity and mortality can be prevented by prompt diagnosis, antibiotics and surgery where indicated. Infection should be suspected in any child presenting with pain or swelling in the limbs, spine or pelvis.

### Pyomyositis

- Pus is present within skeletal muscle, most commonly in the thigh and gluteal regions.
- It is caused by bacterial infection of muscle, in nearly 70% of cases due to *Staphylococcus aureus*.
- It is common in the tropics, but exceedingly rare in the developed world.
- There may be a history of previous injection or trauma to the site.
- Signs include general malaise, swinging fever, decreased range of motion, fluctuant swelling in the later stages, and tenderness.

**Treatment**

If diagnosed early (which is unusual), pyomyositis may respond to antibiotic therapy (flucloxacillin), but most cases will require incision and drainage of the abscess under general anaesthesia.

**At operation**

- Incise along the long axis of the tender/swollen area.
- **Mark this area prior to giving anaesthesia.**
- Drain all pus.
- Irrigate thoroughly.
- Insert a wick to maintain drainage and prevent recurrence of the abscess.

**Post-operative care**

- Give analgesia.
- Give a 5-day course of antibiotics.
- Change the dressings daily.
- Evaluate for signs of recurrence and other foci of infection.

**Osteomyelitis**

This is infection within bone. It is common in resource-limited countries, and has a number of different manifestations:

- acute haematogenous osteomyelitis
- neonatal osteomyelitis
- subacute haematogenous osteomyelitis
- chronic osteomyelitis.

**Acute haematogenous osteomyelitis****Pathogenesis**

- The causes are unknown.
- Infection starts in metaphyseal venous sinusoids.
- There is thrombosis of the vessels.
- Pus develops in the medullary cavity, leading to a build-up of pressure.
- If untreated, pus bursts through the cortex and spreads under the periosteum, rendering bone ischaemic (see **chronic osteomyelitis** below).
- In infants and children the pathogen is almost always *Staphylococcus aureus* (for neonates, see below). The exception is in sickle-cell disease, where *Salmonella paratyphi* is common. In this situation, use cefotaxime or ciprofloxacin.

**Diagnosis**

- Any child with fever and unexplained bone pain.
  - High index of suspicion.
  - Around 50% of cases will have a history of recent infection.
  - The child refuses to move the affected limb.

**Investigations**

- In resource-limited countries, **clinical examination is the mainstay of diagnosis.**
- White blood cell count is unreliable.
- Erythrocyte sedimentation rate is raised in 90% of cases.
- Blood culture is positive in 40–50% of cases.
- Plain X-rays: bony changes take 7–14 days.
- Aspiration and Gram stain; look for acid-fast bacilli.
- Bone scan (if available).

**Treatment**

- Prior to the formation of pus in the medullary cavity, antibiotics alone may suffice.
- Due to the predominance of *Staphylococcus aureus* as the causative organism, the initial antibiotic should be flucloxacillin while culture results are awaited (50 mg/kg IV or orally (maximum individual dose 2 grams) 6-hourly for 3 weeks).
- Once an abscess has formed this should be drained surgically.

**Operative treatment**

- Undertake incision, drilling and drainage of the osteomyelitic abscess.
- Mark the area of maximal swelling and tenderness prior to anaesthesia.
- Make a longitudinal incision.
- Dissect on to and incise the periosteum.
- Drill the cortex of the bone. If there is no pus at one site, drill further holes proximally and/or distally until pus is obtained.
- Copious irrigation is needed.
- Leave the wound open, and apply a dry or antiseptic dressing.
- Monitor post-operatively for recurrence and other foci of infection, and leave the wound to granulate.

**Neonatal osteomyelitis**

There are several features unique to neonatal osteomyelitis.

- In the neonate, metaphyseal vessels communicate with epiphyseal ones, thus permitting the spread of infection into the epiphysis and ultimately into the joint. Therefore acute haematogenous osteomyelitis and septic arthritis may occur together. This can lead to complete lysis of areas such as the femoral head and neck and the proximal humerus, or premature physal arrest.
- As the immune system of the neonate is immature, there may be a less marked inflammatory response to infection, with an absence of fever, raised white blood cell count or erythrocyte sedimentation rate.
- Multiple foci of infection are more common.
- A wider spectrum of infecting organisms is found (not only *Staphylococcus aureus* but also group B streptococci and Gram-negative coliforms).
- Antibiotic treatment consists of gentamicin plus flucloxacillin.

**Subacute haematogenous osteomyelitis**

This differs in presentation from acute haematogenous osteomyelitis in the following ways:

- It often has an insidious onset.
- The clinical signs are less marked.
- Investigations may be inconclusive or equivocal.
- The location is usually metaphyseal, with plain X-rays showing a solitary lytic lesion (abscess) with a sclerotic margin.
- The differential diagnosis includes a neoplasm.

The usual **causative organism** is, as for acute haematogenous osteomyelitis, *Staphylococcus aureus*.

**Treatment** consists of surgical curettage of the lesion followed by antibiotic therapy.

### Chronic osteomyelitis

If acute osteomyelitis goes untreated, the pressure due to the intramedullary pus eventually increases until it bursts through the cortical bone into the subperiosteal space. If still undecompressed, the pus spreads proximally and distally, stripping the periosteum and thus rendering this cortical bone ischaemic (having been deprived of both intramedullary and periosteal blood supply).

The avascular cortical bone therefore dies and becomes a focus of chronic infection called a 'sequestrum'. Simultaneously, a periosteal reaction occurs under the stripped periosteum, resulting in the laying down of new bone or 'involucrum'.

The appearance on plain X-ray is characteristic, with sclerotic sequestrum separated (by the abscess cavity) from an irregular and enveloping involucrum.

Chronic osteomyelitis is difficult to treat even with optimal resources. Some guidelines on its management are as follows:

- If an osteomyelitic abscess is beginning to point, or there are signs of an underlying abscess, this should be incised and drained.
- In weight-bearing bones there should be no attempt at removal of sequestrum until the overlying involucrum is mature. This maintains the potential for weight bearing and ambulation.
- Periods of immobilisation should be minimised in order to retain ranges of motion and function of nearby joints.
- Sequestrum that begins to point through the skin can be removed or excised.
- In many cases the clinical picture that results is one of intermittent flare-ups of infection which can be treated by incision and drainage of abscesses, excision of sequestrate, and antibiotic (flucloxacillin) suppression of infection as required.
- Curative treatment is often elusive even in specialised centres, and a degree of morbidity is unfortunately inevitable.

### Septic arthritis

Septic arthritis is infection of a synovial joint.

#### Features

- It is more common in males than in females.
- The peak incidence is at around 2 years of age.
- The first symptom may be a reluctance to use the limb.
- There is a swollen tender warm joint with a restricted range of motion.
- There is commonly fever (38–40°C).
- The patient is usually **systemically unwell**.

#### Diagnosis

- The mainstay of diagnosis is **clinical examination**.
- The white blood cell count is raised in 30–60% of cases.
- Elevation of the erythrocyte sedimentation rate is more sensitive (except in the neonate).

Plain X-rays are often normal until there is evidence of bone destruction at 7–14 days. Common pathogens include *Staphylococcus aureus*, *Haemophilus influenzae*, group A and B streptococci, pneumococci and Gram-negative coliforms (in neonates).

**Aspiration of the joint is the definitive test.**

### Treatment

- Antibiotic therapy should not begin until after joint aspiration and blood cultures have been taken.
- Start with flucloxacillin (infants and children) or flucloxacillin and gentamicin (neonates).
- Some studies have shown that a combination of **aspiration** and antibiotic therapy is sufficient treatment, but this must be followed by close monitoring to ensure improvement.
- If the child fails to improve, surgical washout and drainage is required either via open arthrotomy or by arthroscopic means (but only if a skilled operator and equipment are available).

### Post-operative care

- Continue antibiotic therapy, and monitor for recurrence.
- Early mobilisation of the affected joint is needed to prevent stiffness.
- If treated early, the prognosis for functional recovery is good. However, if presenting late there may already have been destruction of the articular surface.
- Be alert for coexisting osteomyelitis, which is present in around 15% of cases of septic arthritis.

### Tuberculosis

Tuberculosis as an entity is covered in detail in Section 6.1.N, but it is important to remember the potential orthopaedic manifestations.

- It can cause both osteomyelitis and septic arthritis.
- In both cases the signs are less marked than in their non-mycobacterial forms, and the history is usually more chronic.
- It may be associated with systemic manifestations of tuberculous disease (respiratory and renal).
- Spinal tuberculosis (Pott's disease) can be the cause of both paraplegia and scoliotic deformity.
- Treatment consists of surgical drainage and curettage of abscess cavities combined with antituberculous chemotherapy. For chronic disease and joint destruction, spinal stabilisation and joint arthrodeses may be indicated.

### Non-infective conditions

The non-infective paediatric orthopaedic conditions described below can be extremely difficult to treat in resource-limited settings. First, without any form of population screening procedure in place or comprehensive primary healthcare provision, many cases will present late. Secondly, the advanced diagnostic modalities (ultrasound and arthrography) that are needed to direct treatment may not be available. Finally, where surgery is indicated, the operative techniques often need highly specialist training and/or specialised resources such as internal fixation and perioperative fluoroscopy, which are unlikely to be available in most resource-limited countries.

Fortunately, the conditions described are rare, typically occurring at a rate of less than 0.1%. They thus present far less commonly than the orthopaedic paediatric infections, and cause a lesser burden of handicap overall.

### Developmental dysplasia of the hip

Formerly known as 'congenital dislocation of the hip', this complex condition has now been renamed 'developmental dysplasia' in recognition of its variable characteristics, such

as the fact that it is not always present at birth, nor does it always feature hip dislocation.

- Reported initial (neonatal) rates range from 3 to 17 per 1000 live births, but the rate of established dislocation is much lower, at around 1 per 1000.
- The aetiology is multifactorial; increased rates are seen in female children, firstborns, breech position and oligohydramnios, and there is undoubtedly a genetic influence (increased rates are associated with a positive family history and affected siblings).
- Early detection depends upon neonatal screening, which is often not available in resource-limited countries.
- If screening is to be carried out, it should involve Barlow and Ortolani tests for newborns followed by subsequent re-examination and ultrasonography of suspected cases at 1 month of age.
- Plain X-rays are of limited use before 6 months of age.

### Treatment

As mentioned above, treatment of this condition in resource-limited settings is extremely difficult.

- Up to 6 months of age, gentle closed reduction can be undertaken, and then maintained in a Pavlik harness.
- If a Pavlik harness is unavailable, a plaster spica, maintaining the hips in flexion and abduction, will achieve the same objective.
- In children over 6 months of age, closed reduction can still be attempted, but is increasingly less likely to be successful due to the interposed joint capsule preventing stable concentric reduction.
- If closed reduction fails, open reduction can be attempted if surgical skills allow and infection is avoided.
- Later presentation with proximal femoral and acetabular abnormalities may require complex secondary reconstructive procedures, but these can only be undertaken in specialist hospitals by a specialist surgeon.

The reality of developmental dysplasia of the hip in resource-limited countries is that cases will often not present until after the age of 18 months, when the child has failed to walk or has an obviously abnormal gait. By this time bony changes may have occurred, the only treatment then being complex secondary procedures, the skills and resources for which are usually unavailable in a resource-limited setting.

### Congenital talipes equinovarus

More than two-thirds of cases of talipes equinovarus occur in developing countries. Most children receive either no treatment or substandard care. This results in physical disability that is entirely preventable.

There are three classes of talipes equinovarus (clubfoot):

- **Postural:** this arises from intrauterine positioning, and resolves fully with passive stretching within a few weeks of birth. Parents can be trained to do this.
- **Congenital:** this arises in an otherwise normal child, and has varying degrees of severity. It occurs in 1 in 1000 live births, and is bilateral in 30–40% of cases.
- **Syndromic:** this is associated with other syndromes, such as arthrogyposis, is often severe and is refractive to treatment.

### Treatment

- The goal of talipes treatment is to obtain a functional

plantigrade stable foot by the time the child begins to walk (i.e. before 1 year of age).

- If it is recognised in the neonatal period, gentle daily parental manipulation may be successful, or alternatively manipulation and taping by qualified healthcare professionals (e.g. a physiotherapist). Ponseti management has gained popularity as it does not require surgery and is easily learned ([www.global-help.org/publications/books/help\\_cfponseti.pdf](http://www.global-help.org/publications/books/help_cfponseti.pdf)).
- For cases that fail to resolve in the first 6–12 weeks, serial manipulation and plaster casting is indicated, with cast changes every 2–4 weeks.
- If the deformity still fails to resolve, there may be a place for limited percutaneous soft tissue releases (Achilles tendon or plantar fascia) at the age of 3–9 months. These techniques are relatively easily learned, have low morbidity, and are user-friendly in resource-limited settings. They should be combined with manipulation and casting.
- For the case that still fails to resolve, more extensive surgery, such as a postero-medial release, is required. The timing of this surgery is usually between 6 months and 1 year of age. Although specialist training is required to learn this operation, it can be relatively easily assimilated by the non-orthopaedic surgeon and, being only a soft tissue release, does not require any 'high-tech' surgical resources.
- Unfortunately, as with developmental dysplasia of the hip, children with this condition in resource-limited countries commonly present late (over 18 months of age), when the deformity is fixed and secondary bony changes have occurred. Correction at this stage requires a combination of bony and soft tissue surgery which can really only be undertaken by an orthopaedic specialist surgeon.
- In the adolescent child with fixed chronic deformity, the procedure of choice may be an arthrodesis (fusion) combined with correction of deformity performed at skeletal maturity.

### Perthes disease (Legg–Calve–Perthes disease)

Perthes disease is a disease of uncertain aetiology involving a process of fragmentation and repair of the femoral head, possibly due to underlying idiopathic osteonecrosis.

- It usually occurs in susceptible children between 4 and 8 years of age, but can occur in children as young as 2 years or as old as 12 years.
- It is five times more common in boys, 10% of cases are bilateral, and it is associated with hyperactivity.
- It presents with a limping or waddling gait with groin, thigh or knee pain.
- X-rays show varying degrees and stages of fragmentation and repair of the femoral head.
- The prognosis depends on the degree of fragmentation and the potential for repair and remodelling prior to epiphyseal closure. A good prognosis is therefore associated with early onset and male gender (as the epiphyses close later).

### Treatment

- In the majority of cases no specific treatment is indicated. The femoral head will repair and remodel satisfactorily, and the eventual outcome will be good. Bed rest, activity

restriction and abduction braces have no proven impact on the natural history of the disease.

- In the small proportion of cases that may benefit from surgery, the issue is **containment**. A very deformed femoral head may not sit or move properly in the acetabulum, and thus leads to secondary arthrosis. A proportion of these cases may benefit from varus osteotomies of the proximal femur or pelvic osteotomies. Assessment for these procedures requires arthrography at the very least, and the procedures themselves are very much the preserve of the orthopaedic specialist surgeon in a specialist hospital.

### Slipped upper femoral epiphysis

Slipped upper femoral epiphysis (SUFE) (also known as slipped capital femoral epiphysis, SCFE) is a disease in which the epiphysis becomes posteriorly displaced on the femoral neck.

- The prevalence is 1–10 per 100 000, and is higher in black populations.
- It is twice as common in boys as in girls, the at-risk age group being 10–17 years for boys, and 8–15 years for girls. Most affected children are obese, and in 40% of cases there is bilateral hip involvement.
- The aetiology is unknown, but is possibly endocrine related.
- The onset may be abrupt or gradual. Sudden slips present with severe pain and inability to walk; chronic slips present with pain often referred to the knees, a slight limp, and limited internal rotation of the hip.
- Plain antero-posterior and lateral X-rays are the most important diagnostic investigations. Severity can be classified according to the degree of epiphyseal displacement. Greater than 30% displacement can result in premature osteoarthritis.

### Treatment

- The goal of treatment for SUFE is to stabilise the slippage and to promote premature fusion of the epiphysis if possible.
- Ideal treatment is fixation *in situ* with a single cannulated screw. Given the posterior position of slippage, the point of entry of the screw needs to be anterior on the femoral neck. This procedure needs to be done under fluoroscopic or X-ray control in a specialist hospital.
- Where internal fixation or peri-operative imaging is not available, an alternative would be spica cast immobilisation. However, this is often logistically difficult, and the physis may still be open even after cast removal.
- For the most severe degrees of slippage, in the hands of

a specialist surgeon, reduction and fixation of the slip or femoral neck realignment osteotomies may be indicated.

- The commonest complications of operative treatment for SUFE are chondrolysis and osteonecrosis of the femoral head due to vascular compromise.

### Genu varum and genu valgum

Varying degrees of bowed knees and knock-knee are common in the paediatric population. Most of these are merely variants of the normal physiological knee-angle development appropriate to the child's age. Very few will require any form of intervention.

- Normal development: Babies are born with a varus knee angle that reduces with growth to become neutral at 18 months to 2 years of age. Thereafter the knee becomes increasingly valgus, reaching a peak at 5–7 years, after which the angle gradually declines to the 5–9 degrees of valgus seen in most adults.
- **Blount's disease** is a developmental condition that affects the proximal tibial physis and results in progressive varus deformity.
- Treatment of degrees of genu valgum and genu varum depends upon the age of the child and the severity of the condition. Bracing is of no proven benefit. Various corrective osteotomies are possible, but these should be restricted to those cases with functional handicap, and are certainly not indicated merely on cosmetic grounds.

### Scoliosis

Scoliosis is deformity of the spine characterised by lateral curvature and rotation.

- The commonest cause of paediatric scoliosis in resource-limited countries is probably tuberculosis (Pott's disease). X-ray appearances can be strongly suggestive of this diagnosis, and then antituberculous chemotherapy is commenced.
- The scoliotic deformity is described as idiopathic where there is no known aetiology. Contrary to popular belief, most idiopathic scoliosis is only of cosmetic significance; only the most severe cases will have any degree of cardiorespiratory compromise.
- Scoliotic bracing is expensive, has compliance problems and is unlikely to be available in resource-limited countries. If available it may have a role in slowing the progression of curves which are between 20 and 40 degrees.
- Curves that are under 40 degrees at the time of skeletal maturity are unlikely to progress further.
- Surgical correction requires a specialised hospital and a skilled fully trained surgeon and support staff.

## 5.18 Skin disorders

### BOX 5.18.1 Minimum standards

- Anti-scabies treatment.
- Antibacterial treatment.
- Antifungal treatment.
- Topical steroids.
- Emollients.
- Antiviral treatment.

### Introduction

In resource-limited countries, skin disease is dominated by bacterial infections such as impetigo and parasitic conditions such as scabies and pediculosis. It is often poorly managed, and may incur a significant economic cost to families through use of ineffective remedies. It is important to recognise whether cases reflect individual or community problems; treatment of single cases of scabies will have little impact if there is widespread infection in the community.

### Scabies

Scabies is a parasitic infection caused by the mite, *Sarcoptes scabiei*, which spreads from person to person, usually by direct contact. The adult female burrows a tunnel into the stratum corneum or outer skin layer, producing eggs which hatch into larvae within 3–4 days.

'Outbreaks' in communities may follow a cyclical pattern, with peaks of incidence occurring every 4–7 years. Infection in adults usually reflects overcrowding in households and

TABLE 5.18.1 Topical treatment of scabies

Anti-scabies preparation	Treatment	Side effects
Sulphur	Given as a 5–10% application in white soft paraffin or as soap. Treat for 1–2 weeks	Local irritation
25% Benzyl benzoate emulsion	Initial application, followed by a second one 2–3 days later	Local itching, eczema
5% Permethrin cream	One application (another is often necessary)	Minimal itching
0.5% Malathion lotion	One or two applications	Itching
1% Gamma-benzene hexachloride lotion	One to four applications	Use with caution in children; seizures have been recorded
1% Crothamiton cream	1–2 weeks of treatment	Not very effective, although it can reduce itching

transmission through contact with infected individuals, including infants.

### Clinical presentation

The main sites of infection include fingers, wrists, elbows, ankles, genitals and buttocks; the face and head may be affected in babies, but these sites are seldom involved in older children. Important clues include the following:

- itching in several members of the same household
- lesions in characteristic sites, particularly the lateral borders of the fingers
- papules, pustules and sinuous tracks or burrows (5–10mm).

In onchocerciasis (see Section 6.3.C.g), itching is also common but lesions are seldom found on the fingers.

### Diagnosis

Remove mites from their burrows with a sterile needle and examine them under low power of the microscope.

### Complications

Secondary bacterial (streptococcal) infection is common (see below). In severely immunocompromised individuals (e.g. those with AIDS) a crusted form of scabies, without severe itching but with large numbers of mites, may occur.

### Treatment

The cheapest treatment options are sulphur based. However, they are slow to take effect, and require daily applications for 7–14 days. Permethrin is the most rapidly active but also the most expensive option.

All potentially affected areas are treated, including the soles of the feet and, in babies, the scalp.

**Failure of anti-scabetic agents often occurs because there is no place where individuals can apply these treatments in privacy.** Treat all members of the household, including those without itching.

Clothes should be cleaned or changed after the first treatment. Resistance to gamma-benzene hexachloride occurs. Ivermectin (oral) is highly effective for crusted scabies, but is not suitable for children under 5 years (single dose of 150 micrograms/kg). No food should be taken for 2 hours before or after the dose.

Community-based treatments, although ideal, are seldom practised as they are difficult and, although individually cheap, comparatively costly to apply to large numbers.

### Impetigo

The term **pyoderma** is used to describe a range of superficial bacterial infections that include impetigo, folliculitis, abscesses (furunculosis) or secondary bacterial infection (e.g. of scabies). Impetigo is a form of pyogenic infection that involves the epidermis and is caused by Group A

streptococci or *Staphylococcus aureus*. It is not possible to separate the two infections clinically.

Ecthyma occurs when impetigo penetrates deeper, to affect the dermis and cause ulceration.

### Clinical presentation

Impetigo presents with oozing and yellowish crusted plaques, often on exposed sites such as the face. These plaques may be multiple, and form blisters, in which case *Staphylococcus aureus* is the usual cause. This may be transmitted to other parts of the body and to other children. Secondary infection of scabies may occur; papules become pustular and there may be surrounding impetiginised crusts on scabetic burrows.

Boils (furuncles) are also common, and are always caused by *Staphylococcus aureus*. Lesions are large tender fluctuant masses with surrounding inflammation. They may occur in other members of the same household.

### Complications

A serious complication of streptococcal impetigo or

pyoderma is glomerulonephritis, which follows infection by nephritogenic strains. In tropical environments, post-streptococcal glomerulonephritis more often follows skin infection rather than throat infection.

### Management

Impetigo is transmissible, and treatment should include other contacts with lesions. Cover both *Staphylococcus aureus* and streptococci, unless laboratory facilities for culture are available. A topical agent may be used, but for widespread lesions oral treatment is usual (see Table 5.18.2). The choice of medication is influenced by cost, extent of disease and type of lesions.

Most *Staphylococcus aureus* strains, even in remote communities, are resistant to both penicillin and tetracycline. Most topicalazole antifungal agents (e.g. clotrimazole, miconazole), apart from ketoconazole, have activity against Gram-positive bacteria. Boils are best managed by incision and drainage.

TABLE 5.18.2 Treatment of impetigo

Agent	Route	Use	Cost
Cloxacillin, flucloxacillin	Oral: 12.5–25 mg/kg four times a day	For widespread and severe impetigo. Rapid effect, with clearance in 3–5 days	Expensive
Mupirocin	Topical	For localised infections. Rapid effect, with clearance in 3–7 days	Moderate
Fucidin	Topical	As for mupirocin	Moderate
Clioquinol	Topical	Slow to take effect (7–14 days). May stain skin; irritant	Cheap
Potassium permanganate (alternatives are chlorhexidine and povidone iodine)	Topical	Simple to use, stains skin. Slow to take effect (7–14 days)	Cheap

### Tropical ulcer (tropical phagedenic ulcer)

Tropical ulcer mainly occurs in children and teenagers, but is seldom seen in developed countries. It is patchily distributed in endemic foci throughout Africa, India and the West Pacific. It is associated with humid regions or areas subject to local flooding.

Tropical ulcer is considered to result from synergistic bacterial infection, of which one anaerobic organism is usually *Fusobacterium ulcerans*. Other bacteria present in lesions include spiral bacteria and Gram-negative bacteria. *F. ulcerans* has also been isolated from mud and stagnant water in the vicinity of cases.

The initial lesion is a soft papule with surrounding hyper-pigmentation overlying an area of skin necrosis. This develops over at least 1 week, and when the overlying skin sloughs a regular and deep ulcer, 3–10 cm in diameter, is revealed.

### Complications

With proper care and regular irrigation or cleansing of lesions the area will heal. About 5–10% of lesions may progress to chronic ulceration, and in some cases secondary squamous carcinoma or more serious infection (e.g. underlying osteomyelitis) may develop.

### Management

The objective of treatment is to allow rapid healing without secondary infection.

#### Regimen

- Dilute antiseptic (e.g. potassium permanganate solution), or 0.9% saline for cleansing the ulcer and surrounding skin.
- Daily dressings.
- A single IM dose of benzyl penicillin (50 mg/kg) or oral metronidazole (7.5 mg/kg every 8 hours for 5 days). The former is particularly important in areas where yaws is also endemic, as it will cover both conditions.
- If healing is delayed, local pinch grafting may be necessary.

Cutaneous leishmaniasis (see Section 6.3.A.c).

### Superficial fungal infections

Common childhood fungal infections are scalp ringworm or tinea capitis and oropharyngeal candidiasis.

Tinea infections are caused by dermatophyte fungi, which are adapted to survive on the outer layer of the skin, the stratum corneum, or structures such as hair or nails derived from it. Dermatophyte infections are caused by one of three genera of fungi, *Trichophyton*, *Microsporum*

and *Epidermophyton*, which are acquired by spread from soil, animal or human sources (geophilic, zoophilic or anthropophilic infections, respectively). By convention they are referred to by the term tinea followed by the appropriate Latin word for the site affected – for example, tinea pedis (feet), tinea corporis (body) or tinea capitis (scalp).

Tinea capitis is often endemic in rural or urban areas of resource-limited countries and inner-city areas of industrialised countries. Prevalence rates may reach over 20% in some communities.

The main signs of infection are as follows:

- scaling
- hair loss: this may be diffuse or in localised patches; scalp hairs in affected areas may break at scalp level or a few millimetres above the skin
- itching: this is variable.

The key to the diagnosis is the presence of broken hairs. Confirmation is by culture of scrapings taken from the scalp surface with a sterilised scalpel or sterile scalp brushes. The presence of infection can also be verified by microscopy of hair samples.

### Complications

- Kerion is a severe pustular reaction on the scalp, which accompanies a strong immune response to ringworm infection.
- Favus is a widespread crusting form.
- Secondary infection with bacteria may occur, usually where there are crusts overlying the surface of inflamed lesions.

### Management

Culture of fungus can distinguish whether infection is from a human or animal source, i.e. zoophilic species (*Microsporum canis*, from cats and dogs; *Trichophyton verrucosum*, from cattle) or anthropophilic species (*Trichophyton violaceum*, *T. tonsurans*, *T. soudanense* or *Microsporum audouinii*).

The presence of infections in close contacts (e.g. schoolmates or family) may signal child-to-child spread and alert schools to other infected children. In resource-limited countries, mass treatments have a low priority because of health resources and because cases usually self-heal.

Children with severe symptoms (e.g. kerions, favus or widespread hair loss) should be treated.

- Whitfield's ointment or imidazole antifungal agents (e.g. clotrimazole) are generally ineffective in scalp ringworm.
- The treatment of choice is griseofulvin, which is available in oral tablet or solution form, 10 mg/kg once daily (after food) and up to 20 mg/kg in refractory infections. Single-dose treatments with a 1-gram immediate dose, sometimes repeated after 1 month, have been successful for mass treatment of infected classes in school.
- Terbinafine child 10–20 kg 62.5 mg; child 20–40 kg 125 mg; child > 40 kg 250 mg all once daily for 4 weeks in tinea capitis is an alternative.
- If possible, a topical treatment such as an imidazole cream (clotrimazole) two or three times daily, ketoconazole shampoo or selenium sulphide shampoo should be given to prevent spread to others. Occasionally, kerions may require topical or oral steroids, but these are not part of their initial treatment.

## Eczema (atopic dermatitis)

Eczema is a specific inflammatory disease involving the epidermis and dermis. In childhood the commonest form of eczema is atopic dermatitis. The latter is uncommon in rural areas of resource-limited countries, and appears to be associated with urban environments and increased affluence.

### Clinical presentation

Severe itching and a scaling rash affect the skin flexures (e.g. the elbows, behind the knees, the neck). Scratching may be very severe, and sufficient to disturb sleep.

### Management principles

- **Moisturise the skin with emollients.** Thicker more greasy preparations such as white soft paraffin or a 50:50 mixture of white soft paraffin and liquid paraffin are preferred to creams, as they provide longer-lasting effects.
- **Treat inflammatory lesions with topical corticosteroids** (once or twice daily). Weaker-strength preparations (1% hydrocortisone) are best, although it may be necessary to use medium to strong topical steroids in some cases (never use the latter on the face). Use corticosteroids only intermittently, relying on emollients for long-term management.
- **Treat complications.** These are secondary bacterial infections, usually *Staphylococcus aureus* and acute herpes simplex (eczema herpeticum): apply aciclovir cream five times a day for 5–10 days (until healed) or aciclovir orally if severe, 20 mg/kg four times a day for 5–7 days, and contact dermatitis which may include allergy to topical medicaments such as lanolin and corticosteroids. An oral antibiotic (e.g. cloxacillin or flucloxacillin 12.5–25 mg/kg four times a day) in acute flare-up of eczema may produce a good response.

Atopic eczema ranges from a mild skin rash to a severe condition that can dominate family life and may cause major family stress. Food allergy is a rare cause, and skin testing for precipitating factors is usually not helpful. In industrialised countries there are patient organisations (e.g. the National Eczema Society in the UK) which provide support and advice to patients and their families.

## Hypopigmentation and hyperpigmentation disorders

These are often secondary to other inflammatory processes which should be treated. There are no effective, cheap or easily administered treatments for the pigmentary changes themselves. The common fungal disease, pityriasis versicolor, may present with hypopigmented patches on the trunk which coalesce; however, these are scaly. Treatment with topical antifungal azole creams (e.g. clotrimazole, miconazole) is effective.

### Further reading

Regular updates on the management of skin disease in resource-limited environments are available in the *Community Dermatology Journal*, which can be accessed without charge on [www.ifd.org](http://www.ifd.org)  
WHO (1997) *Drugs used in skin diseases*. <http://apps.who.int/medicinedocs/en/d/Jh2918e>

## 5.19 Surgical disorders

### BOX 5.19.1 Minimum standards

- Surgeon experienced in working with children's disorders.
- Anaesthetist experienced in children's anaesthesia.
- Equipped theatre with appropriately sized instruments where relevant.
- Pain relief.
- Fluid management.
- Ultrasound.
- Radiography.
- Blood transfusion
- Cytology.
- Chest drain insertion.

### Introduction

Children's surgery is a specialist subject. There are some emergency operations that may have to be performed by a competent general surgeon, such as appendectomy and surgery for a strangulated inguinal hernia, but most of the operations that are needed on very young children and infants require specialist knowledge and experience. Children's surgery is therefore likely to be a tertiary-level referral service.

### Indirect inguinal hernia

This is the protrusion of the abdominal viscus into a peritoneal sac (the processus vaginalis) in the inguinal canal. The contents of the sac are usually intestines, but may be omentum, Meckel's diverticulum, or ovary and Fallopian tube in females.

- Around 50% of cases are seen in the first year of life, mostly before 6 months of age.
- Patent processus vaginalis (not a hernia) is present in 80% of boys at birth, in 40% at 2 years, and in 20% of adult men.
- A bulge in the groin, which sometimes extends to the scrotum, and which appears when the child cries or strains but disappears when he relaxes, is certainly a hernia. Hernias are seldom symptomatic except when they are very large or are incarcerated or strangulated. On physical examination, cough or crying impulse is the most important sign. A soft bulge that is reducible on digital pressure is also a diagnostic feature. Hernia in neonates may be transilluminant, so it is not a very reliable test to differentiate with hydrocoele.

Needle aspiration is contraindicated in any inguinal swelling because of the risk of perforating the intestines.

### Differential diagnosis

This should include the following:

- **Lymphadenopathy:** firm, immobile, non-reducible, and no cough impulse.

- **Hydrocoele:** can reach the upper pole of the swelling, transilluminant, no cough impulse is present.
- **Hydrocoele of the cord:** separate from testes, non-reducible, no cough impulse, upper limit is reachable, moves on pulling on the same-sided testis.
- **Undescended testis:** scrotum empty and hypoplastic, cough impulse, may be reducible.
- **Femoral and direct inguinal hernias:** rare, but should be kept in mind.

### Treatment

All inguinal hernias should be promptly repaired unless there is another medical condition that makes the anaesthetic risks prohibitive. Premature infants with hernia should not be discharged without a repair of the hernia, as the risk of incarceration is high. An anaesthetist with paediatric anaesthesia experience is required, as anaesthesia-related risks are higher in children. Post-operative apnoea may occur in premature babies and at times may require ventilatory support. If these facilities are not available, the baby should be referred to higher centres or the surgery deferred until the risks associated with anaesthesia are low.

There are reasons for avoiding delay, especially in infants.

- Spontaneous disappearance of inguinal hernia does not occur.
- The risk of incarceration is greater in infants.
- Operation is technically more difficult and the risk of injury to the vas and testicular vessels is greater in long-standing and incarcerated hernia.
- Increasing age does not affect the risk of anaesthesia so long as an experienced anaesthetist is available.

A herniotomy is performed through an incision in the lowest transverse inguinal skin crease. The sac is identified and transfixed. Herniorrhaphy is not required, as the cause is a patent processus vaginalis. Bilateral exploration and repair are indicated in patients with bilateral hernias, but routine contralateral prophylactic exploration is no longer recommended.

### Incarcerated hernia

This occurs when the intestine becomes stuck at the internal inguinal ring. If it is prolonged, the blood supply may also become compromised, causing strangulation. There is a sudden increase in the size of the hernia with severe pain and symptoms of bowel obstruction (vomiting and abdominal distension). On examination a hard tender fixed mass in the groin is palpable, with increased bowel sounds on auscultation. It may be confused with the torsion of testis, acute inguinal lymphadenitis and tense infected hydrocoele.

### Treatment

This includes the following:

- adequate sedation and administration of analgesics to calm the baby
- cold fomentation (to reduce the oedema)
- the application of gentle pressure to reduce the hernial contents (however, signs of peritonitis are a contraindication).

After reduction of the hernia, the child should be admitted to the hospital and checked hourly to ensure that there is no damage to the intestine or testis, and to reduce a recurrent incarceration promptly if it occurs.

**Herniotomy is performed after 48 hours to allow tissue oedema to subside.**

## Hydrocoele

This is accumulation of fluid in the scrotum; there is communication via a patent processus vaginalis (PPV) with the peritoneal cavity. Rarely hydrocoele is secondary to epididymo-orchitis, tumour and torsion of the testis.

- It is usually asymptomatic.
- The testis is not palpable separately, and the upper pole of the swelling is reachable, reduces on lying down and is transilluminant (hernia in a neonate may also be transilluminant).
- No cough impulse is present.

## Differential diagnosis

Hydrocoele should be differentiated from **inguinal hernia**, and underlying pathology such as **tumours** and **torsion of testis** should not be missed. In older children, **spermatocoele** and **varicocoele** are non-transilluminant, have a worm-like feeling on palpation, and are separate from the testes.

## Surgical treatment

This is rarely indicated. More than 90% of hydrocoeles will spontaneously disappear. **Surgery is indicated if it has not disappeared by the age of 2 years**, and for hydrocoeles that are larger and symptomatic. Herniotomy or PPV ligation, as performed for inguinal hernia, is the procedure of choice.

## Undescended testis (cryptorchidism)

An undescended testis is one that cannot be made to reach the bottom of the scrotum. It is the second most common problem in paediatric surgery after indirect inguinal hernia, and should be distinguished from the more common **retractile testis**.

The incidence of undescended testis is 2.7–3% at birth in full-term infants, decreasing to 1.5% after 1 year of age, and thereafter the incidence remains the same. It is more common in premature infants, approaching 100% at a gestational age of 32 weeks or less.

- An **ectopic testis** is one that has strayed from the inguinal canal, usually to the thigh, perineum, base of the penis, or femoral or abdominal region.
- An **ascending testis** is one that is in the scrotum at birth, but the spermatic cord fails to elongate at the same rate as body growth, so the testis becomes progressively higher in the inguinal canal during childhood.

An **impalpable testis** is quite uncommon (less than 10%),

and **agenesis** is rare (20% of all impalpable testes). A fully descended but grossly hypoplastic testis may be impalpable and only identified by exploration. Normal descent of testes occurs around the seventh month of fetal life when the gubernaculum swells and shortens, drawing the testis through the inguinal canal into the scrotum. Failure of descent may occur because of hormonal failure (inadequate gonadotrophins and testosterone), a dysgenetic testis, or an anatomical abnormality such as an abnormal or misplaced gubernaculum, obstruction of the inguinal canal or scrotum, or a short vas or vessels.

## Sequelae of non-descent

- The higher temperature of the extrascrotal testis causes testicular dysplasia with interstitial fibrosis and poor development of seminiferous tubules, thus hampering spermatogenesis. Testosterone production is unaffected by position. Thus a male with bilateral undescended testes will develop secondary sexual characteristics, but will be sterile.
- Due to dysplasia, there is an increased risk of malignancy (10- to 20-fold higher). The risk of malignant degeneration is not altered greatly by orchidopexy, but a position where it is palpable helps early diagnosis and gives a better prognosis. Malignancy usually develops in the second or third decade of life.
- A testis in the inguinal region is more prone to direct trauma and torsion.

## Examination

An unhurried examination with warm hands and environment greatly helps in picking up a testis in an abnormal position. A hypoplastic scrotum may suggest that it has never housed a testis. In older children, squatting may coax the testis into the normal position, thus differentiating a retractile testis. Always look for an associated hernia. The position and size of the testis should be noted. If it is impalpable, ectopic locations of the testis should be examined. For a testis that cannot be felt at all, an ultrasound examination may be helpful. Bilateral non-palpable testes may require laparoscopic examination and hormonal profiles in a higher centre.

## Treatment

The histological changes in the testes occur as early as 6 months of postnatal life, and therefore a child who has an undescended testis should be operated at the earliest time possible to prevent such changes.

The best time for orchidopexy is about 1 year of age, and preferably before the child's second birthday.

- The hernial sac should be dissected from the cord structures and a high ligation done.
- The testis is placed in an extra-dartos pouch in the scrotum after an adequate dissection and mobilisation of the vas and vessels. Retroperitoneal dissection and careful snipping off of lateral peritoneal bands will give an adequate length to the cord.
- In about 50% of cases of impalpable testis a useful testis can be brought down, and in the remaining 50% there is either no testis present (testicular agenesis or intrauterine torsion-vanishing testis), or there is a useless and potentially neoplastic testis, which is removed.
- For an abdominal testis, laparoscopy is useful for identifying and confirming the position of the testis and

simultaneously permitting the ligation of spermatic vessels (Fowler–Stephen's stage I operation). Later the testis can be brought into the scrotum after dividing the artery, the testicular blood supply being supported by the artery to the vas.

- For psychological reasons, if orchidectomy has been undertaken, prosthetic replacement should be performed later on.
- In bilateral undescended testes, especially with hypospadias, an intersex disorder should be suspected and the child should be further investigated.

### Prognosis

There is a 2% recurrence rate, 2–5% incidence of atrophy, 70–80% fertility after unilateral orchidopexy, and 40% fertility after bilateral orchidopexy.

### Phimosis

Phimosis is defined as excessive tightness of the foreskin, preventing retraction behind the glans. It occurs in 1–2% of males. The foreskin normally cannot be retracted in infants, and non-retractability of the foreskin is not pathological until the age of 3 years. Forced retraction may cause phimosis by producing tears in the foreskin, which heals with scarring and contraction. If there is pooling of urine and repeated attacks of balanoposthitis, simple dilatation of the foreskin can be done and the mother given advice about local hygiene.

After the age of 3 years, the foreskin becomes naturally retractile. Explain to the mother that daily retraction and cleansing of the glans will prevent recurrence of the phimosis. At the same time it is of utmost importance to emphasise the importance of reducing the prepuce over the glans to avoid paraphimosis, which is an inability to bring the foreskin into its natural position because it is trapped in the sulcus at the base of the glans.

Circumcision for phimosis is only indicated where the prepuce skin is scarred and fibrotic due to balanitis xerotica obliterans.

### Hypospadias

This is a condition where the urethra opens on the ventral aspect of the penis at a point proximal to the normal site. When it opens on the dorsal aspect (termed 'epispadias') there is usually associated exstrophy of the bladder.

- Hypospadias is one of the commonest congenital anomalies of the male genitals, occurring in 1 in 300 male births. There are various degrees of severity depending on how far back the urethral meatus lies. It may be associated with undescended testes, and in severe cases there is a possibility of an intersex problem.
- Ventral curvature of the shaft of the penis is called a 'chordee'. It is due to fibrosis of the urethral plate, shortened skin, or fibrosis of the corpora cavernosa. The prepuce is deficient ventrally, and an unsightly dorsal hood of redundant skin is present.
- Congenital short urethra is a deformity where there is ventral curvature of the shaft of the penis without hypospadias.

The disabilities of hypospadias are cosmesis of the penis, a stream that is deflected downwards or splashes, and in

severe hypospadias, boys have to void in a sitting position (like females). Uncorrected chordee interferes with intercourse, and there is infertility in severe hypospadias (penoscrotal and perineal), as semen is not directed into the vagina.

### Treatment

Hypospadias should be corrected before school age so that the child does not feel ostracised in society. In severe cases of hypospadias, intersex disorders and associated urological abnormalities such as pelvic-ureteric junction obstruction or renal agenesis should be ruled out.

### Principles of surgery

These are as follows:

- correction of chordee to straighten the penis (orthoplasty)
- movement of the urinary meatus to its normal position on the tip of the penis (urethroplasty)
- correction of the deformity of the glans to give it a conical shape (glansplasty).

**No infant with hypospadias should be circumcised, as the prepuce is essential for the repair.** Repair can be undertaken as a one-time or staged procedure. It depends on the degree of chordee and the severity of the hypospadias.

### Bladder stones

In resource-limited countries, bladder stones are quite common due to the prevalence of malnutrition. The stones are composed of ammonium acid urate and oxalate, and are seen in lower socio-economic groups. Such stones are usually related to a high dietary intake of rice or wheat and low intake of milk and animal protein (see Section 5.10.B).

Children present with increased frequency of urine and strangury or haematuria (the child usually holds the penis and rubs it with the finger and cries during micturition). Children may present with an episode of retention of urine if the bladder stone becomes impacted at the bladder neck or in the urethra.

During rectal examination, a stone may be palpable on bimanual palpation. A plain abdominal X-ray may reveal calcified stones. Abdominal ultrasonography will detect non-calcified stones.

### Treatment

Open stone surgery is the modality of choice. Endoscopic removal can be performed in some children if the necessary equipment and expertise are available.

If there is no infection, two-layered closure of the bladder is sufficient, requiring no catheter or suprapubic drainage. Once the stones have been removed, recurrence is rare.

### Cervical swellings

The neck is one of the commonest sites of cystic and solid swellings during childhood. Lesions are either developmental anomalies arising from the remnants of branchial arches, thyroglossal tract, jugular lymphatics or the skin, or acquired as in diseases of the salivary gland, lymph nodes or thyroid gland.

- Lymphangiomas (cystic hygroma).
- Branchial cysts/fistulae.
- Thyroglossal cyst.

- Ectopic thyroid/thyroid swellings.
- Epidermal cyst.
- Swelling of salivary glands.
- Haemangiomas.
- Lymph-node swellings.

### Lymphadenopathy

Enlargement of the lymph nodes may result from acute or chronic infection and from primary or secondary neoplasia.

- Infection is the commonest cause of lymph node enlargement in childhood, secondary to scalp and skin infections, including lice.
- Tuberculosis is the most important pathogen in resource-limited countries.
- In many cases the lymph nodes are reacting to an upper respiratory tract infection or an ear infection. This is known as **non-specific reactive hyperplasia**, and is much more common. Thus not every enlarged lymph node needs a surgical biopsy.
- Primary tumours of the lymph nodes include lymphoma and leukaemia.

**Enlargement of a lymph node by more than 1 cm is significant, and a persistent node more than 3 cm in diameter requires fine-needle aspiration cytology or surgical biopsy.**

A careful history with regard to repeated upper respiratory tract infections, boils on the scalp or drainage area, and ear discharge, should be taken. A positive family history of tuberculosis is an important feature of tubercular lymphadenitis. A history of the pattern of fever, loss of weight and appetite, and the presence of night sweats are important features when making a differential diagnosis.

On careful physical examination, all sites of lymph nodes (cervical, axillary, inguinal and abdominal) should be examined. The size, number, consistency, tenderness, and presence or absence of fluctuations should be noted. On abdominal examination, liver, spleen and mesenteric lymph nodes should be palpated. The drainage area of the lymph nodes should be examined for boils, furuncles, injury or neoplastic swelling. The tonsils should be inspected for enlargement and suppuration.

- In **acute lymphadenitis**, the affected nodes are enlarged, painful and tender, restricting movement of local areas of the body. Fever and leukocytosis are common. Untreated infections may resolve spontaneously, progress to suppuration and abscess formation, or become chronic.
- In **tubercular lymphadenitis**, lymph nodes are enlarged and painless, and become matted together and fixed to adjacent structures. Caseation leads to the formation of 'cold' abscesses, which lack the local and systemic signs of acute inflammation (fever, tenderness and erythema). When a cold abscess ruptures through the deep fascia (a 'collar-stud abscess') the skin becomes red and thin, takes on a blue tinge and then gives way to establish an indolent tubercular sinus. On aspiration, straw-coloured fluid is present, in contrast to the thick pus that is usually present in an acute abscess. Confirmation depends on culture of the organisms or visualisation of acid-fast bacilli on microscopy.
- In **primary neoplasia (e.g. leukaemia)** the nodes are painless, rubbery in consistency and discrete. Liver and spleen enlargement may or may not be present.

Systemic features of low-grade fever, night sweats, or loss of weight and appetite point towards the diagnosis.

- **Secondary enlargement of the lymph nodes** due to neoplasia is rare in childhood.
- **Primary cancers** are soft-tissue sarcomas and very rare. The nodes are large, firm to hard in consistency, and fixed to underlying structures.

### Investigations

- Full blood count.
- The erythrocyte sedimentation rate is usually raised in chronic infection and neoplasms. Leukocytosis is seen in acute lymphadenitis and abscess formation. Leukaemia will usually be diagnosed by the appearance of leukaemic cells in peripheral blood.
- Mantoux test. To diagnose tuberculosis, start with 1 in 10 000 and then 1 in 1000. A strongly positive test is a pointer towards the diagnosis; if the test is negative, it does not rule out the disease (especially in the presence of HIV infection).
- X-ray of the chest.
- To identify there is the pulmonary lesion of primary complex or the hilar lymphadenopathy seen in cases of tuberculosis. Mediastinal widening is seen in patients with lymphomas.
- Fine-needle aspiration cytology (FNAC) is helpful if there are persistent lymph nodes that do not decrease in size after a 1-week course of antibiotics and another week of observation. Lymphomas cannot be definitely diagnosed on FNAC, and a surgical biopsy is mandatory.

### Treatment

#### Acute lymphadenitis

- Antibiotics are prescribed. Penicillin is usually appropriate, as most infections occur outside the hospital setting. Oral or IV preparations may be used. If improvement has not occurred within 48 hours, a broad-spectrum antibiotic such as an oral or IV cephalosporin may be started.
- Anti-inflammatory medication (to relieve the pain and reduce the swelling).
- Hot fomentation (to relieve the pain and reduce the swelling).

Fluctuation, or other local signs of abscess formation, indicate the need for **incision and drainage of pus**, which is best performed under general anaesthesia. All of the loculi are broken and necrotic material is curetted out.

**Always visualise and remember the important structures nearby.** A sample should be sent for microscopy (including Ziehl-Neelsen staining), culture and sensitivity, and appropriate antibiotics prescribed. The precipitating cause of acute lymphadenitis should also be treated.

#### Tubercular lymphadenitis

Antitubercular treatment leads to resolution (a full course of 9 months should be undertaken, with four drugs for 2 months and two drugs for the next 7 months; see Section 6.1.N).

Cold abscesses require drainage, and repeated aspirations may be preferable to avoid sinus formation, pending diagnosis and initiation of treatment.

### **Lymphomas and leukaemias**

After diagnosis, further investigations will be required to stage the disease and its treatment (see Section 5.14).

### **Cystic hygroma**

This is a hamartoma of the jugular lymph sac which presents in infancy and is more common in boys than in girls. It produces a major neck swelling and is diagnosed by inspection. The swelling is usually found as a unilateral, fluctuant, transilluminant swelling centred on the carotid triangle. The cysts are of varying sizes and contain clear fluid. A haemangiomas element may be present in the swelling, giving it a reddish tinge instead of a light blue colour. Cysts may enlarge suddenly due to viral or bacterial infection or haemorrhage. If the cyst compresses airways and vessels, it may cause stridor, respiratory distress and superior vena caval syndrome. Initially these lesions can be treated by aspiration and intralesional injection of bleomycin (a less expensive anti-cancer drug), at a dose of 300–600 micrograms/kg; these procedures can be repeated every 2–6 weeks, producing excellent results in the majority of cases. Surgical excision is difficult, and removal should be attempted without sacrificing important structures, in some cases in conjunction with sclerotherapy.

### **Branchial cysts, sinuses and fistulae**

Sinuses and fistulae most commonly arise from the second branchial cleft, and occasionally from the first or third one. They present as a small discharging sinus on the skin overlying the lower third of the sternomastoid muscle. Parents often notice a drop of clear fluid coming from a very small opening. Sinuses and fistulae usually present in early childhood, and may sometimes be complicated by infection and abscess formation. Treatment consists of surgical excision of the whole tract up to the pyriform fossa to prevent recurrence. Methylene blue is injected or a nylon thread guided in the fistula to delineate it during surgical dissection for appropriate excision.

### **Thyroglossal cyst**

The descent of the thyroid gland from the floor of the fetal mouth leaves a tract from the foramen caecum of the tongue to the thyroid isthmus. A cyst lined by respiratory epithelium may arise anywhere along the tract, but is usually subhyoid (75%). The swelling is in the midline and moves with swallowing and also with protrusion of the tongue. An infected cyst may be mistaken for acute bacterial lymphadenitis, or an ectopic thyroid may cause a similar swelling.

The thyroglossal cyst and the entire tract along with the central portion of hyoid bone should be excised to minimise the risk of recurrence (Sistrunk's operation).

### **Epidermoid cyst**

Inclusion dermoid cysts arise from ectodermal cells that become detached during fetal growth. They are often in the midline or along lines of embryonic fusion. They contain sebaceous cheesy material surrounded by squamous epithelium. They enlarge slowly and should be removed completely; the capsule should not be breached to prevent recurrence.

### **Haemangiomas**

These are the most common tumours of infancy and the most common congenital anomalies. They are present in around 1–3% of all newborn infants. This figure increases to 10% by 1 year of age. Haemangiomas can be capillary or cavernous, although both types may be present.

The natural history of capillary haemangiomas is as follows:

- They initially present shortly after birth as a pale pink or bright red spot or patch on the skin.
- There is subsequently rapid growth in infancy for 3–6 months, followed by a static phase.
- At 18–24 months the lesion starts to involute. Around 50% will involute by 5 years and 90% by 7 years. Rarely the lesion persists and requires excision.

A cavernous haemangioma has a deeper component in subcutaneous tissues or muscles, and is less likely to regress completely.

### **Management**

Management of these lesions consists of an accurate diagnosis and careful observation. Parents need reassurance when the lesion is growing rapidly. Problems of ulceration, bleeding and (rarely) infection occur secondary to minor trauma. These are best treated non-operatively.

- Surgical excision is indicated when there is functional or gross cosmetic disability (e.g. a haemangioma on the eyelid), or a vital organ is threatened.
- Steroids may be used to induce involution in large haemangiomas (prednisolone 1–2 mg/kg/day for 2–4 weeks; the dose is tapered off before stopping the therapy). These can be repeated in cycles, with a gap of 4–6 weeks. Intra-lesional steroids can be used to induce regression in the size of haemangiomas in and around the eye.

### **Obstructive jaundice in infancy**

This is most commonly caused by extrahepatic biliary atresia, choledochal cyst or inspissated bile syndrome.

- The most difficult differential diagnosis is neonatal hepatitis.
- If jaundice in the newborn persists, the stools are never yellow or green, and the urine is brown, a conjugated bilirubin level should be measured and urobilinogen and bilirubin looked for in the urine.
- Ultrasound may help in diagnosis. Strongly suspected cases need referral for radioactive scan and further management.

### **Empyema thoracis (see Section 5.3.B)**

This is defined as an accumulation of pus in the pleural space. In most children this results from an infected pleural effusion associated with ongoing uncontrolled pulmonary sepsis or pneumonia. An infection of the pleural space is unlikely when there is a healthy underlying lung that is completely expanded. Empyemas and effusions may be diffuse and involve the entire pleural space, or they may be intralobar, diaphragmatic or paramediastinal.

Before the advent of antibiotic therapy, *Pneumococcus* and *Streptococcus* species were the organisms most frequently associated with empyema. Currently

*Staphylococcus aureus* is the most common organism. In resource-limited countries, *Mycobacterium tuberculosis* is an important cause.

Other reasons for empyema include extension of lung abscess, trauma and extension of subphrenic abscess.

An empyema usually presents with pleuritic chest pain and a heavy sensation on the involved side. The child is febrile, tachypnoeic, tachycardic and may have a cough that is productive (purulent sputum).

### Examination

On examination there is reduced respiratory excursion, pain and dullness on percussion. A friction rub or distant to absent breath sounds may be heard on auscultation of the involved side.

- Chest X-rays in the antero-posterior and lateral views are necessary for the accurate localisation of the empyema. The underlying lung may show consolidation or evidence of infection by tubercular organisms. There may be evidence of a mediastinal shift to the opposite side. The presence of pneumatoceles indicates staphylococcal infection.
- An ultrasound scan may help to distinguish fluid from consolidation in a patient with complete opacification. It is also helpful for localising a loculated empyema that may be drained. It is essential for evaluating the condition of the underlying lung in order to decide whether to proceed with decortication or pneumonectomy.

### Management

Treatment depends on the cause, whether the condition is acute or chronic, the state of the underlying lung, the presence of a bronchopleural fistula, the ability to obliterate the space, and the patient's clinical condition and nutritional status.

- Fluid from the effusion should be aspirated (by thoracocentesis) under ultrasound control after giving local anaesthesia (see Section 5.3.B).
- If the fluid is serosanguinous, thoracocentesis and appropriate antibiotics (benzylpenicillin and flucloxacillin) given by the IV route until the temperature settles (change the antibiotics according to sensitivity), and then orally, for a total period of 6 weeks, can be a definitive treatment.
- If the fluid is thick and purulent, a tube thoracostomy is indicated. An intercostal tube should be placed in a dependent position to encourage the pleural space to drain completely. Simultaneously, physiotherapy should be instituted to expand the lung and obliterate the space (see Section 8.3 for placement of chest drains).
- If loculated and undrained pockets are present and the lung is not expanding on tube thoracostomy, an open surgical procedure (decortication) will be required, but adequate time should be given to non-operative treatment. If the underlying lung is badly damaged, and will not expand on vigorous physiotherapy, pneumonectomy is indicated.
- In tubercular empyema, a 6- to 8-week course of antitubercular treatment (see Section 6.1.N) is essential for optimum results. Surgical therapy should be withheld, except for emergency drainage, until the tubercular disease in the lung has regressed or stabilised, as shown on the serial chest X-rays.

## Urinary tract infection (UTI) due to surgical causes

Recurrent UTI requires investigation to exclude the following structural and functional abnormalities:

- vesico-ureteric reflux (see Section 5.6.B)
- posterior urethral valves
- neurogenic bladder (see Section 4.2.D)
- urethral strictures
- bladder stones (see above)
- diverticulum of the bladder and urethra
- voiding dysfunction.

## Umbilical pathology

### Umbilical hernia

- This is a defect in the umbilical ring, which generally closes at birth, leading to protrusion of a loop of bowel or omentum through it. Some degree of herniation is seen in 20% of newborn babies, and still more in premature babies or when there is any increase in intra-abdominal pressure (e.g. due to ascites or VP shunt).
- Swelling appears on crying and straining, and decreases when the child is calm.
- It can be reduced with an audible gurgle.

**Most umbilical hernias close spontaneously in the first 12 months of life**, but they may take up to 3 years. Strangulation and incarceration are virtually unknown; therefore it is safe to wait. **Strapping with coin application is contraindicated**, as it leads to maceration of skin and infection, without any real advantage of inducing closure.

**Surgical indications are a large hernia that has not closed by 3 years of age or an incarceration.**

### Umbilical discharge

- **Purulent discharge** is seen in umbilical sepsis. **Neonatal tetanus** is a serious condition in which mortality is very high (see Section 3.4) (cow dung application, as practised in rural India, is one cause). Portal thrombosis may occur secondary to it and manifest later as portal hypertension. Appropriate antibiotics (benzylpenicillin) should be instituted at the earliest possible stage, and local hygiene maintained.
- **Mucus/serous discharge** is seen in umbilical polyps and **granulomas**. Silver nitrate application will enable these to epithelialise. If these persist, excision will be required. Umbilical fistula may be present and require exploration and excision.
- **Urinary discharge** is seen with a patent urachus in association with a lower urinary tract obstruction. It is quite rare. Surgical treatment involves excision of the urachal remnant after investigation and relief of any underlying outlet obstruction.
- **Faecal discharge** is seen with a patent vitello-intestinal duct. This is a persistence of the connection between the yolk sac and the midgut, which normally disappears at about the sixth week of gestation. All remnants need to be excised, which may necessitate a laparotomy to search for any discontinuous segments of the tract.

## Appendicitis

Appendicitis is the most common abdominal surgical emergency. Although diagnosis and treatment have improved,

**appendicitis continues to cause significant morbidity, and is still (although rarely) a cause of death. However, abdominal pain unrelated to appendicitis is also common, and in many cases a few hours of active observation are recommended before proceeding to surgery.**

Appendicitis results from luminal obstruction following infection or impaction by a faecolith. Inflammation of the appendix does not inevitably lead to perforation, as spontaneous resolution may occur.

### Clinical presentation

- Presentation is very variable.
- Pain is invariably present and nearly always the first symptom. Early visceral pain is non-specific in the epigastric or umbilical region, and **only later does pain become localised over the appendix**, most typically at McBurney's point. Pain with a pelvic appendix is often delayed in onset because the inflamed appendix does not contact the peritoneum until rupture occurs and infection spreads. Pain of a retrocaecal appendix may be in the flank or back.
- Anorexia, nausea and vomiting typically follow the onset of pain within a few hours.
- Diarrhoea occurs more frequently in children than in adults, and can result in misdiagnosis. It may indicate a pelvic abscess.
- The child with acute appendicitis lies in bed with minimal movement. There may be fever and tachycardia.
- The patient may be asymptomatic before perforation occurs, and symptoms may be present for longer than 48 hours without perforation. In general, however, the longer the duration of symptoms, the greater the risk of perforation.

### Examination

Examination of the chest to rule out a lower respiratory tract infection is essential.

The single most important aspect of evaluation is serial examination undertaken by the same person. This decreases the number of unnecessary operations. Analgesia should not be withheld as was previously advised.

### Investigation

There may be an increase in the white blood cell count, but this is unreliable.

Ultrasonography is an effective diagnostic aid, with a sensitivity of about 85% and a specificity of about 90%. Demonstration of a non-compressible appendix that is 7 mm or larger in antero-posterior diameter is the primary criterion.

### Management

- The initial management involves IV fluids and adequate analgesia.
- In a patient who presents with peritonitis, adequate fluid resuscitation (see Section 5.5.B) must be performed before surgery is undertaken.
- For early non-ruptured appendicitis, peri-operative antibiotics (cefuroxime and metronidazole) should be given.
- For perforated appendicitis after appendicectomy, saline irrigation of the peritoneal cavity with the patient in the head-high position is advisable in an attempt to remove as much infected material as possible. Intravenous antibiotics should be given for at least 5 days:

- Cefuroxime (50 mg/kg 8- to 12-hourly) plus metronidazole (7.5 mg/kg 8-hourly IV over 20 minutes)

#### OR

- Ampicillin IV (25–50 mg/kg 8-hourly; maximum 4 grams/day) plus gentamicin (7 mg/kg once daily) plus metronidazole (7.5 mg/kg 8-hourly).
- If the initial presentation is with an appendicular mass, conservative treatment with IV antibiotics is given until the symptoms subside, with a plan for an interval appendicectomy.

### Complications

Complications following appendicectomy include wound infection, abscess formation (local, subphrenic or pelvic) and paralytic ileus. A late complication may be an adhesive bowel obstruction.

### Pyloric stenosis

This is a classical cause of gastric outlet obstruction in infants. It has a prevalence rate of about 1.5 to 4 in 1000 live births among white populations, but is less common in Africans and Asians. It is more common in males than in females, with a ratio of between 2:1 and 5:1. There appears to be an increased risk to firstborn infants with a positive family history.

#### Cause

No definite cause has been established. Pathologically there is marked muscle hypertrophy, primarily involving the circular layer, which produces partial or complete luminal obstruction.

#### Presentation

Pyloric stenosis typically presents at 2–8 weeks of age, with a peak occurrence at 3–5 weeks. The **vomiting is projectile and non-bilious**. Occasionally there is coffee-ground vomiting due to gastritis or oesophagitis. The child remains hungry after vomiting, and is otherwise not ill looking or febrile. Around 2–5% of infants have jaundice associated with indirect hyperbilirubinaemia. Non-bilious projectile vomiting, visible gastric peristalsis in the left upper abdomen, and in those presenting late a hypochlorhaemic hypokalaemic metabolic alkalosis are the cardinal features of pyloric stenosis.

#### Diagnosis

A definite diagnosis can be made in 75% of infants with pyloric stenosis by careful physical examination of the upper abdomen. **An absolute prerequisite for this is a calm and cooperative child, a warm environment, good light and patience.** With the patient in the supine position, in the mother's left arm and sucking on the left breast, and the surgeon sitting on the left side of the patient, the left hand is used to feel the classically described 'olive' to the right of the rectus muscle, often palpated against the spinal column. Visible gastric peristalsis is often noticed.

#### Investigations

- Ultrasonography is the most commonly used imaging technique for diagnosis. A positive finding is a pyloric canal length of 16 mm or more and a pyloric muscle thickness of 4 mm or more. A diameter of more than 14 mm is also considered abnormal.

- Blood investigations in an advanced situation may show the typical hypochloraemic hypokalaemic metabolic alkalosis.

### Management

- It is most important to prepare the patient appropriately and adequately for anaesthesia and surgery.
- Intravenous fluid resuscitation with 5% glucose in 0.9% saline with 20–40 mEq/litre of potassium chloride is the optimal fluid.
- Urine output and serum electrolytes should be monitored.
- The stomach should be aspirated before the operation.
- Ramstedt's pyloromyotomy performed through a right upper quadrant or supraumbilical incision is curative, and is associated with a low morbidity.
- The majority of these patients can be started on feeds about 6 hours after surgery.
- Those who present with haematemesis from gastritis may benefit from delay of feeding for an additional 6–12 hours after surgery.
- Vomiting in the early post-operative period is thought to be secondary to discordant gastric peristalsis or atony.

### Intussusception

This is the telescoping of a portion of the intestine into the lumen of an immediately adjoining part. Typically it occurs in a well-nourished child aged 4–12 months. The male:female ratio is 3:2, and it is more common in Caucasians.

The pathogenesis of intussusception is unclear. It usually originates in the ileum close to the ileocaecal junction and proceeds into the ascending colon. In 2–8% of cases there is a specific lead point such as a Meckel's diverticulum, polyp or duplication cyst. Adenoviral infection resulting in lymphoid hyperplasia may act as a lead point.

### Clinical presentation

- The infant is suddenly disturbed by what appears to be violent abdominal pain. The pain is colicky, intermittent and severe. With spasms the infant draws up the knees to the abdomen, screams, becomes pale and may sweat, and vomiting occurs soon afterwards. The infant may pass a normal stool, appears to recover immediately, and may resume normal eating habits, until stricken by another bout of colicky abdominal pain. The vomiting is initially reflex, but with a delayed diagnosis becomes secondary to intestinal obstruction and is often bile-stained.
- Classically, the infant passes stool that resembles redcurrant jelly. Many parents describe this as the presenting symptom, and consequently it is often treated as bacillary dysentery initially.
- **The triad of pain, vomiting and blood per rectum is present in only one-third of patients.** One in 10 infants with intussusception will have diarrhoea before signs and symptoms attributable to intussusception become obvious. This is often a cause for delay in diagnosis.
- Pallor, persistent apathy and dehydration are common signs.
- Abdominal examination reveals emptiness in the right lower quadrant and a **sausage-shaped mass in the right hypochondrium**, extending along the line of the transverse colon. **The mass is not always easy**

**to palpate, and its absence does not rule out an intussusception.**

- Fever and leukocytosis are common, and tachycardia results from episodes of colic and hypovolaemia from dehydration.

### Investigations

- Abdominal X-ray may show a soft tissue mass across the central abdomen with dilated loops of bowel.
- **Ultrasonography has become the standard non-invasive diagnostic test, and is very reliable. Doughnut (target or concentric ring) and pseudo-kidney sign suggest a diagnosis of intussusception.**

### Management

**The most important aspect of treatment is adequate resuscitation prior to intervention.** This involves establishing reliable IV access, collecting blood for baseline investigations and for cross-matching, passing a nasogastric tube for decompression, and giving IV fluids and analgesia. Some patients may require one or more boluses of 10–20 mL/kg of albumin or Ringer-lactate solution when first seen.

Broad-spectrum IV antibiotics such as a combination of cefuroxime (25–50 mg/kg 8-hourly, depending on the degree of infection) and metronidazole (7.5 mg/kg 8-hourly IV over 20 minutes) are started, and the urine output is monitored.

Management is initially non-surgical (i.e. with the use of air or barium enema). Sedation should be used for the procedure.

- **A surgeon and theatre should be ready when the radiologist attempts reduction. If perforation occurs, surgery should be performed immediately.**
- **An absolute contraindication to rectal reduction is evidence of peritonitis, indicating the presence of a gangrenous intestine.**

If hydrostatic reduction fails and if the patient is stable, a repeat reduction may be attempted. Once the intussusception reduces, the child should be observed overnight with careful monitoring of fluid and electrolytes.

If reduction fails, the child is taken for surgery, where by gentle manipulation (pushing and not pulling) the intussusception can be reduced. The appendix may be removed, recorded and the parents informed. If a pathological lead point is found, a resection anastomosis is performed. If the bowel is not viable, it is resected and a primary anastomosis is performed. Feeds are started the day after the operation and increased gradually.

Intravenous antibiotics should be given for at least 48 hours, and longer (for 7 days) if peritonitis is present.

**The interval between the onset of symptoms and institution of treatment is of paramount importance, and mortality can be reduced if the condition is recognised and treated early.**

### Intestinal obstruction

**This is the most common condition requiring emergency surgery in infants and children.** Most causes result from complications of congenital anomalies or from inflammatory conditions that affect the bowel.

### Causes

- **Extrinsic causes:** incarcerated hernia and vascular bands, intussusception, anomalies of rotation (volvulus and Ladd's bands, paraduodenal and paracaecal hernias), post-operative adhesions.
- **Intrinsic causes:** inspissation of bowel contents (meconium ileus, distal intestinal obstruction syndrome in patients with cystic fibrosis), roundworm obstruction.
- **Peristaltic dysfunction:** Hirschsprung's disease.
- **Inflammatory lesions:** tuberculosis, Crohn's disease.

### Symptoms and signs

Patients present with cramping abdominal pain with anorexia, nausea and vomiting, which progresses to become bile-stained. Abdominal distension occurs, with the degree being directly related to the site of obstruction in the gastrointestinal tract, such that the distension is greater the more distal the obstruction.

On examination, the patient may have tachycardia and signs of dehydration. Tenderness and hyperactive bowel sounds are present on abdominal examination.

Chest and abdominal films are taken to confirm the diagnosis of obstruction and rule out the presence of free air.

### Treatment

- The goal of treatment is to relieve obstruction before ischaemic bowel injury occurs.
- Intravenous access is established and blood collected for baseline investigations, including a full blood count, urea, creatinine and electrolytes, and cross-matching.
  - Intravenous fluids (Ringer-lactate or Hartmann's solution with 10% glucose) are started according to the guidelines of 4 mL/kg/hour for the first 10 kg, 2 mL/kg/hour for the next 10 kg, and 1 mL/kg/hour for the next 10 kg.
  - For example, a child weighing 22 kg would need  $40 + 20 + 2 = 62$  mL/hour.
- Some patients may need one or more IV boluses (10–20 mL/kg) with Ringer-lactate or Hartmann's solution or albumin at the start of resuscitation.
- A nasogastric tube is passed for decompression.
- Give broad-spectrum IV antibiotics such as:
  - cefuroxime 50 mg/kg 8-hourly or 12-hourly in the neonate, and metronidazole 7.5 mg/kg 8-hourly IV **or**
  - benzylpenicillin 50 mg/kg 6-hourly plus gentamicin 7 mg/kg once daily plus metronidazole 7.5 mg/kg 8-hourly.
- Once the patient is adequately resuscitated and fluid and electrolyte imbalances have been corrected, laparotomy is performed and the cause treated. Transfer to a facility where paediatric surgical and anaesthetic skills are available should be undertaken if the patient's condition will tolerate this. Otherwise, or in the absence of such a facility in the country, surgery should be performed.
- At all times adequate analgesia should be given (see Section 1.15).

### Hirschsprung's disease

This is characterised by an absence of ganglion cells in the affected intestine. The incidence is about 1 in 4400–7000 live births; the male:female ratio is about 4:1, and in long segment disease it approaches 1:1. The longer the segment of aganglionosis, the higher is the familial incidence.

### Associated conditions

These include Down's syndrome (4–16%), Waardenburg syndrome, multiple endocrine neoplasia 2A and Von Recklinghausen's disease. A higher incidence of enterocolitis has been noted in patients with Hirschsprung's disease and Down's syndrome.

### Presentation

The usual presentation is with delay of passage of meconium beyond 48 hours after birth. (Around 95% of full-term infants pass meconium within 24 hours after birth, and the remainder pass it within 48 hours.) The child then has episodes of constipation, abdominal distension, vomiting and poor feeding, and fails to thrive. They may also present with a history of constipation with explosive diarrhoea, the latter indicating the development of enterocolitis.

### Differential diagnosis

Hirschsprung's disease should be considered in the differential diagnosis of any child who has constipation dating back to the newborn period. However, childhood constipation related to dietary and habitual problems needs to be carefully ruled out in order to avoid unnecessary X-rays and biopsies.

### Examination

On examination the child has a distended abdomen, and after a rectal examination there is often explosive passage of flatus and faeces.

- A plain X-ray of the abdomen may show dilated bowel loops with paucity of air in the location of the rectum. Barium enema may show the characteristic coning, although a simple colonic dilatation can occur in any chronic constipation.
- Rectal biopsy remains the gold standard for diagnosis. It should be performed at least 2 cm above the anal valves, as the normal anus has a paucity or absence of ganglion cells at the level of the internal sphincter. Although suction rectal biopsy with acetylcholinesterase staining has become the accepted standard for diagnosis in most centres, a full-thickness rectal biopsy under general anaesthesia is equally useful if such facilities are not available.

### Treatment

Enterocolitis remains the major cause of morbidity, and has a mortality rate of around 6–30%. It manifests clinically as explosive diarrhoea, abdominal distension and fever. The pathophysiology is not fully understood. The diagnosis is made on clinical grounds, and treatment is conservative, consisting of IV fluids and rectal washouts to decompress the colon.

### Surgery

The surgical treatment of Hirschsprung's disease has evolved from a three-stage procedure (initial colostomy with multiple seromuscular biopsies, pull-through of the ganglionic colon as the second stage, and closure of colostomy as the third stage) through a two-stage procedure (colostomy at the transition zone initially, and pull-through as a second stage) to a one-stage procedure without a colostomy. The essential prerequisite for a primary pull-through is adequate preparation with colonic washouts.

---

### Perforative peritonitis

The causes of perforation include amoebiasis, typhoid, tuberculosis, roundworm perforation and Hirschsprung's disease (see Section 6).

Management starts with an adequate history and clinical examination, followed by chest and abdominal X-rays. Adequate resuscitation should be carried out as outlined in the section on intestinal obstruction. After this a laparotomy is performed and the cause treated. Treatment includes fluid resuscitation if necessary, and antibiotics (either a third-generation cephalosporin or an aminoglycoside plus metronidazole).

# Section 6

## Infections in children

## 6.1 Bacterial infections

### 6.1.A Botulism

#### BOX 6.1.A.1 Minimal standards

- Consider the diagnosis.
- Ideally give specific anti-toxin.
- Wound care when appropriate including antibiotics.
- High dependency care.

#### Introduction

Botulism intoxication is a rare, potentially fatal (5–10%) paralytic illness caused by botulinum toxin. The disease is caused by ingestion of the anaerobic *Clostridium botulinum* bacterium, which produces toxin in the intestinal tract or secretes the toxin directly into a wound. Person-to-person transmission of botulism does not occur.

Botulism can be prevented by killing the spores by pressure cooking or autoclaving at 121°C (250°F) for 3 minutes or providing conditions that prevent the spores from growing. Food-borne botulism results from contaminated foodstuffs in which *C. botulinum* spores have been allowed to germinate in anaerobic conditions. This typically occurs in home-canned food substances which have been inadequately heated and in fermented uncooked dishes. Given that multiple people often consume food from the same source, it is common for more than a single person to be affected simultaneously. Symptoms usually appear 12–36 hours after eating, but can also appear within 6 hours to 10 days.

Wound botulism results from the contamination of a wound with the bacteria, which then secrete the toxin into the bloodstream. Wounds may not be obviously or grossly infected but are usually deep and contain avascular areas.

The toxin, which is absorbed from the bowel or wound into the blood stream, causes paralysis by blocking the release of acetylcholine at the neuromuscular junction.

#### Signs and symptoms

Muscle weakness starts in the muscles supplied by the cranial nerves controlling eye movements, the facial muscles and the muscles controlling chewing and swallowing. Double vision, drooping of both eyelids, loss of facial expression and swallowing problems may occur, as well as difficulty with talking. The weakness then spreads to the arms (starting in the shoulders and proceeding to the forearms) and legs (again from the thighs down to the feet) (a symmetric descending flaccid paralysis in a proximal to distal pattern).

Severe botulism leads to reduced power in the muscles of respiration. There may be hypoventilation and difficulty coughing which when severe can lead to respiratory failure, coma from hypoxaemia and carbon dioxide retention and

eventually death if untreated. Infants may present with prolonged apnoeic episodes.

Botulism can also cause disruptions to the autonomic nervous system. This is experienced as a dry mouth and throat (due to decreased production of saliva), postural hypotension (decreased blood pressure on standing, with resultant light-headedness and fainting), and eventually constipation (due to decreased bowel peristalsis). Some of the toxins (B and E) also precipitate nausea and vomiting.

The classic triad described is bulbar palsy and descending paralysis, lack of fever, and full consciousness.

#### Differential diagnosis

Botulism differs from other flaccid paralyses in that it always manifests initially with prominent cranial paralysis and its invariable descending progression, in its symmetry, and in its absence of sensory nerve damage.

In children the differential diagnosis is as follows:

- Guillain–Barré syndrome
- tick paralysis
- poisoning
- poliomyelitis
- psychiatric illness.

In infants it is as follows:

- meningitis
- electrolyte–mineral imbalance
- Reye's syndrome
- rare congenital abnormalities.

#### Infant botulism

Infants, especially those under 6 months of age, are susceptible to botulism. Infant botulism results from the ingestion of the *C. botulinum* spores, and subsequent colonisation of the small intestine. The composition of the intestinal microflora (normal flora) in infancy is insufficient to competitively inhibit the growth of *C. botulinum* and levels of bile acids (which normally inhibit clostridial growth) are lower than later in life. Ingestion of honey is a recognised source of botulism in infants.

- Typical symptoms of infant botulism include diminished suckling and crying ability (difficulty or poor feeding and an altered cry).
- Neck weakness progressing to generalised floppiness with a complete descending flaccid paralysis.
- Constipation. Although constipation is usually the first symptom of infant botulism, it is commonly overlooked.

Honey is the only known dietary reservoir of *C. botulinum* spores linked to infant botulism. For this reason honey should not be fed to infants under 1 year of age. Other

cases of infant and paediatric botulism are acquired from spores in the soil.

### Complications

Botulism is very dangerous when affecting the respiratory system leading not only to respiratory failure, but also impaired clearing of secretions leading to pneumonia.

Laboratory confirmation is undertaken by demonstrating the presence of toxin in serum, stool, or food, or by culturing *C. botulinum* from stool, a wound or food.

However, laboratory testing may take hours or days. Initial diagnosis and appropriate treatment depend on clinical diagnosis through a thorough history and physical examination.

### Diagnosis

Diagnosis is likely in resource-limited settings to be made on clinical grounds.

Consider diagnosing botulism if the patient's history and physical examination suggest botulism. However, other diseases such as Guillain-Barré syndrome, poliomyelitis and poisoning can appear similar to botulism, and special tests (when available) may be needed to exclude these other conditions. The presence of more than one affected family member is strongly suggestive of botulism.

A definite diagnosis can be made if botulinum toxin is identified in the food, wound or stool. Botulinum toxin can be detected by a variety of techniques, including enzyme-linked immunosorbent assays (ELISAs), electrochemiluminescent (ECL) tests and mouse inoculation or feeding trials.

### Treatment

Botulinum antitoxin (if available) should be administered as soon as possible. Antitoxin does not reverse paralysis, but arrests its progression.

Before administration of antitoxin, skin testing should be performed for sensitivity to serum or antitoxin.

After skin testing, and ensuring that treatment for potential anaphylaxis is immediately available (adrenaline, IV fluids and bag-valve-mask), administration of one vial of antitoxin IV is recommended. There is no need to re-administer the antitoxin since the circulating antitoxins have a half-life of 5–8 days.

Close monitoring of respiratory function (including SpO<sub>2</sub> monitoring) is essential to detect respiratory failure. Physiotherapy to encourage deep breathing exercises may help to prevent retained secretions and pneumonia. When required, and available, artificial ventilation may be needed often for 2–8 weeks' duration in severe cases.

The treatment of children, pregnant women or immunocompromised patients with botulism does not differ from the above approach.

Antibiotics are required to remove the bacteria in cases of wound botulism. Oral (or intravenous) metronidazole (30 mg/kg per day, given at 6-hourly intervals; maximum 4 grams/day) is effective in decreasing the number of vegetative forms of *C. botulinum* and is the antimicrobial agent of choice. Penicillin V orally 25 mg/kg 6-hourly is an alternative treatment. Therapy for 10–14 days is recommended.

Other antibiotics may be required to treat secondary chest infections.

Remember that the child is fully conscious and can feel pain. Good nursing care is essential.

If a deep wound is thought to be responsible it should be treated to remove dead tissue and the source of the toxin-producing bacteria.

Each case of food-borne botulism is a potential public health emergency and it is important to identify the source of the outbreak and ensure that all persons who have been exposed to the toxin have been identified, and that no contaminated food remains.

## 6.1.B Buruli ulcer

### BOX 6.1.B.1 Minimum standards

- WHO global public health initiative.
- Antibiotics: rifampicin, streptomycin and clarithromycin.
- Surgery.
- Dry reagent-based polymerase chain reaction (PCR) assay.

### Introduction

Buruli ulcer is a highly destructive ulcerating condition caused by *Mycobacterium ulcerans*, which ranks third among mycobacterial infections affecting immunocompetent humans.

Any part of the body may be affected, particularly areas exposed to minor trauma. Management is a combination of medical treatment to eradicate the infective agent and surgical to excise the infected tissue.

### Background and epidemiology

The disease occurs in several parts of Africa, Papua New Guinea, the Americas, South East Asia, China and Australia. The organism is found in soil or stagnant water and predominantly affects children in whom infection usually occurs following a minor penetrating injury.

Intercurrent helminthic infections may also predispose to ulceration. HIV infection, and other immunodeficiency states, can exacerbate Buruli ulcer and lead to severe complications.

### Clinical features

A non-ulcerative lesion usually precedes ulceration. Four non-ulcerative presentations are recognised:

- **papule:** painless, may be itchy, non-tender intradermal lesion
- **nodule:** painless firm lesion 1–2 cm diameter in the subcutaneous tissue, usually attached to the skin

- **plaque:** painless well-demarcated elevated dry indurated lesion > 2 cm in diameter
- **oedematous:** diffuse extensive non-pitting swelling, ill-defined margin, firm, usually painful, with or without colour change over affected skin.

Subsequently an ulcer forms with central necrosis and often spreads very rapidly in all directions.

### Characteristic features

- Ulcer is usually painless (hence delay in healthcare-seeking behaviour).
- Edge of ulcer is deeply undermined.
- Satellite ulcers often communicate with the original ulcer by subcutaneous tunnels.
- Skin between adjacent ulcers is often unattached to the underlying tissues.
- The extent of damage is always greater than it appears from the surface.
- Regional adenitis and systemic symptoms are unusual (and if present suggest primary or secondary bacterial infection).
- Erosion of underlying tissue may involve nerves, blood vessels and bone (in up to 15% of cases).

### Complications

These include the following:

- tetanus
- osteomyelitis
- scarring
- ankylosis
- contractures.

Around 25% of patients develop long-term complications that may include amputation or loss of sight.

### Differential diagnosis

- **Papule:** granuloma annulare, herpes, insect bites, leishmaniasis, acne, pityriasis, psoriasis.
- **Nodule:** boil, cyst, leishmaniasis, lipoma, lymphadenitis, mycosis, onchocerciasis.
- **Plaque:** cellulitis, haematoma, insect bites, leishmaniasis, leprosy, mycosis, psoriasis.
- **Oedema:** actinomycosis, cellulitis, elephantiasis, necrotising fasciitis, onchocerciasis, osteomyelitis.
- **Ulcer:** cutaneous diphtheria, guinea worm, leishmaniasis, necrotising fasciitis, neurogenic ulcer, tropical ulcer, tuberculosis, sickle-cell disease, squamous-cell carcinoma, syphilis, venous ulcer, cutaneous amoebiasis, yaws.

### Investigations

- Slough from ulcer usually contains numerous acid-fast bacilli on Ziehl–Neelsen stain (sensitivity 40%).
- Culture unhelpful (sensitivity 20–60%, time consuming (8 weeks), expensive, frequently gives false-positive results).
- Biopsy and histopathology (sensitivity is 90%).
- Polymerase chain reaction (PCR) is increasingly used in diagnosis (it is rapid, only taking 2 days, and has a sensitivity of more than 95%). Recently, a highly sensitive dry reagent-based PCR assay has been developed that is better suited for use in most endemic countries.

## Management

The current recommendation is for combined medical and surgical management.

- 1 **Small early lesion (e.g. nodules, papules, plaques, ulcers < 5 cm in diameter):** for papules and nodules, if immediate excision and suturing is possible, start antibiotics at least 24 hours before surgery and continue for 4 weeks. Otherwise, treat all lesions in this category with antibiotics for 8 weeks.
- 2 **Non-ulcerative and ulcerative plaque and oedematous form: large ulcerative lesions (> 5 cm in diameter): lesions in the head and neck region, particularly the face:** treat with antibiotics for at least 4 weeks, then surgery (if necessary), followed by another 4 weeks of antibiotics.
- 3 **Disseminated/mixed forms (e.g. osteitis, osteomyelitis, joint involvement):** treat with antibiotics for at least 1 week before surgery and continue for a total of 8 weeks.

Necrotic ulcers should be excised with care to remove all affected tissue by extending the margin into healthy tissue. Excision is followed by primary closure or split-skin grafting. Reconstructive surgery and physiotherapy may be required for patients with contractures and other permanent disabilities and disfigurements.

### Antibiotics

Antibiotic combination treatment, by reducing ulcer size, makes larger ulcers more amenable to surgery and grafting.

### Africa

Oral rifampicin (10 mg/kg) once daily plus intramuscular streptomycin (15 mg/kg) once daily for 8 weeks.

Overall treatment success rate 96% when used in conjunction with surgery depending on size of ulcer at presentation.

**Note:** for treatment of early (less than 6 months' duration) ulcers of limited size (< 10 cm), 4 weeks of streptomycin and rifampicin followed by 4 weeks of rifampicin and clarithromycin is as effective as 8 weeks of streptomycin and rifampicin.

### Australia

Oral rifampicin plus one other oral antibiotic (either clarithromycin or ciprofloxacin) for 3 months:

- 1 when histology of resection margins shows either necrosis or acid-fast bacilli or granulomata, **or**
- 2 when initial lesion was large enough to require grafting, **or**
- 3 for complex recurrent disease.

Amikacin (IV) is recommended where surgical resection is necessarily incomplete.

Recommended antibiotics and doses for children are as follows:

- Rifampicin 10–20 mg/kg/day up to maximum 600 mg daily.
- Clarithromycin 15–30 mg/kg/day in two divided doses if under 12 years, up to a maximum of 500 mg twice daily if over 12 years.
- Ciprofloxacin 20 mg/kg/day in two divided doses, up to a maximum of 500–750 mg twice daily.

### Prevention and public health aspects

Long trousers and other mechanical barriers.

BCG offers some protection.

The *Global Buruli Ulcer Initiative*, launched by the WHO in 1998, advocates the following:

- health education and staff training in the communities most affected
- development of educational materials adapted to the needs of the countries
- community-based surveillance system to increase early detection and referral for treatment in collaboration with diseases such as leprosy and Guinea worm
- assessment of local health services and resources currently available for the diagnosis and treatment of Buruli ulcer in endemic areas
- strengthening of the capacity of health systems in endemic areas by upgrading surgical facilities and improving laboratories
- rehabilitation of those already deformed by the disease.

## 6.1.C Diphtheria

### BOX 6.1.C.1 Minimum standards

- ABC (especially airway protection).
- Immunisation and prophylaxis of contacts.
- Early parenteral antibiotics.
- Dexamethasone.
- Early antitoxin.
- Bed rest, close observation and ECG monitoring.
- Intubation/tracheostomy.

### Introduction

In countries with adequate coverage of immunisation (over 70%), diphtheria is now uncommon. Epidemics still occur associated with a fall in level of immunisation, as happened in the mid-1980s and early 1990s in Russia and Ukraine and other republics of the former USSR. The disease affects all ages.

### Epidemiology

- When levels of immunisation are low, children are the

major group affected. Young infants are protected by maternal antibody.

- With improvement in immunisation rates, affected age groups shift to older children and adults. Boosters at school entry and school leaving are essential to provide adequate herd immunity.
- Mass movement of people, for example refugees or army personnel, are important sources of spread in epidemics.
- It is more common in autumn and winter.
- In tropical countries, skin infection by *Corynebacterium diphtheriae* provides a reservoir that results in natural immunity of the carrier and subclinical spread within the community.

### Pathogenesis

*C. diphtheriae* invades the upper respiratory tract. The incubation period is 2–4 days.

TABLE 6.1.C.1 Clinical features of diphtheria

Site	Comments
Pharynx + + +	Affected in over 90% of cases
Tonsil ±	Yellow/white to grey/black (if haemorrhagic) thick membrane which extends beyond the tonsils and covers the adjacent pharyngeal wall. Bleeds when separated from underlying tissue. Pharyngeal membrane may extend to nares, palate or larynx. There may be distortion of soft palate, tonsils, etc. If confined to tonsils, little toxæmia
Nasal ±	Serosanguinous discharge, sore nose and lip Little toxæmia Highly infectious
Neck	Enlarged, tender cervical nodes, 'bull neck'
Skin 0– +	Any type of lesion (e.g. bites, impetigo) may be infected. May progress to ulcer with punched-out sharp edges. Important reservoir for transmission and natural immunisation. May result in respiratory colonisation
Other sites	Conjunctiva, ear and vulva
Levels of toxæmia	Low-grade fever (rarely > 38.9°C)
0, ±, +, ++, +++	Weak, rapid pulse, limp, apathetic, restless Rarely haemorrhagic diathesis

- Diphtheria toxin causes necrosis and exudation in local tissue which results in formation of the 'membrane'. An attempt at removal of the membrane causes bleeding.
- Toxin is distributed by blood and lymphatic system resulting in toxæmia, and causing cardiac and neurological complications.
- Non-toxin-producing *C. diphtheriae* may cause focal disease but not cardiac and neurological complications. Vaccination does not protect against this organism.

**TABLE 6.1.C.2 Complications of diphtheria**

Complication	Weeks	Comments
Toxaemia	1	Related to extent of membrane and amount of toxin absorbed. May result in cardiovascular (CVS) collapse in first 10 days. Disseminated intravascular coagulation. Survivors of severe toxaemia usually have further CVS and neurological complications
Myocarditis	2–3 Range 1–6	Onset related to severity of toxaemia Soft first heart sound, apical systolic murmur ECG: conduction abnormalities, ST-T wave changes. <b>Echocardiogram:</b> left ventricular dilation, reduced contractility, hypertrophied left ventricle, sometimes pericardial fluid Biochemistry: <b>blood myoglobin levels elevated, elevated lactate dehydrogenase, elevated creatine phosphokinase</b> Mortality: high in early onset, severe carditis
Palatal paralysis	1	Probably due to local absorption of toxin: 'fluids come down nose' Resolves in a few days
Visual accommodation	4–5	Blurring of vision, sometimes strabismus
Bulbar, heart, respiratory and limb nerves	6–8	Bilateral, resolve completely if patient survives

## Clinical features

Symptoms are initially due to disease of upper respiratory tract and associated toxaemia. Later symptoms relate to the level of toxin absorbed into the circulation. Cases with small membranes and low toxaemia recover spontaneously and most remain subclinical.

## Diagnosis

- Unless all children with upper respiratory symptoms, including croup, have an appropriate examination, diphtheria will be missed.
- A portion of membrane or a swab taken from beneath it should be sent for Gram stain and culture. The laboratory should be informed of suspected diagnosis so that appropriate culture medium is used.

## Management

See also Section 5.1.

The aim is to neutralise toxin released into blood by the bacillus and to kill the bacteria.

- Admit to isolation (on ICU if possible) cared for by staff who are fully immunised.
- Be prepared for intubation/tracheostomy, especially if laryngeal diphtheria is suspected.
- Dexamethasone (150 microgram/kg twice daily IV or orally) should be given in cases of moderate to severe airway obstruction and when there is swelling of the neck until airway obstruction resolves.
- Take great care when examining the throat or taking a sample of the membrane as it may precipitate complete airway obstruction.
- Give intravenous or nasogastric maintenance fluids if the child cannot drink.
- Give benzylpenicillin 50 mg/kg 4-hourly IV. Change to procaine benzylpenicillin 25 000–50 000 units/kg IM once daily (must not be given IV) when toxic symptoms have subsided or where toxicity is slight or, if the child can drink, to penicillin V 12.5 mg/kg 6-hourly. Erythromycin 40–50 mg/kg per day in four divided doses (maximum 2 grams/day) IV, and orally when child can

swallow, is an alternative. Antibiotics should be given for 7–10 days.

- **Antitoxin must be given as soon as possible** (after the test dose). The dose is dependent on the severity of the disease rather than the site of the membrane, although the two usually coincide:
  - Nasal and tonsillar (mild disease): 20 000 units IM.
  - Laryngeal with symptoms (moderately severe): 40 000 units IM or IV.
  - Nasopharyngeal (moderately severe): 60 000–100 000 units IV depending on severity and combined sites/delayed diagnosis (malignant disease), also 60 000–100 000 units IV.
  - In practice, give 60 000 units to all cases with visible membrane and neck swelling.

Commercially available antitoxin is extremely expensive but highly purified. Some countries (e.g. Vietnam) make their own antitoxin but it is much **less purified** than the Aventis Pasteur vaccine for example, and **cannot be given intravenously**.

## Test dose and desensitisation

### See also Section 5.1.B on anaphylaxis.

- As antitoxin is from horse serum, a test dose with 0.1 mL of 1 in 1000 dilution in saline is given intradermally.
  - Positive reaction is 10 mm erythema occurring within 20 minutes.
  - If there is no reaction, give full-dose IV/IM as appropriate.
- Have adrenaline 1 in 1000 and syringe available to give IM if anaphylaxis occurs (10 micrograms/kg).
- Desensitisation: (if test dose is positive) give graduated doses of increased strength every 20 minutes commencing with:
  - 0.1 mL of 1 in 20 dilution in saline subcutaneously followed by 1 in 10 dilution
  - then 0.1 mL of undiluted subcutaneously, then 0.3 mL and 0.5 mL IM
  - then 0.1 mL undiluted IV.

**Additional treatment**

- Give oxygen if cyanosed or  $\text{SaO}_2 < 94\%$ . Use nasal cannulae or a face mask held close to the child's face by the mother. **Do not use nasal or nasopharyngeal catheters** as these can precipitate complete airway obstruction. Be aware that giving oxygen does **not** compensate for hypoventilation which, if severe, will require intubation and cricothyroidotomy or tracheostomy (see Section 8.2). Note that intubation may dislodge the membrane, causing complete airway obstruction.
- Bed rest and observation for 2–3 weeks at least, depending on severity.
- Regular monitoring of cardiac function. Serial ECGs two or three times per week through the critical period from admission until towards the end of the second week of illness. Rhythm disturbances, particularly atrioventricular block sometimes going on to complete heart block are not uncommon, and are often the earliest evidence of cardiac involvement.
- With severe cardiac involvement (which often follows from severe local disease) the children develops a low-output state and may die from cardiac failure or arrhythmias. Poor urine output and rising creatinine are early indicators of poor prognosis and should be monitored, together with serum potassium which should be kept in the normal range (see Section 9.A). Strict bed rest is essential for all children until the critical period for

cardiac complications has passed (minimum of 2 weeks from onset).

- Captopril at the earliest sign of any cardiac involvement may be helpful (100 micrograms/kg once daily as a test dose with the child supine and monitoring blood pressure carefully, followed by 100–200 micrograms/kg 8-hourly).
- Prednisolone 1.5 mg/kg/day for 2 weeks may be of value in reducing the incidence of myocarditis.
- Nasogastric feeds if palatal or bulbar paralysis occurs. Bulbar problems rarely become evident until several weeks later, so even if children come through the phase of upper airway obstruction and survive the cardiac problems, they should remain in close contact with the hospital for at least 6 weeks.
- Immunise on discharge.

**Prevention**

- Maintaining immunity at all age levels in the community is important. Additional immunisation at school entry and leaving (see Section 1.17).
- Give immunised household contacts a booster of toxoid.
- Give all unimmunised contacts one dose of IM benzathine benzylpenicillin (600 000 units for children under 5 years and 1.2 million units for those over 5 years). This drug must not be given IV. Immunise and check daily for signs of diphtheria.

**6.1.D Leprosy****BOX 6.1.D.1 Minimum standards**

- Public health measures.
- Clinical awareness.
- Multi-drug treatment (MDT) with rifampicin, dapsone and clofazimine.
- Protective footwear,
- Support and counselling.
- Reconstructive surgery.

**Introduction**

A campaign to eliminate leprosy below a prevalence of 1 in 10 000 greatly reduced total numbers, but new cases, especially in India and Brazil, are still being detected in worryingly large numbers. It remains the prototype of a disfiguring skin disease. It is caused by *Mycobacterium leprae*, an organism that invokes an immunological response in the skin and especially focusing on superficial cutaneous nerves, resulting in anaesthesia and paralysis of hand, foot and facial muscles. There is a range of disease from an effective immune response with few surviving bacteria termed paucibacillary leprosy, to a poor immune response with very large numbers of bacteria termed multibacillary leprosy. Unfortunately, the present public health picture of leprosy is that the majority of new cases are multibacillary and the percentage of children affected is greater than before. The incubation period is very long (up to 8–10 years) and disability is often present by the time it is diagnosed.

In countries where the prevalence is low, leprosy may be forgotten and those trained to recognise it disbanded.

The expectation is that general health services will oversee the patient as he or she moves from an anxious family to a traditional health practitioner to a health centre. The latter will be overwhelmed by common skin disease such as impetigo, cutaneous fungus disease and scabies, and current policy is to train all health workers in health centres to manage these correctly and thereby increase the likelihood of detection and better management of rarer diseases such as leprosy. Conditions not diagnosed or not responding should be guided through an effective referral system to greater expertise.

The global registered prevalence of leprosy at the beginning of 2009 stood at 213 036 cases, while the number of new cases detected during 2008 was 249 007. The number of new cases detected globally has fallen by 9126 (a 4% decrease) during 2008 compared with 2007.

Pockets of high endemicity still remain in some areas of Angola, Brazil, Central African Republic, Democratic Republic of Congo, India, Madagascar, Mozambique, Nepal, and the United Republic of Tanzania.

**Diagnosis**

At one end of the clinical spectrum of leprosy is an early single lesion with very few bacilli which may resolve spontaneously and certainly responds well and quickly to antibiotics. It is hypopigmented, flat and insensitive to light touch, pinprick and hot and cold.

The spectrum passes through an increasing number of such lesions that are unlikely to resolve spontaneously, and

increasingly, over a period of years, infiltration and swelling which is often nodular, from asymmetry to symmetry, to greater numbers of bacilli, to eventual widespread infiltration of the skin. The bacteria are shed into the environment from the nose and wounds.

Early diagnosis requires a full examination of all the skin, tests of any suspicious lesion for numbness, and a biopsy of infiltrated lesions, especially nodules, the presence of a granuloma alerting to the need for bacterial stains.

Cutaneous nerves, ulnar, radial, posterior cervical, lateral popliteal and muscular cutaneous on the dorsum of the foot must be palpated for thickening. Early signs include flexion of the fourth and fifth finger, dropped foot, and reduction in blinking.

### Differential diagnosis

**Vitiligo** is totally de-pigmented, whiter than leprosy and usually symmetrical. There is no sensory loss. It is long lasting.

**Pityriasis alba** is very common, mild, dry eczema, usually symmetrical on both cheeks and the extensor surface of both limbs. It varies over days or weeks and responds to moisturising ointments or hydrocortisone.

**Pityriasis versicolor** is a common infection of the skin from *Malassezia furfur* producing depigmentation and fine scaling especially of the upper trunk. The organism and the slight inflammation it causes accounts for a dull red to brown discolouration of white skin. Pigmented skin loses pigment due to exfoliation. It responds to selenium sulphide shampoo, Whitfields (benzoic acid and salicylic acid) ointment or ketoconazole, plus sun exposure for rapid re-pigmentation.

**Post-inflammatory depigmentation** is preceded by undisputed injury such as a burn, chickenpox, fungal infection or psoriasis. There may be loss of normal skin texture as in a scar.

### Reactions

Reactions are immunological responses to *Mycobacterium leprae* or its antigen. There are two types.

Erythema nodosum-like with multiple tender, symmetrical red lumps anywhere in the skin due to immune complexes and accompanied by fever and malaise. It often responds to rest and non-steroidal anti-inflammatory drugs but persistent reactions will need oral steroids. There is usually a history of prior diagnosis of leprosy.

The other type of reaction is focused on a previous plaque or infected nerve. There is redness, swelling and tenderness. It is destructive of nerves. An early prescription of an initially high dose of prednisolone is necessary (1 mg/kg/day). Complete withdrawal of steroids should only occur after several weeks if nerve destruction is to be avoided.

### Treatment

Multidrug therapy cures leprosy. Multidrug therapy should be given under supervision by experts able to provide full advice on the preventive management of disability, who

may confirm the diseases by skin smears or biopsies and can manage reactions. Standard drug therapy is available free from government programmes for the elimination of leprosy. WHO guidelines for multidrug therapy include a single dose for a single lesion, or two drugs for lesions which contain more than one bacteria. A daily regimen for 1 year of three drugs is necessary for more widespread multibacillary disease. Lepromatous leprosy is subject to reaction even after 1 year of therapy and patients must be educated to return for diagnosis and appropriate therapy promptly. Relapse after completion of therapy is uncommon but well documented.

### WHO-recommended treatment for paucibacillary leprosy in children (10–14 years)

**Once a month:** On day 1, two capsules of rifampicin (300 mg + 150 mg) plus one tablet of dapsone (50 mg).

**Once a day:** On days 2–28, one tablet of dapsone (50 mg).

Full course: six blister packs over 6 months.

For children younger than 10 years, the dose must be adjusted according to body weight.

### WHO recommended treatment for multibacillary leprosy in children (10–14 years)

**Once a month:** On day 1, two capsules of rifampicin (300 mg + 150 mg) plus three capsules of clofazimine (50 mg × 3) plus one tablet of dapsone (50 mg).

**Once a day:** On days 2–28, one capsule of clofazimine every other day (50 mg), plus one tablet of dapsone (50 mg) daily.

Full course: 12 blister packs over 12 months.

For children younger than 10 years, the dose must be adjusted according to body weight.

Children may be more troubled by the haemolytic side effect of dapsone, and are less tolerant to rifampicin. New drug regimens include ofloxacin, minocycline and clarithromycin. Several experimental and clinical studies have demonstrated that these drugs either alone or in combination with other anti-leprosy drugs have significant bactericidal activity. Patients presenting with single skin lesion paucibacillary leprosy can be treated with only one dose containing rifampicin 20 mg/kg, ofloxacin 15 mg/kg and minocycline 100 mg (only for children over 12 years).

Multibacillary leprosy patients who do not accept clofazimine can be treated with this combination given monthly for 24 months.

There is still a fear of the stigma of leprosy. The emphasis of therapy is that it is a cure and rapidly renders the patient non-infectious.

Support and counselling is necessary for the patient along with education for family and community, or else the cured patient may still not be acceptable to either family or community.

## 6.1.E Leptospirosis

### BOX 6.1.E.1 Minimum standards

- Recognition and treatment of shock.
- Antibiotics: amoxicillin, penicillin (parenteral for severe disease), doxycycline.
- Public health measures.

### Introduction

Leptospirosis is a zoonotic disease caused by *Leptospira* species with a worldwide distribution. It is endemic in the tropics and its incidence in these countries appears to be increasing. The possible reasons include an increase in the rat population and seasonal flooding. Transmission to humans is from infected animal urine. The onset is usually abrupt. It is an acute febrile disease with varied manifestations characterised by vasculitis. The severity of disease ranges from asymptomatic or subclinical to self-limited systemic illness (approximately 90% of patients) to life-threatening illness with jaundice, renal failure, and hemorrhagic pneumonitis. The clinical course is usually biphasic and with multisystemic involvement. The initial (septicaemic) phase lasts 4–7 days, the second (immune) phase 4–30 days. It can be lethal in the acute period, and is similar to diseases such as dengue, malaria, hepatitis and viral illnesses.

Risk factors for infection include occupational exposure (farmers, ranchers, abattoir workers, veterinarians, loggers, sewer workers, rice field workers, laboratory workers), recreational activities (fresh water swimming, canoeing, trail biking), household exposure (pet dogs, domesticated livestock, rainwater catchment systems, and infestation by infected rodents), and skin lesions (contact with wild rodents).

### History and examination

- **Enquire about** headache, fever, abdominal pain, breathing difficulties and cough, diuresis, bleeding, diarrhoea or vomiting.
- **Assess** vital signs (blood pressure, pulse, respiratory rate), 'alarm signs', blood film for malaria parasite. Consider dengue fever.
- **Watch out for** 'alarm signs' of leptospirosis: abdominal pain, respiratory distress, jaundice, bleeding and oliguria.

### Clinical manifestations

Leptospirosis is associated with a variable clinical course. The disease may manifest as a subclinical illness followed by seroconversion, a self-limited systemic infection, or a severe, potentially fatal illness accompanied by multiorgan failure. Physical examination is often unrevealing. An important but frequently overlooked sign is **conjunctival suffusion**.

Below are common clinical manifestations:

- **General symptoms:** headache, myalgia, vomiting and anorexia, arthralgia, macular rash.
- **Central nervous system:** CSF pleocytosis and elevated protein, meningism, neurological symptoms.
- **Renal system:** pyuria, haematuria, proteinuria, oliguria/anuria, dysuria, back pain.
- **Gastrointestinal system:** abdominal pain, diarrhoea,

constipation, abnormal liver function tests, hepatomegaly, jaundice, gastrointestinal bleeding.

- **Respiratory system:** cough, pharyngitis, otitis media, chest pain, pneumonitis, pulmonary oedema and haemoptysis.
- **Cardiac system:** arrhythmias, conduction and other ECG abnormalities.
- **Haematology:** blood clotting disorder, petechiae, bruises, epistaxis, thrombocytopenia, lymphadenopathy, splenomegaly.
- **Eyes:** conjunctival bleeding, photophobia, retro-orbital pain, uveitis, papilloedema.

### Classification

- **Mild disease:** headache, fever, myalgia, no evidence of bleeding.
- **Moderate disease:** headache, fever, myalgia, abdominal pain and jaundice.
- **Severe disease:** Weil's disease or icterohaemorrhagic fever: shock, abdominal pain, respiratory failure, pulmonary haemorrhage, acute renal failure, altered consciousness and bleeding.

### Diagnosis

1 **Clinical:** Features that are significantly associated with leptospirosis include:

- conjunctival suffusion
- haemorrhage
- abdominal pain
- hepatosplenomegaly
- oedema.

2 **Laboratory:**

- **Cultures:** blood culture in initial phase and urine in the second phase. Blood (50% yield) and CSF specimens are positive during the first 10 days of the illness. Urine cultures become positive during the second week of the illness.
- **Serology:** Serological tests (microscopic agglutination test (MAT), macroscopic agglutination test, indirect haemagglutination, and enzyme linked immunosorbant assay – ELISA) are most often used for confirmation.
  - The gold standard is considered to be the MAT. However, this test is cumbersome which requires live organisms, considerable expertise, and is performed only by reference laboratories. MAT is most specific when a fourfold or greater rise in titre is detected between acute and convalescent serum specimens. However, a single titre of > 1:800 is strong evidence of current or recent infection with leptospira.
  - Rapid diagnosis with specific IgM (ELISA) can be made by two commercially available rapid tests, the microplate IgM ELISA and an IgM dot-ELISA dipstick test. If one of these assays is positive, sera for MAT can be sent to a reference laboratory.
  - **Newer tests:** Polymerase chain reaction (PCR), not widely available, but shows considerable promise for a quick, accurate diagnosis.

- **Routine labs:** white blood cell (WBC) counts may range between 3000 and 26000/microlitre; thrombocytopenia, raised serum bilirubin, hyponatremia, proteinuria, pyuria, microscopic haematuria, elevated creatine kinase and minimal to moderate elevations of hepatic transaminases may be seen.
- 3 **X-rays:** chest radiographs may show small nodular densities, confluent consolidation or a ground-glass appearance.

### Differential diagnosis

Malaria, dengue fever, scrub typhus, acute viral illnesses including influenza, other rickettsial disease, typhoid fever and rare causes such as ehrlichiosis and hantavirus infections.

### Complications

These include renal failure, uveitis, haemorrhage, acute respiratory distress syndrome, myocarditis and rhabdomyolysis. Vasculitis with necrosis of extremities may be seen in severe cases. Severe leptospirosis may require ICU admission. Multi-organ failure in 75% and mortality in over 50% of these patients may be seen.

### Management

The majority of *Leptospira* infections are self-limiting. Many antibiotics have antileptospiral activity, and if the illness is severe and the diagnosis is recognised, antibiotic therapy should be given.

#### Mild disease:

- Discharge home with advice about hydration and 'alarm signs'.
- Antibiotics:
  - Children under 10 years of age: amoxicillin 15 mg/kg three times daily for 7 days or, if allergic, erythromycin 10–15 mg/kg/day three times daily for 7 days.
  - Children over 10 years: doxycycline 100 mg twice daily for 7 days.

#### Moderate disease:

- Observe for 48 hours, monitor vital signs 4-hourly.

- If abdominal pain and respiratory distress settle, discharge.
- Antibiotics: benzylpenicillin 25–50 mg/kg IV 6-hourly for 3 days, then change to oral penicillin. Amoxicillin is an alternative.

#### Severe disease:

- Give oxygen as required, IV fluids (see Section 5.5), and pass a nasogastric tube.
- Keep an accurate fluid-balance chart.
- Pulmonary haemorrhage may require assisted ventilation with PEEP.
- Pulmonary oedema: treat with fluid restriction, oxygen and diuretics.
- Management of disseminated intravascular coagulation, renal failure and myocarditis.
- Antibiotics: Intravenous therapy with benzylpenicillin (250 000 to 400 000 units/kg/day in four to six divided doses; maximum dose 6 million units daily: note 600 mg = 1 million units), or doxycycline (4 mg/kg/day in two equally divided doses; maximum dose 200 mg daily), or ceftriaxone (80–100 mg/kg once daily; maximum dose 4 grams daily), or cefotaxime (150–200 mg/kg/day in three to four equally divided doses; maximum dose 12 grams daily). Doxycycline should be avoided in children less than 8 years of age.
- For children less than 8 years of age with severe penicillin allergy, therapy with oral azithromycin (10 mg/kg once on day 1, maximum dose 500 mg/day, followed by 5 mg/kg/day once daily on subsequent days, maximum dose 250 mg/day) or oral clarithromycin (15 mg/kg/day divided into two equal doses, maximum dose 1 gram/day) may be given.
- The duration of treatment is usually 5–7 days.

### Prevention

Vaccination of domestic animals against leptospirosis provides substantial protection. The major control measure is to avoid potential sources of infection such as stagnant water, water derived from run-off from animal farms, rodent control, and protection of food from animal contamination.

Currently no vaccine is available for human immunisation, but doxycycline prophylaxis during period of exposure has been shown to be protective.

## 6.1.F Lyme disease

### BOX 6.1.F.1 Minimum standards

Antibiotics: doxycycline, amoxicillin and ceftriaxone.

### Introduction

This disease is caused by the bacterium *Borrelia*. *Borrelia burgdorferi* is the main cause in North America, whereas *Borrelia afzelii* and *Borrelia garinii* cause most European cases. The prevalence of Lyme disease in sub-Saharan Africa is presently unknown, but cases have been reported. The abundance of hosts and tick vectors would support the presence of this infection in Africa where it is probably grossly under-diagnosed.

### Transmission

Lyme disease is transmitted to humans from a natural reservoir among rodents by ticks that feed on both rodents and other animals, such as deer.

Tick bites often go unnoticed because of the small size of the tick in its nymphal stage, as well as tick secretions that prevent the host from feeling any itch or pain from the bite. However, transmission is quite rare, with only about 1% of recognised tick bites resulting in Lyme disease. This may be because an infected tick must be attached for at least a day for transmission to occur.

Days to weeks following the tick bite, the spirochetes spread via the bloodstream to joints, heart, nervous system,

and distant skin sites, where their presence gives rise to the variety of symptoms of disseminated disease.

If untreated, the bacteria may persist in the body for months or even years, despite the production of antibodies against *Borrelia* by the immune system.

### Diagnosis

Lyme disease is diagnosed clinically based on symptoms, objective physical findings (such as erythema migrans (EM), facial palsy or arthritis) or a history of possible exposure to infected ticks, as well as serological blood tests. The EM rash is not always a bull's-eye (see below) (i.e. it can be red all the way across). When making a diagnosis of Lyme disease, healthcare providers should consider other diseases that may cause similar illness. Not all patients infected with Lyme disease will develop the characteristic bull's-eye rash, and many may not recall a tick bite.

### Signs and symptoms

Many of the symptoms are not specific to Lyme disease.

The incubation period from tick bite to the onset of symptoms is usually 1–2 weeks, but can be much shorter (days), or much longer (months).

### Early localised infection

The classic sign of early local infection with Lyme disease is a circular, outwardly expanding rash called erythema chronicum migrans (also erythema migrans or EM), which occurs at the site of the tick bite 3–30 days after the bite. The rash is red, and may be warm, but is generally painless. Classically, the innermost portion remains dark red and becomes thicker and firmer; the outer edge remains red; and the portion in between clears, giving the appearance of a bull's-eye. EM is thought to occur in about 80% of infected patients. Patients can also experience flu-like symptoms, such as headache, muscle soreness, fever, and malaise. Lyme disease can progress to later stages even in patients who do not develop a rash.

### Early disseminated infection

Within days to weeks after the onset of local infection, the *Borrelia* bacteria begin to spread through the bloodstream. EM may develop at sites across the body that bear no relation to the original tick bite. Other discrete symptoms include migrating pain in muscles, joints, and tendons, and heart palpitations and dizziness.

Various acute neurological problems appear in 10–15% of untreated patients. These include facial palsy, arthritis and meningitis. Radiculoneuritis causes shooting pains that may interfere with sleep, as well as abnormal skin sensations. Mild encephalitis may lead to memory loss, sleep disturbances, or mood changes.

The disease may also have cardiac manifestations including cardiac arrhythmias.

### Late disseminated infection

After several months, untreated or inadequately treated patients may go on to develop severe and chronic symptoms that affect many parts of the body, including the brain, nerves, eyes, joints and heart. Many disabling symptoms can occur.

Chronic encephalomyelitis, which may be progressive, can involve cognitive impairment, weakness in the legs, awkward gait, facial palsy, bladder problems, vertigo, and back pain. In rare cases untreated Lyme disease may cause frank psychosis, which has been misdiagnosed as schizophrenia or bipolar disorder. Panic attacks and anxiety can occur; there may also be delusional behaviour, including somatoform delusions, sometimes accompanied by a depersonalisation or derealisation syndrome, where the patients begin to feel detached from themselves or from reality.

Lyme arthritis usually affects the knees.

### Treatment

In most cases, the infection and its symptoms are eliminated by antibiotics, especially if the illness is treated early. Delayed or inadequate treatment can lead to the more serious symptoms, which can be disabling and difficult to treat.

The antibiotics of choice for early infections are given orally for 10–28 days:

- 1 In children over 8 years: doxycycline, 4 mg/kg/day in two divided doses (maximum of 100 mg per dose).
- 2 In younger children (less than 8 years): amoxicillin 50 mg/kg/day in three divided doses. Doxycycline should not be given in pregnancy, instead use amoxicillin 250–500 mg three times daily for pregnant girls. If early infection is severe, ceftriaxone 50 mg/kg IV/IM once daily can be given at any age.

Late-diagnosed chronic Lyme disease is treated with oral or intravenous antibiotics for a minimum of 4 weeks, frequently ceftriaxone 50–75 mg/kg once a day IV.

## 6.1.G Meningococcal disease

### BOX 6.1.G.1 Minimum standards

- Early parenteral antibiotics.
- Treatment of shock.
- Neurological assessment and cerebral protection.
- Frequent reassessment of clinical status.
- Electrolyte monitoring and replacement.
- Replacement of platelets, clotting factors and red cells.
- Follow public health procedures.

### Introduction

Meningococcal disease is caused by *Neisseria meningitidis*, a Gram-negative diplococcus which is a commensal of the human nasopharynx. Endemic meningococcal disease primarily affects children under 5 years old. Some areas, in particular the meningitis belt in sub-Saharan Africa, suffer from epidemics of meningococcal disease. Temperate climates usually experience an increase in disease during winter months, whereas in sub-Saharan Africa, conditions during the dry season cause a sharp rise in incidence.

Predominant disease-causing organisms are serogroups A, B and C and W135, with other serogroups generally only causing infection in specific patient groups (e.g. complement deficiency and the immunocompromised). Serogroup A is associated with epidemic disease in the meningitis belt of Africa, Middle East and southern Mediterranean regions, and less commonly in other developing countries. Serogroups B and C are largely responsible for endemic disease in temperate countries, although serogroup C is now less common in countries where the serogroup C vaccine has been widely introduced.

**TABLE 6.1.G.1 Signs and symptoms of meningococcal meningitis and septicaemia**

Meningococcal meningitis	Meningococcal septicaemia
<i>Symptoms</i>	<i>Symptoms</i>
Fever	Fever
Headache	Petechial/purpuric rash
Nausea and vomiting	Shivering/rigors
Rash	Malaise and lethargy/confusion
Drowsiness or irritability	Headache
Neck and back pain, and stiffness	Nausea and vomiting
Convulsions	Limb and joint pain
<i>Signs</i>	Absence of neck stiffness
Fever	Collapse
Non-blanching rash	<i>Signs</i>
Neck stiffness/positive Kernig's sign/opisthotonus	Fever
Decreased conscious level	Petechial/purpuric rash
<i>Infants</i>	Shock:
Signs of meningitis may be non-specific with neck stiffness frequently absent.	Tachycardia
Bulging fontanelle may be present.	Low pulse volume
Suspect meningitis in any febrile infant, especially where there is marked irritability, vomiting and poor feeding	Cool peripheries
	Capillary refill time > 3 seconds
	Hypotension (late sign)
	Urine output reduced (< 1 mL/kg/hour)
	Tachypnoea
<b>Both meningitis and septicaemia can coexist in the same child.</b>	Hypoxaemia
	Decreased conscious level

## Clinical features

In general, meningococcal disease presents either as **meningitis** or as **meningococcal septicaemia**, although many patients present with a mixed picture. In developed countries, the majority of cases may present with septicaemia and frequently with shock, whereas in African serogroup A epidemics, meningitis is the commonest presentation.

Meningococcal disease should be suspected in any patient who presents with a non-blanching (petechial or purpuric) rash. However, 13% of cases may present with a maculopapular rash and 7% may have no rash. Severity of rash does not correlate with severity of disease.

## Life-threatening features of meningococcal disease

- **Shock:** particularly uncompensated shock (hypotension and tachycardia). Shock causes the majority of deaths due to meningococcal disease and is a medical emergency.
- **Raised intracranial pressure:**
  - Decreased conscious level (Glasgow Coma Scale score or Modified Children's Coma Score < 8 or deteriorating).
  - Focal neurological abnormalities, especially false localising signs (e.g. pupillary dilatation).
  - Abnormal postures (decorticate or decerebrate).
  - Convulsions.
  - Rising blood pressure with falling pulse rate.

## CSF features consistent with meningococcal meningitis

- Turbid or purulent (may be clear or blood stained), white blood cell count > 500 cells/mm<sup>3</sup> (< 3 cells/mm<sup>3</sup> in normal CSF).
- Protein usually > 0.8 grams/litre (< 0.6 grams/litre in normal CSF).
- Glucose reduced compared with blood glucose concentration.
- Gram-negative diplococci (intra- or extracellular) in 72% of previously untreated cases.

## When not to perform a lumbar puncture

Lumbar puncture may precipitate coning if there is significantly raised intracranial pressure. In septicaemia, lumbar puncture is unlikely to be helpful and may cause rapid deterioration in an unstable child.

### Contraindications to lumbar puncture: suspected critically raised intracranial pressure

- Glasgow Coma Scale score/Modified Children's Coma Score < 8 (or if child is unresponsive to pain).
- Focal neurological signs, including pupillary abnormalities.
- Unexplained hypertension/bradycardia.
- Shock (see below).
- Significant clotting disorder or low platelet count (50 × 10<sup>9</sup>/litre) is present.

## Management of meningococcal disease

See Section 5.16.B for a discussion of isolated meningococcal meningitis.

## Principles

In suspected cases, give an injection of benzylpenicillin before transfer of child to hospital. Recommended doses of benzylpenicillin by age group are as follows:

- < 1 year: 300 mg
- 1–10 years: 600 mg
- > 10 years: 1.2 grams.

On admission, early antimicrobial therapy should be given, such as benzylpenicillin with chloramphenicol (for dose and alternatives, see Table 6.1.G.3). Ideally this should be given intravenously, but if this is not possible it can be given intramuscularly.

Close monitoring and aggressive supportive therapy

TABLE 6.1.G.2 Investigations in meningococcal disease

Investigations		Comment
Microbiology	Lumbar puncture <sup>†</sup>	For Gram stain and culture (remember contraindications for performing lumbar puncture)
	Throat swab	Culture*
	Blood culture	Gold standard diagnostic test for septicaemia, positive in 30% or more of previously untreated cases
Special microbiology: advanced methods	Meningococcal serology: CSF or blood. Meningococcal PCR	Acute and convalescent blood samples required
Haematology	Full blood count	Low haemoglobin  In early septicaemia or in lone meningitis usually high neutrophil count. Low white cell count with neutropenia in severe septicaemia. Low platelet count ( $< 50 \times 10^9/\text{litre}$ ) in disseminated intravascular coagulation
	Coagulation screen	Prolonged PT, KCTT and TT Raised fibrin degradation products
Biochemistry	Urea, creatinine, electrolytes including calcium, magnesium, phosphate	Hypokalaemia Hypocalcaemia Hypophosphataemia Metabolic acidosis Raised urea and creatinine (if severe, suspect pre-renal failure)

\* Meningococci should be cultured on Mueller–Hinton or chocolate agar to identify and serogroup with antibiotic sensitivities.

<sup>†</sup> Where laboratory facilities are scarce, diagnosis of meningitis is made on CSF alone: appearance, cell count, glucose sticks, Albutix.

are needed if features of shock or raised intracranial pressure develop.

**Never delay antimicrobial therapy if facilities are not available for immediate lumbar puncture or blood culture.**

**The most appropriate available antibiotic should be used.** In general, intravenous benzylpenicillin with intravenous chloramphenicol are the drugs of choice where meningococcal disease is the most likely diagnosis. Where the diagnosis is uncertain, or where there is a high prevalence of penicillin resistant meningococci, broad-spectrum antibiotics should be used (see Table 6.1.G.3), ideally including a third-generation cephalosporin.

Do not delay administration if cefotaxime or ceftriaxone are unavailable (use benzylpenicillin, ampicillin or chloramphenicol instead for the initial dose).

The risk of transmission disappears after 24–48 hours of antibiotic therapy. Isolation is not essential, but staff should maintain good hygienic practice and wear masks and gloves during invasive procedures such as intubation, airway and mouth care, and line insertion.

Parenteral antibiotic treatment should be given for 7–14 days if the diagnosis of meningococcal disease is certain. Once culture and sensitivity results are available, treatment should be modified appropriately.

TABLE 6.1.G.3 Antibiotic doses in meningococcal disease

Antibiotic	Route	Dose and frequency
Ampicillin	IV	400 mg/kg/24 hours in four divided doses (maximum single dose 3 grams)
Benzylpenicillin	IV	300 mg/kg/24 hours in six divided doses (maximum single dose 2.4 grams)
Cefotaxime	IV	200 mg/kg/24 hours in four divided doses (maximum single dose 4 grams)
Ceftriaxone	IV/IM	80 mg/kg/24 hours once daily (maximum single dose 4 grams)
Chloramphenicol	IV	100 mg/kg/24 hours in four divided doses*
	Oral	100 mg/kg/24 hours in four divided doses <sup>†</sup>

\* Chloramphenicol should be used with caution in infants less than 3 months of age. Monitoring of serum levels is recommended, and lower doses with wider dosage intervals may be required.

<sup>†</sup> Oral chloramphenicol is usually used only following 3–4 days of parenteral antibiotics. Although not recommended for children less than 3 months of age or in malnourished children, the evidence for harmful effects is slight.

### Important notes

- Early recognition of life-threatening disease (shock and raised intracranial pressure) is vitally important. There is a very high risk of death if patients are not resuscitated aggressively at presentation.
- Assess airway patency, breathing and circulation (ABC) and examine for signs of shock and raised intracranial

pressure (see above). Management regimens differ for different presentations: shock; raised intracranial pressure; meningitis uncomplicated by either shock or raised intracranial pressure.

- Many children present with a mixed picture and may require treatment of shock as well as management of neurological complications.

- Meningococcal disease is often progressive and patients may continue to deteriorate after antibiotic and supportive therapy have been initiated. All suspected cases should be closely monitored for cardiovascular and neurological deterioration for at least 24 hours.
- Management of children with severe shock or raised intracranial pressure who do not respond fully to initial resuscitation is complex. Every effort should be made to admit these patients to an appropriate intensive-care facility.

## Shock

**This is a medical emergency** (see also Section 5.5.A and 5.5.C)

- Assess **ABC** and give high-flow oxygen.
- Check blood glucose levels (e.g. using BM Stix).
- Obtain intravenous or intra-osseous access.
- Take blood for culture, full blood count, grouping and cross-matching, coagulation screen, and urea and electrolytes.
- Commence appropriate intravenous antibiotics.
- Do not perform a lumbar puncture.
- Commence fluid resuscitation immediately using 20 mL/kg of crystalloid or colloid given as fast as possible. Reassess and use further fluid boluses of 20 mL/kg if signs of shock persist. Use either Ringer-lactate or Hartmann's solution (or 0.9% saline if neither of these are available) or other non-glucose-containing crystalloid or a colloid such as 4.5% human serum albumin.
- Blood products such as packed cells, plasma and platelets may be required. Arrange for supplies if available.
- Patients who remain shocked after 40 mL/kg colloid/crystalloid will probably benefit from inotropic support (e.g. dopamine 10–20 micrograms/kg/minute IV by peripheral intravenous cannula).
- Shocked patients are at significant risk of developing pulmonary oedema as fluid therapy increases. Ideal therapy is mechanical ventilation for patients who require more than 40 mL/kg fluids.
  - In resource-limited countries, where facilities for mechanical ventilation are unavailable, further fluid boluses should be undertaken cautiously with repeated boluses of 5–10 mL/kg of crystalloid, colloid or blood products as appropriate.
  - If pulmonary oedema develops (with tachypnoea, hypoxia, cough and fine crackles, raised jugular venous pressure and hepatomegaly) further fluid administration should be withheld until the patient stabilises. Inotropic support, as described above, may be of benefit.
- Full neurological and cardiovascular assessment with regular (at least hourly) assessment of: pupillary responses, conscious level, pulse, blood pressure, capillary refill time, respiratory rate and effort, pulse oximetry (if available) and temperature.
- Regular (ideally 4-hourly initially) monitoring of electrolytes (sodium, potassium, **calcium and magnesium, phosphate**, urea and/or creatinine) and glucose and replacement of deficits.
- **Blood gases should be undertaken to detect metabolic acidosis from shock or respiratory acidosis due to ventilatory insufficiency.**
  - Severe metabolic acidosis (pH < 7.0), which does not respond to fluid therapy, may require cautious sodium bicarbonate correction (1 mEq/kg slowly IV).
  - Regular blood gas monitoring is essential for ventilated patients.

- Monitor full blood count and coagulation regularly if initially abnormal.
  - Blood or packed cell transfusion should aim to maintain haemoglobin levels around 7–10 g/dL in the early phases of shock.
  - Platelets and coagulation factors (usually fresh frozen plasma and cryoprecipitate) should be replaced as required in order to control bleeding.
- Hydration will usually be via the intravenous route, but nasogastric feeding is appropriate if tolerated.
  - Urine output should be monitored (by an indwelling catheter if the conscious level is depressed). Insert a nasogastric tube for gastric drainage if there is persistent vomiting or if the conscious level is decreased.

## Suspected raised intracranial pressure

**This is a medical emergency.**

### Actions

- Assess ABCD, give high-flow oxygen (10 litres/minute), and obtain intravenous or intra-osseous access.
- Treat shock (see above), if present.
  - Exercise caution with fluid therapy as there is a conflict of need between raised intracranial pressure (RICP) and shock. The former requires less fluid, and the latter needs more.
- Do not perform a lumbar puncture.
- Give mannitol 250–500 mg/kg IV (this should be repeated if signs of raised intracranial pressure persist, up to a maximum total dose of 2 grams/kg or if available a serum osmolality up to 325 mOsm/litre).
  - Hypertonic saline may be used as an alternative (e.g. 3% saline 3 mL/kg).
  - If mannitol or 3% saline is unavailable, give furosemide 1 mg/kg IV.

**If signs of raised intracranial pressure persist**, ideal management would include:

- Rapid sequence induction of anaesthesia and intubation for both airway protection (if Glasgow Coma Scale score is < 8 and/or the child is unresponsive to painful stimuli) and stabilisation of PCO<sub>2</sub>.
- Mechanical ventilation with optimal sedation and maintenance of PCO<sub>2</sub> within the normal range (ideally 4.5–5.5 kPa).

Other useful techniques include the following:

- Place the patient supine in a 30-degree head-up position.
- Avoid placing a central venous catheter in the internal jugular vein.
- Give antipyretics to maintain normal temperature.
- Undertake a full neurological and cardiovascular assessment with regular (at least hourly) assessment of: pupillary responses, conscious level, pulse, blood pressure, capillary refill time, respiratory rate and effort, pulse oximetry (if available) and temperature.
- Monitor electrolytes, gases, clotting and full blood count as recommended for shock.

**Prognosis**

- Even with optimal intensive care, around 5–10% of patients with meningococcal septicaemia will die. Where intensive care is unavailable this may rise to more than 40%.
  - Mortality of other causes of acute meningitis is generally much lower (around 2%).
- The most frequent complication of meningitis is hearing impairment or deafness, which may affect up to 10% of survivors.
- Survivors of septicaemia may require skin grafting of necrotic lesions and amputation of necrotic digits or limbs.
- In general, most survivors make a virtually complete recovery, although subtle neurological abnormalities (e.g. behavioural and developmental problems, mild motor abnormalities) are not uncommon.

**Prevention of meningococcal disease****Education**

Increasing awareness of primary healthcare workers and general public about the presenting symptoms of meningococcal disease and emphasising the need for early presentation and treatment may have a major impact on mortality and morbidity.

**Prophylaxis of contacts**

Transmission is via droplet spread to close contacts. Around 4–25% of people are colonised at any one time, but outbreaks of disease are not generally related to colonisation rate. Household contacts of a case may be at 800 times increased risk of disease compared with the general population.

Chemoprophylaxis is used to prevent secondary cases by eliminating nasal carriage. Administer as soon as possible (within 48 hours after presentation of the index case).

Follow local public health guidelines when determining who should receive antibiotic prophylaxis. In general, only immediate family (or those sharing accommodation) and kissing contacts should be treated. Healthcare workers should receive prophylaxis only where they have experienced extensive contact with the patient's respiratory secretions (e.g. during intubation).

**Drugs for prophylaxis**

Give rifampicin for 2 days for all household contacts:

- adults: 600 mg twice daily
- children aged 1 month to 12 years: 10 mg/kg twice daily
- neonates: 5 mg/kg twice daily.

In many countries rifampicin is protected from use for any disease other than TB. In this case consider giving ciprofloxacin orally as a single dose: adults, 500 mg; children aged 5–12 years, 250 mg; children aged 1 month to 5 years, 125 mg.

**Vaccination**

Where the index case has proven serogroup A or C disease, consideration should be given to vaccinating close contacts with appropriate polysaccharide or polysaccharide conjugate vaccine.

During larger outbreaks or epidemics, wider-scale prophylaxis is occasionally used, but should only be carried out under guidance of local/national public health authorities. Public education regarding presenting symptoms of meningococcal disease and emphasising the need for early presentation may be more beneficial than wide-scale distribution of antibiotics.

Vaccines based on the **capsular** polysaccharide of serogroups A and C ( $\pm$ Y and W-135) have been available for several years, and have been used for vaccination of contacts (as above) and for protection of travellers to endemic areas. They are unable to reliably induce immunity in infants and young children as their duration of protection is short.

They are not generally used for population vaccination campaigns except in epidemic situations.

**Conjugated** polysaccharide vaccines for serogroups A, C, Y and W-135 are now available and offer the possibility of inducing long term immunity in all age groups.

A vaccine against serogroup B has recently received a license.

Where widespread epidemics of meningococcal disease occur (e.g. in the meningitis belt in sub-Saharan Africa), mass vaccination campaigns have proved useful in reducing attack rate. Such campaigns are administered by local public health authorities.

**6.1.H Pertussis****BOX 6.1.H.1 Minimum standards**

- Immunisation.
- Erythromycin.
- Oxygen.
- Close monitoring for apnoea and hypoxaemia.

**Introduction**

Infection with the organism *Bordetella pertussis* (a Gram-negative bacillus) causes a clinical syndrome commonly referred to as 'whooping cough'. The illness classically has three stages.

- Stage 1: **Catarrhal stage** (1–2 weeks). The symptoms are those of an upper respiratory infection.

- Stage 2: **Paroxysmal stage** (2–4 weeks). The child has severe episodes of coughing – usually up to 10 coughs without drawing breath, and then a sharp inspiration or 'whoop'. The prolonged coughing (often with vomiting) may lead to poor feeding, with weight loss and sometimes rectal prolapse. Other complications such as subconjunctival haemorrhages and ulceration of the frenulum may develop.
- Stage 3: **Convalescent stage** (1–2 weeks). The episodes of coughing subside. Occasionally the child may continue to cough for months.

**Pertussis should be prevented by universal infant immunisation.** In some countries, immunisation is also given to the

mother during pregnancy (28 to 38 weeks gestation) to prevent pertussis in infancy.

### Effects on the young infant

Infants may become infected with pertussis before they have been immunised, or if immunisation is not available (or the parents have refused it). Young infants with pertussis have a different and serious clinical picture that includes the following:

- apnoea with hypoxaemia
- bradycardia
- seizures
- cough and poor feeding.

### Diagnosis

The laboratory facilities needed to diagnose pertussis are not available in many hospitals. **Culture from a pernasal swab should be undertaken on Bordet–Gengou medium.** An absolute lymphocytosis (with a typical clinical picture) is highly suggestive (the total lymphocyte count may be over  $30 \times 10^9/\text{litre}$ ).

### Treatment

The following groups of children should be admitted to hospital

- infants under 6 months of age
- children with complications such as pneumonia, convulsions, dehydration or severe under-nutrition
- those with apnoea or cyanosis.

### Supportive treatment

- Maintain nutrition and hydration.
- Give oxygen according to the criteria for acute lower respiratory infection (ALRI) (see Section 5.3.A).

- Give gentle suction of secretions (avoid triggering coughing).
- Low-dose continuous oxygen (0.5–1.0 litre/minute) via nasal cannulae may reduce apnoeic episodes in infants. Do not use nasopharyngeal cannulae, which can provoke coughing spasms.
- Do not give cough suppressants, sedatives or antihistamines.
- Encourage breastfeeding. If the infant cannot drink, pass a nasogastric tube.
- If there is severe respiratory distress, consider intravenous maintenance fluids to avoid aspiration, but avoid malnutrition.
- In some infants, the frequency of apnoeic episodes is high and requires ventilatory support.

### Specific treatment

- Treat pneumonia that is complicating pertussis, according to the ALRI protocol in Section 5.3.A.
- Give DTP vaccine to any unimmunised siblings (see Section 1.17).
- Treat convulsions (see Section 5.16.E).
- Erythromycin will eradicate pertussis from the nasopharynx but has little effect on the severity or duration of clinical symptoms unless it is started very early in the disease. The oral dose of erythromycin is 12.5 mg/kg 6 hourly for neonates for 7 days and 125 mg 6 hourly for age 1 month to 2 years for 7 days. Azithromycin (10 mg/kg once daily) may also be given, and the course is shorter (3 days) but is not recommended under 6 months of age. Prophylaxis of other infants in the family is of no proven benefit, and has side effects.

## 6.1.1 Relapsing fevers

### BOX 6.1.1.1 Minimum standards

- Public health measures to kill lice.
- Antibiotics: erythromycin, ceftriaxone.
- Close observation for the Jarisch–Herxheimer reaction.

### Epidemiology

**Epidemic or louse-borne relapsing fever (LBRF)**, caused by *Borrelia recurrentis*, is transmitted by the human body louse (*Pediculus humanus*) (and occasionally the head louse (*P. capitis*) or, possibly, the crab louse (*Phthirus pubis*)), which becomes infected following a blood meal and remains infected for life. Humans are the reservoir host. The louse is crushed when the host scratches. *Borrelia* enters the new host via abrasions and mucous membranes. Bloodborne and congenital infections may also occur. Currently only endemic in Ethiopia, LBRF occurs in epidemics in situations of poor hygiene and overcrowding.

**Endemic or tick-borne relapsing fever (TBRF)** occurs in widespread endemic foci: central, eastern and southern Africa (*Borrelia duttonii*); north-western Africa and the Iberian peninsula (*B. hispanica*); central Asia and parts of the Middle East, India and China (*B. persica*); and various

regions of the Americas (*B. hermsii*, *B. turicatae*, *B. venezuelensis*). Animal reservoirs include wild rodents, lizards, toads, owls, pigs and chickens. Transmission to humans occurs following the bite of an infected argasid (soft) tick of the genus *Ornithodoros* via tick saliva or coxal fluid. Human congenital infections may also occur. TBRF is a common and under-diagnosed cause of fever in many parts of Africa.

### Pathology

*Borreliae* multiply in blood by simple fission. They have a predisposition for reticulo-endothelial system and CNS, causing widespread vascular endothelial damage and platelet sequestration in the bone marrow. Clinical severity tends to correlate with the level of spirochaetaemia and relapses result from antigenic variation.

### Clinical features

- Incubation period usually 4 to 8 days (range 2–15 days).
- TBRF usually clinically milder, but may be associated with up to 11 relapses.
- LBRF more severe, and rarely gives rise to more than three relapses.

- Typical features include sudden-onset high fever, headache, confusion, meningism, myalgia, arthralgia, nausea, vomiting, dysphagia, dyspnoea and cough (which may be productive of sputum containing *Borrelia*).
- Hepatomegaly is common (associated with jaundice in 50% of patients with LBRF, and in less than 10% of those with TBRF). Splenomegaly is common and splenic rupture may occur.
- Petechiae, erythematous rashes, conjunctival injection and haemorrhages are more common in LBRF.
- Complications include myocarditis, pneumonia, nephritis, parotitis, arthritis, neuropathies, meningoencephalitis, meningitis, acute ophthalmitis and iritis.
- The case fatality rate (CFR) may reach 70% in epidemics of LBRF, and is lower in children than in adults.
- CFR is usually less than 10% in untreated cases of TBRF, but tends to be higher in children and pregnant women.

### Differential diagnosis

Malaria, typhus, typhoid, meningococcal septicaemia/ meningitis, dengue, hepatitis, leptospirosis, yellow fever, other viral haemorrhagic fevers.

### Diagnosis

- Giemsa- or Field-stained blood films reveal spirochaetes.
- *Borrelia* is also visible on unstained blood films using dark-field or phase-contrast microscopy.
- Centrifuge anticoagulated whole blood to concentrate spirochaetes above the buffy coat.
- The acridine orange-coated quantitative buffy coat (QBC) technique is also useful.
- Polymerase chain reaction (PCR) assays are now available for diagnosis and speciation.
- Serology is unreliable.
- Examination of the vector may be useful.

### Treatment

- A single dose of antibiotic is effective in about 95% of cases of LBRF, and in up to 80% of cases with TBRF.
- Single-dose treatment is recommended in LBRF epidemics.
- TBRF relapses are less likely with a 5- to 10-day course of treatment.

Effective antibiotics include tetracycline, doxycycline,

penicillin, erythromycin, chloramphenicol and ciprofloxacin. Choice will depend on the patient's age, contraindications and drug availability.

Ceftriaxone is recommended for patients presenting with meningitis or encephalitis.

In epidemics of LBRF, treatment of close contacts may also be recommended.

### Usual dosage recommendations:

- LBRF: a single dose of one of the following:
  - doxycycline, 100 mg (non-pregnant adults)
  - tetracycline, 500 mg (non-pregnant adults)
  - erythromycin, 500 mg in adults and children over 5 years
  - erythromycin, 250 mg in children up to 5 years.
- TBRF: a 5-day course of one of the following:
  - doxycycline, 100 mg twice daily (non-pregnant adults)
  - erythromycin, 2 grams divided into two to four doses daily (adults)
  - erythromycin, 50 mg/kg divided into two to four doses daily (children).

### Complications

**A Jarisch–Herxheimer reaction (JHR) may occur in up to 80–90% of patients treated for LBRF, and in up to 50% of those treated for TBRF. This may be fatal in around 5% of cases.**

- The reaction usually commences within 2 hours of the first dose of antibiotic.
- Symptoms include rigors, restlessness and anxiety, then a sharp rise in temperature, tachycardia and initial rise blood pressure, followed by marked vasodilation and sweating, which may result in collapse and shock.
- All patients must be closely monitored for a JHR. Intravenous fluids may be required to maintain blood pressure.
- Steroids are of no benefit.

### Prevention and control

**LBRF:** improve hygiene, reduce crowding, delouse (DDT, permethrin or malathion powder to skin and clothing), heat treat/destroy clothing. Antibiotic prophylaxis may be recommended in high-risk situations.

**TBRF:** avoid tick habitats.

## 6.1.J Sexually transmitted diseases

### BOX 6.1.J.1 Minimum standards

- Health education programmes.
- Child protection in cases of abuse.
- Antibacterial drugs.
- Antiviral drugs.
- Podophyllin/trichloroacetic acid.

### Introduction

Anogenital infections in childhood are most commonly acquired through sexual contact or abuse, but may also arise as a result of close personal contact within the family

or on the playground, and some systemic infections may be transmitted by sexual means without being considered venereal illnesses.

The diagnosis of sexually transmitted disease is considered in the following circumstances:

- a history of recent sexual abuse
- the isolation of sexually transmitted organisms in cases without obvious trauma leading to a diagnosis of chronic sexual abuse
- specific syndromes and diseases usually transmitted by the sexual route in adults
- congenital syphilis or perinatally acquired chlamydia

or gonorrhoea transmitted from the mother *in utero* or postnatally (see Section 3.4)

- HIV infection not acquired perinatally, through transfusion or another known mechanism.

There are more than 20 different infections that may be spread by the sexual route. These range from the classic sexually transmitted diseases (e.g. syphilis, gonorrhoea), through conditions that are mainly sexually transmitted (e.g. genital herpes, human papillomavirus), to those infections that can also be transmitted by sexual means (e.g. hepatitis B and C).

## Sexual abuse

### Children known to have been abused recently

Sexually abused children are at risk of acquiring an infection from the perpetrator. In relation to the high frequency of sexual abuse, the typical sexually acquired infections are fairly rare, but the risk depends on a number of epidemiological factors.

The diagnosis of potential infection of a child presenting with sexual abuse includes an active microbiological search by culture of vulval, perineal or anal swabs. Bacterial infections such as gonorrhoea, syphilis or chlamydia are usually manifested soon after the assault, with the development of local ulcers and infected vaginal or vulval discharge.

The sexually transmitted viral diseases such as herpesvirus type 2 can also become evident soon after the incident, but diseases with a longer latency period such as human papillomavirus are more difficult to link directly to the episode of sexual abuse.

The management of the child potentially infected after sexual abuse consists of the following:

- management of the sexual abuse (see Section 7.6)
- local management of injuries, including tetanus toxoid if applicable
- bacteriological swabs
- serological tests for syphilis, hepatitis B and HIV, repeated 6 weeks later
- prophylactic broad-spectrum antibiotics: ceftriaxone 50 mg/kg IM as a single dose (maximum dose 4 grams) plus erythromycin 20–40 mg/kg/day in three divided doses for 7 days
- post-exposure hepatitis B vaccination if not previously vaccinated; follow-up doses at 1–2 and 4–6 months after the first dose
- assessment of the risk of HIV transmission and prophylaxis if indicated.

Children are at higher risk because episodes of assault are often multiple and mucosal trauma is likely.

Factors that should be assessed include the following:

- assailant's HIV status or likelihood of having HIV
- time elapsed since incident (< 72 hours)
- exposure characteristics
- possible benefits and risks associated with post-exposure prophylaxis (PEP).

PEP is generally well tolerated in children. The choice of antiretroviral drugs will depend on local availability and policy. An example is a combination of zidovudine, lamivudine

and lopinavir/ritonavir. Follow-up and appropriate treatment of identified infection (see below) should be undertaken.

### The presence of a sexually transmissible infection in a child alerting to the possibility of sexual abuse

This group of children presents with symptoms and signs suggestive of genital, urinary or lower intestinal infection. In children aged around 2–10 years, the finding of genital, anal or pharyngeal infection with *Neisseria gonorrhoeae*, *Treponema pallidum* or *Chlamydia trachomatis* should prompt a search for evidence of sexual abuse. However, herpesvirus type 2, *Trichomonas vaginalis*, *Mycoplasma* species and bacterial vaginosis are not so commonly acquired as a result of sexually transmitted infection in this age group. Although human papillomavirus types 6, 11, 16 and 18 are also usually transmitted by sexual means and may present with condylomata, a long latency in the onset of clinical signs means that these may have been transmitted from mother to child during birth, and close domestic contact other than sexual abuse has also been shown in such cases.

### Specific syndromes or diseases usually associated with sexual transmission in adolescent children

These conditions occur particularly in sexually active adolescents. In view of the rampant spread of HIV infection, the approach to the management of sexually transmitted diseases in children and adolescents must include the following aspects:

- Treatment of the symptoms and causes in a typical syndromic approach to STDs, as described below.
- Identification of those without symptoms. There is a recognised risk of co-infection, and as both syphilis and HIV may be asymptomatic, serological tests for syphilis (VDRL or RPR) and HIV (ELISA) should be offered with appropriate counselling in all patients.
- Prevention of new infection by education about safe sex practices and condom use.
- Motivation to engage in health-seeking behaviour.

### Genital ulcers and lymphadenitis

The infections presenting with genital ulcers with or without inguinal adenopathy and bubos are most often acquired as a result of voluntary or involuntary sexual activity, but may occur as a result of non-sexual inoculation through close domestic or play contact or indirect transmission. The patient should be carefully examined to determine the site, number, size and appearance of the ulcers, the type of exudate, the presence of associated pain, erythema and swelling, or of draining lymphadenopathy.

Regional epidemiological factors determine the relative frequency and likelihood of genital herpes (herpesvirus type 2), syphilis, chancroid, lymphogranuloma venereum or granuloma inguinale.

### Genital herpes

This causes painful vesicular or shallow ulcerative lesions on the genitals. Grouped or single lesions occur on a thin erythematous base but with generally uninfamed intervening epithelium. These regress spontaneously but may recur. Oral aciclovir 200 mg five times daily for 5 days does not

prevent future recurrences, but if started early, will reduce the intensity and duration of symptoms. Locally, anaesthetic and antiseptic creams help to relieve symptoms.

### **Chancre of primary syphilis**

This is a painless ulcer with a serous exudate which is highly infectious. The diagnosis can be made by direct dark-field examination or immunofluorescent antibody stains. At this stage, serological tests for syphilis are usually still negative. The treatment in children over 12 years consists of benzathine benzylpenicillin, 50 000 U/kg IM as a single dose (50 000 U = 37.5 mg). Benzathine benzylpenicillin must not be given IV.

### **Chancroid**

This is caused by *Haemophilus ducreyi*. Painful papulovesicles or ulcers on the genitals are associated with suppurative inguinal adenopathy. In the absence of adenopathy, the condition has to be differentiated from herpes or syphilis, the latter of which is usually painless. In treatment of children over 12 years of age, the following are satisfactory: azithromycin 1 gram orally as a single dose, ceftriaxone 250 mg IM as a single dose, or erythromycin base 500 mg orally four times daily for 7 days.

### **Lymphogranuloma venereum**

Patients with lymphogranuloma venereum (LGV) commonly present with unilateral tender inguinal and/or femoral lymphadenopathy. Genital ulcers are usually less obvious and have often disappeared by the time of presentation. LGV is caused by *Chlamydia trachomatis*. Treatment for children over 12 years of age is with doxycycline 100 mg orally twice daily or erythromycin 500 mg orally four times daily, and should be continued for 21 days.

### **Granuloma inguinale**

*Klebsiella granulomatis* is the cause of this ulcerative disease. The lesions are painless and slowly progressive. Subcutaneous granulomas often occur on the genitals and perineum, but regional lymphadenopathy is absent. Treatment is with doxycycline or erythromycin, as for LGV. Alternatively azithromycin, ciprofloxacin or trimethoprim-sulfamethoxazole can be used.

### **Urethritis and vulvovaginitis**

These patients present typically with a discharge from urethra or vagina. The character of the discharge may be non-specific or it may have typical features allowing a presumptive diagnosis concerning its aetiology. Together with the discharge, there may be other features such as itching, discomfort or dysuria. There may be inflammatory erythema and swelling of the tissues. Where pruritus is a major symptom, *Trichomonas* or *Candida albicans* should be suspected. The appearance of the discharge may be typically white cheesy in *Candida*, or creamy-purulent and frothy in *Trichomonas* infection, but often is fairly non-specific.

The organisms responsible for this mode of presentation include *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas*, *Candida* species, *Gardnerella vaginalis* and *Ureaplasma* species. In the syndromic approach to the management of patients with surface epithelial infection, broad-spectrum treatment aimed at gonorrhoea, *Chlamydia* and *Trichomonas* or *Candida* is given at the same time as

bacterial swabs are taken for culture. Where laboratory resources are scarce, bacteriological investigations may be reserved for those not responding appropriately to the first course of therapy.

Recommended treatment for children over 12 years of age includes ceftriaxone 250 mg IM as a single dose, or cefixime 400 mg orally in a single dose, against *Neisseria gonorrhoeae*. Azithromycin, 1 gram orally as a single dose, or doxycycline 100 mg orally twice daily for 7 days (alternatively, erythromycin 40–50 mg/kg/day given as 4 divided doses 6 hourly for 14 days for children under 12 years) should be added for *Chlamydia*. If *Trichomonas* or bacterial vaginosis due to *Gardnerella vaginalis* is identified or strongly suspected, metronidazole is added as 15–30 mg/kg/day in three divided doses for 7 days. *Candida* infection can be treated with a short course (3 days) of topical azoles such as clotrimazole, miconazole or butoconazole cream. An alternative is treatment with local nystatin (100 000 U/mL three to four times daily), but this is less effective.

### **Acute balanoposthitis**

Inflammation of the glans and prepuce can have a large number of infectious and also non-infectious causes. In the usual case, there is erythema and swelling of the glans and prepuce together with local exudate. Most such cases are not due to sexually transmitted infection, but are caused by beta-haemolytic streptococci, *Staphylococcus aureus* or *Candida albicans*. These may arise secondary to local trauma including ritual circumcision. Allergic contact dermatitis and rarer causes such as psoriasis or pemphigus should also be considered. Sexually transmitted organisms include *Chlamydia*, *Gardnerella vaginalis*, *Trichomonas*, *Candida albicans*, syphilis, herpes virus and papillomavirus. If 'milking' along the length of the urethra produces a purulent discharge, STDs are also more likely.

Accordingly, the evaluation of a boy presenting with balanoposthitis includes examination for the presence of urethral discharge and a urine dipstick. A swab should be sent for microbiological confirmation. A suggested treatment for children over 12 years is azithromycin 1 gram orally in one dose, or erythromycin 40–50 mg/kg per day in four divided doses for 14 days, plus metronidazole 15–30 mg/kg per day in three divided doses for 7 days. In the presence of urethral discharge, treatment should also include antibiotic cover for gonorrhoea.

### **Genital warts**

Condylomata acuminata are fleshy, soft, pedunculated or flat warty lesions that may sometimes have quite a narrow base. They occur singly or in clusters. In sexually active adolescent boys, they may occur on the shaft or corona of the penis, and in girls on the genital mucosal surface both inside and outside the vagina. Perineal cutaneous condylomata are not always acquired sexually. Human papillomavirus (HPV) types 6 and 11 cause these warts. Apart from the visible wart, the infection may be quite asymptomatic, particularly where lesions occur intravaginally. They must be differentiated from the flat papular condylomata lata of syphilis, skin tags and molluscum contagiosum.

Local treatment is satisfactory in most instances, although recurrences occur. Trichloroacetic acid or 10–25% podophyllin may be applied to external lesions, taking care not to involve normal skin. Other precautions to avoid the development of complications include limiting the

application to less than 0.5 mL of podophyllin and an area of over 10 cm<sup>2</sup> of warts per session. The preparation should be washed off 1–4 hours after application to reduce local irritation. The process can be repeated in 7 days. Other treatment modalities include cryotherapy, surgical excision, curettage or electrocautery. An alternative is not to treat, and to await possible spontaneous resolution.

The association with genital dysplasia and carcinoma should be remembered, and therefore Pap smears and regular follow-up are indicated in girls with human papillomavirus infection.

Two HPV vaccines are now available. They offer protection against HPV types that cause a large percentage of carcinomas as well as genital warts.

## Pelvic inflammatory disease (PID) and epididymitis

The deep infections of the upper female genital tract present with features of infection, such as fever and leucocytosis,

together with lower abdominal pain and a vaginal discharge. There may be signs of pelvic peritonitis or a tender mass on vaginal or rectal examination. Epididymitis in males presents typically with unilateral pain, swelling and tenderness of the testis, together with urethral discharge. This can be distinguished from testicular torsion by means of an ultrasound examination. In sexually active adolescents, these infections are most often caused by *Neisseria gonorrhoeae* or *Chlamydia trachomatis*. Such patients may be very ill and require hospitalisation including possible surgical drainage. General supportive therapy is given as required. The antibiotic therapy aims at the above two organisms and outpatient treatment typically includes a third-generation cephalosporin like ceftriaxone plus doxycycline. Metronidazole may be added to treat bacterial vaginosis which frequently accompanies PID.

In severe cases, or where there is no response to the above treatment within 72 hours, intravenous broad-spectrum antibiotics including an aminoglycoside and clindamycin should be given.

## 6.1.K Streptococcal disease

### BOX 6.1.K.1 Minimum standards

- Antibiotics: penicillin and erythromycin.
- For resistant pneumococci: cefotaxime/ceftriaxone, vancomycin.
- Pneumococcal vaccine post-splenectomy and in sickle-cell disease.

### Introduction

Streptococci are Gram-positive bacteria, of which the most important are:

- Group A streptococcus
- Group B streptococcus
- *Streptococcus pneumoniae*.

### Group A streptococci (GAS) *Streptococcus pyogenes*

This is a common commensal in the throat. It causes many diseases, as described below.

#### Head and neck

- Acute pharyngitis, retropharyngeal abscess and otitis media (see Section 5.1.C).
- Tonsillitis: GAS likely if exudate, tender anterior cervical lymph nodes, fever, no cough. Penicillin V for 10 days is the treatment of choice, but amoxicillin may be better tolerated in liquid form. GAS is always sensitive to penicillin. In penicillin allergy use a macrolide (although there is resistance to this group of antibiotics).
- Sinusitis: follows otitis media: coryza, postnasal drip, headache, fever.
- Brain abscess: this is a rare complication resulting from direct extension of an ear or sinus infection, or from haematogenous spread (see Section 5.16.K).

### Skin and soft tissue

- Impetigo: purulent, yellow-crust skin lesions (see Section 5.18).
- Pyoderma: papule becomes vesicular then pustular with a thick crust and surrounding erythema.
- Erysipelas: erythematous warm painful skin lesions with raised borders associated with fever.
- Cellulitis: local pain, tenderness, swelling and erythema associated with fever.

Skin infections are commonly co-infected with *Staphylococcus aureus*, which should be treated with flucloxacillin. Treat invasive disease with IV flucloxacillin, benzylpenicillin and clindamycin.

### Necrotising fasciitis

- Pain disproportionate to physical findings: erythema may be absent or rapidly progress to purple with haemorrhagic fluid-filled blisters or bullae. Fever, malaise, myalgia, diarrhoea, anorexia. Spread through fascial planes requires early surgical exploration and resection. Give intravenous immunoglobulin (IVIG) (if available).

### Myositis

- CT or MRI (if available) is useful for diagnosis.

### Scarlet fever

- This presents with tonsillitis and a characteristic rash, circumoral pallor and strawberry tongue. Rash starts with generalised blanching erythema which is punctate (i.e. like sandpaper) and palpable, followed by desquamation.

### Pneumonia

- Invasive GAS can rapidly progress to necrotising pneumonia with empyema (see Section 5.3.B).

**Septicaemia**

- Risk factors include burns and chickenpox. The main symptoms are fever, tachycardia, tachypnoea and hypotension.

**Mediastinitis**

- Rare but serious, frequent fatalities as often diagnosed late.

**Toxic shock syndrome**

- Systemic shock with multi-organ failure. Give IVIG (if available) (see Section 5.5.C).

**Rheumatic fever****Acute rheumatic fever**

- **Major criteria:** carditis, Sydenham chorea, polyarthritis, erythema marginatum, subcutaneous nodules.
- **Minor criteria:** fever, arthralgia, raised ESR or CRP, prolonged PR interval on ECG.

Two major or one major and two minor criteria with evidence of preceding GAS throat infection confirm a diagnosis of rheumatic fever (see Section 5.13).

Rheumatic heart disease results in chronic valvular damage, predominantly of the mitral valve.

**Glomerulonephritis**

- Acute renal failure with haematuria and proteinuria days after streptococcal pharyngitis (see Section 5.6.A).

**Group B streptococci (GBS)*****Streptococcus agalactiae***

This species colonises 15–45% of healthy women and can cause severe infections in the puerperium and in the neonate.

Postpartum infection (see Section 2.5.G).

**Neonatal infection**

- Early onset (first week of life) (see Section 3.4) associated risk factors: prematurity, prolonged rupture of membranes, maternal intrapartum fever, chorioamnionitis, maternal UTI, previous baby with GBS disease.

- Late onset (1 week to 3 months of age) causes sepsis and meningitis: not prevented by peripartum antibiotics.

Empirical IV treatment with ampicillin and gentamicin for 5 days. Then, once GBS is confirmed, treat sepsis with benzyl penicillin for 7 days if meningitis is excluded by lumbar puncture. If meningitis is not excluded, treat for 14 days.

**Maternal**

- Septic abortion, puerperal sepsis, urinary tract infection.

***Streptococcus pneumoniae***

Gram-positive diplococcus (lancet shaped). At least 85 pathogenic serotypes are known. Types 1, 3, 4, 6, 7, 8, 9, 12, 14, 18, 19 and 23 are the most virulent.

- Common infections include pneumonia, meningitis, peritonitis, otitis media, sinusitis, arthritis and conjunctivitis.
- Pneumococcal infections are more common in children with defective splenic function (e.g. sickle-cell anaemia, splenectomy); also nephrotic syndrome, chronic renal failure, diabetes mellitus, malabsorption, heart failure, skull fracture, neurosurgery and those with congenital or acquired immunodeficiency such as agammaglobulinaemia, and HIV infection.
- Patients with white blood cell counts of more than  $15 \times 10^9/\text{litre}$  are likely to have bacteraemia.
- Culture of *Streptococcus pneumoniae* from the respiratory tract is not useful because many people are asymptomatic carriers.

**Treatment**

- In the last two decades, resistance of *S. pneumoniae* to antibiotics such as penicillin and chloramphenicol has emerged.
- In many countries, up to 5–40% of isolates may be resistant to penicillin G.
- If resistance to chloramphenicol or penicillin is suspected, give either cefotaxime or ceftriaxone. If resistance to these two drugs is considered, add vancomycin to ceftriaxone or cefotaxime. If results of sensitivity confirm susceptibility to penicillin G, ceftriaxone or cefotaxime should be given and vancomycin should be stopped.

**TABLE 6.1.K.1 Antibiotic doses for streptococcal disease**

Disease	Antibiotic	Dose and route	Dose interval	Duration/comments
Otitis media	Amoxicillin (oral)	12.5 mg/kg orally	8 hours	5–7 days
	Amoxicillin – clavulanic acid	12.5 mg/kg orally	8 hours	5–7 days
	Cefaclor	12.5 mg/kg orally	8 hours	5–7 days
	Erythromycin	12.5 mg/kg orally	6 hours	5–10 days
Sinusitis	As for otitis media	As for otitis media	As for otitis media	As for otitis media
Meningitis	Penicillin G	50 mg/kg IV	4–6 hours	10–14 days for all antibiotics below
	Chloramphenicol	Load 50 mg/kg IV, then 25 mg/kg	6 hours	
	Cefotaxime	50 mg IV	6–8 hours	Maximum single dose 4 grams
	Ceftriaxone	100 mg IV	24 hours	Maximum single dose 4 grams/day
	Vancomycin	Load 15 mg/kg IV then 10 mg/kg IV	6 hours	Total daily dose not more than 2 grams Drug levels needed
	Meropenem	10–20 mg/kg slow IV injection over 5 minutes	8 hours	Maximum single dose 2 grams

**Pneumococcal vaccine**

- Give pneumococcal conjugated vaccine (e.g. Prevenar 13), two doses starting at 2 months of age, with 2 months between doses, with a reinforcing dose at 12–13 months, or if over 1 year old give a single dose.
- At-risk groups (see above) should have conjugate vaccine (any age) followed by polysaccharide vaccine (23 serotypes) over 2 years of age with a repeat dose every 5 years.

**Chemoprophylaxis**

- Daily oral penicillin V (125 mg twice daily for children

under 5 years, 250mg twice daily for older children) is recommended for children at risk (see above).

**Other groups of streptococci (C, D, E, F, G, H, K, L, M, N, O and V)**

- These cause diseases such as infective endocarditis, urinary tract infection and pneumonia. Susceptibility to penicillin is variable, and treatment with an aminoglycoside (e.g. gentamicin) and penicillin G or ampicillin is recommended.

**TABLE 6.1.K.2 Streptococci and related conditions**

Streptococci	Group Lancefield	Reaction (Haemolytic)	Disease caused
<i>S. pyogenes</i> (GAS)	A	J	Tonsillitis, pyoderma, impetigo, scarlet fever (subsequent rheumatic fever, acute glomerulonephritis) Necrotising fasciitis, toxic shock syndrome
<i>S. agalactiae</i> (GBS)	B	J	Neonatal sepsis/meningitis
<i>S. equisimilis</i> (GCS)	C	J	Endocarditis, pneumonia, cellulitis, septicaemia
<i>S. faecalis</i> (GDS)	D	J or none	Normal gut flora. May cause peritonitis, urinary tract infection, endocarditis and septicaemia
<i>S. viridians</i>	–	I	Mouth commensal. May cause endocarditis, dental caries
<i>S. pneumoniae</i>	–	–	Pneumonia, meningitis, otitis media, sinusitis

**6.1.L Tetanus**

**BOX 6.1.L.1 Minimum standards**

- Immunisation and prevention.
- ABC, especially airway protection.
- Anti-tetanus immunoglobulin and tetanus toxoid.
- Wound care.
- Diazepam, magnesium sulphate and phenobarbitone for acute spasms.
- Morphine.
- Early IV penicillin and/or metronidazole.
- Close observational care in a high-dependency area.

**Introduction**

Generalised tetanus (lockjaw) is a neurological disease manifesting as trismus and severe muscular spasms. It is caused by a neurotoxin produced by the anaerobic bacterium *Clostridium tetani* in a contaminated wound. The different forms of tetanus include the following:

- **Neonatal tetanus** is a form of generalised tetanus occurring in newborn infants lacking protective passive immunity because their mothers are not immune.
- **Localised tetanus** manifests as local muscle spasms in areas contiguous to a wound.
- **Cephalic tetanus** is a dysfunction of cranial nerves associated with infected wounds on the head and neck. Both of the latter conditions may precede generalised tetanus.

Tetanus continues to cause thousands of deaths per year worldwide (see Figure 6.1.L.1). The World Health

Organization estimates that 59 000 newborns worldwide died in 2008 as a result of neonatal tetanus.

**FIGURE 6.1.L.1 Total tetanus global annual reported cases and coverage, 1980–2010. Source: WHO/IVB Database, 2011.**

- For infection to occur, two conditions must be met:
- 1 a wound with a degree of necrosis
  - 2 a wound contaminated with material containing *Clostridium tetani* (a Gram-positive obligate anaerobe widely distributed in the environment).

The umbilical stump is a common site of entry for neonatal tetanus, which carries up to 60–80% mortality. Ear piercing in neonates is also a common cause (e.g. in Vietnam). In up to 30% of infected children no wound can be found. Cases

of tetanus in older children follow small puncture wounds, accidents and trauma in the partial or unvaccinated child.

### Pathogenesis

Once the *C. tetani* spore is inoculated into necrotic tissue with a low oxygen concentration it changes into a vegetative form, which elaborates the powerful toxin, tetanospasmin, which ascends peripheral nerves to the spinal cord where it binds to cerebral gangliosides and impairs inhibitory synapses. This causes muscle rigidity, spasm and autonomic overactivity.

### Clinical presentation

A previously well neonate presents at 3–20 days with irritability, decreased sucking, trismus, muscle spasms or convulsions. An older child presents following a minor injury or bite. Some infections follow chronic otitis media.

The clinical presentation depends upon the distance the injury is from the spinal cord. The incubation period ranges from 3 to 21 days. The shorter the incubation period and the time from onset of symptoms to the first spasm, the worse the outcome.

More than 90% of patients develop trismus ('locked jaw') due to the short pathway of the fifth cranial nerve. As the disease progresses, spasm of muscle groups supplied by other cranial nerves occurs, including the seventh cranial nerve, resulting in facial muscle rigidity and risus sardonicus. Spasm of the pharyngeal muscles may result in dysphagia, and spasm of the laryngeal muscles may result in asphyxia. The **generalised muscle spasms are extremely painful**, and may be prolonged, giving rise to opisthotonus. The sympathetic system can be affected, causing lability of temperature, blood pressure and cardiac function.

Early signs will be helpful in making the diagnosis. The mother may complain of an abnormal cry ('baby cannot cry well'), because she has noticed that trismus prevents the mouth from opening. This happens before suckling is affected. If one is uncertain, a slight touch stimulus may initiate spasm or rigidity. History of the birth (usually at home) and of how the cord was cut is informative, although not particularly discriminating. Contamination at birth (e.g. being born on to the floor with or without cord cutting with an unsterile instrument) is more likely to result in tetanus than for example contamination following a circumcision, but either could be responsible.

The diagnosis of tetanus is made clinically by excluding other causes of tetanic spasms, such as hypocalcaemic tetany, phenothiazine reaction, strychnine poisoning, and hysteria in the older child.

### Management of established tetanus

The approach to treatment given in this subsection is appropriate for both neonatal and childhood tetanus.

The aims of management are as follows:

- neutralising existing toxin and preventing its further production
- control of spasms
- prevention of complications
- providing adequate nutrition.

### On admission

- Secure and maintain the airway, and ensure adequacy of ventilation.
- Insert an intravenous line. IV infusions, even slow IV administration of drugs, may not be possible, because of lack of a suitable IV giving set (even as simple as a burette type) equipment or skilled time. However, an IV cannula should be left *in situ* for drug and antibiotic administration.
- **IM injections must be avoided at all costs, as they will provoke spasms.**
- If the baby or child is in **acute spasm**, this should be terminated by giving **diazepam by bolus IV infusion over 15 minutes (dose 300 micrograms/kg) or rectally (400 micrograms/kg)**. Ensure that for intravenous infusion, diazepam is diluted to 100 micrograms/mL and that extravasation does not occur (very irritant).
- Also give an IV loading dose of 25–40 mg/kg of magnesium sulphate over 20–30 minutes (maximum loading dose is 2 grams).
- **Always have a bag-mask available in case the patient stops breathing as a result of the diazepam and/or magnesium.**
- When the patient is stable, a nasogastric tube, ideally passed by an anaesthetist, will allow fluids, food and drugs to be given with minimal disturbance. Feeds need to be given frequently (ideally hourly) and in small amounts due to reduced gut motility. **In the neonate, regular breast milk feeds via a nasogastric tube are essential.**
- Any obvious wound should be debrided and cleansed, especially if extensive necrosis is present, and previously ill-advised sutures should be removed. In neonatal tetanus, wide excision of the umbilical stump is not indicated.
- Finally, the disease itself does not induce immunity, so after recovery tetanus vaccine must be given for future prevention.

### Antibiotics

- Oral (or intravenous) metronidazole (30 mg/kg per day, given in divided doses at 6-hourly intervals; maximum dose 400 mg) is effective in decreasing the number of vegetative forms of *C. tetani* and is the antimicrobial agent of choice.
- IV benzylpenicillin 100–200 mg/kg/day, given in divided doses at 4- to 6-hourly intervals; (75 mg/kg/day in the neonate in 3 divided doses) for the first 48 hours then oral penicillin V 25 mg/kg 6 hourly is an alternative treatment. Therapy for 10–14 days is recommended. Oral therapy can be given after the initial period.

Associated septicaemia is not uncommon in the neonate, and additional broader-spectrum antibiotics will often be required (see Section 3.4 for treatment of neonatal sepsis). Hospital-acquired infections are also common, especially pneumonia, and should be appropriately treated.

### Neutralisation of toxin

Antitetanus human immunoglobulin (HTIG) is the preparation of choice for neutralising unbound tetanospasmin. It is given by intravenous infusion over 30 minutes at a dose of **5000–10 000 units immediately on admission**. Adverse reactions are rare. **Local instillation is of no benefit.**

For neutralisation of the toxin, HTIG is not available in most countries where it is needed. An equine immunoglobulin may be available and is used (500–1000 units/kg IM; maximum dose 20 000 units). There is a risk of anaphylaxis (see Section 5.1.B for management), so adrenaline must be immediately available if equine immunoglobulin is given. Immune globulin intravenous (IGIV) contains antibodies to tetanus and can be considered for treatment in a dose of 200–400 mg/kg if HTIG is not available.

### Management of spasms and hypertonicity

- Spasms can usually be controlled by slow IV injection of diazepam, 200 micrograms/kg followed by IV 25–40 mg/kg of magnesium sulphate over 20–30 minutes (maximum loading dose 2 grams).
- Subsequently give IV diazepam (200 micrograms/kg every 4–6 hours) and magnesium sulphate (10–20 mg/kg 2- to 4-hourly IV).
- Stop diazepam if magnesium alone controls the spasms.
- Reduce the dose of diazepam if apnoeic episodes occur.
- **Always have a bag-mask available in case the patient stops breathing as a result of the diazepam and/or magnesium.**
- Give paracetamol 25 mg/kg 6-hourly for pain (20 mg/kg in the neonate). If this is insufficient, the WHO pain ladder approach should be adopted. Oral or IV morphine may be needed (see Section 1.15).

### Alternative antispasmodic or sedative drugs

- Phenobarbitone (15 mg/kg in one or two divided doses) as a loading dose then 5 mg/kg given once daily can be used for breakthrough spasms.

### Ventilation and prevention of complications

**Hospitals in regions with a high prevalence of neonatal tetanus may not have appropriate facilities for ventilation, or even for emergency intubation of neonates; bag-and-mask ventilation, when apnoeic attacks occur, may be the only alternative.**

Many patients have major problems with pharyngeal spasms/upper airway obstruction and are sometimes best managed with a tracheostomy and pharmacological control

of the spasms (sometimes the tracheostomy may need to be undertaken as an emergency procedure). Up to a third of those who need a tracheostomy do not require ventilation.

- Intubation can be very difficult because of pharyngeal/laryngeal spasm, and often a mini-tracheostomy without prior intubation may be appropriate, provided experts for the procedure and anaesthesia are present.
- Infusions of morphine are essential to minimise suffering due to severe pain. Under no circumstances should paralysing drugs be given to children who are intubated and ventilated without infusions of morphine.

Neonates rarely receive ventilation. Also, few places where tetanus occurs will have appropriate ventilators, or staff who are skilled in intubation and ventilation of children. An alternative way to support breathing is by bag-and-mask ventilation as often as necessary for the apnoeas that occur secondary to bouts of spasms and/or the drugs given to treat the spasms.

**Good nursing and frequent monitoring, with particular attention to gentle suction under direct vision of secretions from the airway, maintenance of adequate hydration, temperature, mouth hygiene, turning of the patient to avoid orthostatic pneumonia and bed sores, will reduce complications.**

- The child should be nursed in a quiet environment with low-level lighting. Sudden loud noises should be avoided.
- It will be helpful to involve the mother in management to call the staff if the baby goes into spasm or stops breathing. She can also be taught to feed the baby by tube (including checking position by suction of the tube before each feed) and taught minimal handling techniques. She could also count minor spasms, although she may not be able to chart them.
- Invasive procedures should be kept to a minimum and preceded by appropriate analgesia. There must be **continuous** observation by experienced personnel.
- In a high-dependency care unit, cardiac function should ideally be monitored by ECG to detect toxin-induced arrhythmias and autonomic instability.

**TABLE 6.1.L.1** Guide to tetanus prophylaxis in routine wound management in children

History of absorbed tetanus toxoid (doses)	Clean, minor wounds		All other wounds <sup>a</sup>	
	Td or Tdap <sup>b</sup>	HTIG <sup>c</sup>	Td or Tdap <sup>b</sup>	HTIG <sup>c</sup>
Less than 3 or unknown	Yes	No	Yes	Yes
3 or more <sup>d</sup>	No <sup>e</sup>	No	No <sup>f</sup>	No

Td = adult-type diphtheria and tetanus toxoid vaccine, Tdap = booster tetanus toxoid, reduced diphtheria toxoid and acellular pertussis, HTIG = human tetanus immune globulin.

<sup>a</sup> Such as, but not limited to, wounds contaminated with dirt, faeces, soil and saliva, as well as puncture wounds, avulsions, and wounds resulting from missiles, crushing, burns and frostbite.

<sup>b</sup> Tdap is preferred to Td vaccine for adolescents who never have received Tdap vaccine. Td is preferred to tetanus toxoid (TT) vaccine for adolescents who have received Tdap vaccine previously, or when Tdap vaccine is not available.

<sup>c</sup> Immune globulin intravenous should be used when HTIG is not available.

<sup>d</sup> If only three doses of fluid toxoid have been received, a fourth dose of toxoid, preferably an adsorbed toxoid, should be given. Although licensed, fluid tetanus toxoid rarely is used.

<sup>e</sup> Yes, if 10 years or more have elapsed since the last tetanus-containing vaccine dose.

<sup>f</sup> Yes, if 5 years or more have elapsed since the last tetanus-containing vaccine dose. More frequent boosters are not needed, and can accentuate adverse effects.

- High-dependency care of severe cases of tetanus may be necessary for up to 3–4 weeks.

It is important to realise that the child/baby has unimpaired consciousness and is aware of what is taking place. Prescribe regular and frequent analgesia, as antispasmodics alone do not prevent the suffering resulting from painful spasms or painful procedures. The spasms are also very frightening and distressing for the parents.

Rigidity will take longer to resolve than the spasms.

### Monitoring

**Only absolutely essential blood tests should be performed, to avoid precipitating spasms.**

- Glucose, urea and electrolytes.
- A chart of the occurrence of spasms can be helpful.
- Cardiac monitoring.
- Pulse oximetry.
- Fluid input/output.
- Caloric intake.

### Prognosis

The prognosis for neonatal tetanus is poor, especially with a short incubation period (< 7 days) or with rapid evolution of symptoms. Pyrexia, tachycardia and frequent spasms (> 20 spasms in 24 hours) also indicates a poor prognosis. Quality of nursing care and the **availability of high-dependency care facilities greatly affect the outcome, and where these facilities are available mortality may be as low as 20%.**

**In children who survive neonatal tetanus, motor difficulties may be permanently present. Older children may have muscle weakness and atrophy, and difficulties with speech, balance and memory.**

### Prevention

**Every child should receive tetanus vaccine according to the expanded programme of immunisation (EPI). All pregnant women should receive two doses antenatally, as this will protect the baby for the first 4–6 months of age.**

Tetanus toxoid should be given, combined with diphtheria and pertussis, to infants according to national schedules. Note that both HIV infection and placental malaria reduce the transplacental transfer of anti-tetanus antibodies *in utero*. Sterile handling of the umbilical cords by midwives or appropriately trained traditional birth attendants should also reduce the incidence of neonatal tetanus. Sterilisation of hospital supplies will prevent the rare instances of tetanus that may occur in a hospital from contaminated sutures, instruments or plaster casts.

A booster tetanus toxoid vaccine with or without tetanus immune globulin (TIG) in the management of wounds depends on the nature of the wound and the history of immunisation with tetanus toxoid (see Table 6.1.L.1).

## 6.1.M Trachoma

### BOX 6.1.M.1 Minimum standards

- Bilamellar tarsal rotation.
- Oral azithromycin.
- Ocular tetracycline.
- The WHO SAFE strategy: Surgery for trichiasis, Antibiotics to clear infection, and Facial cleanliness and Environmental improvement.

### Introduction

Trachoma is the most common infectious cause of blindness worldwide. It is caused by *Chlamydia trachomatis*, certain serotypes of which preferentially infect the conjunctival epithelium. The organism is transmitted from person to person by direct contact, fomites (objects capable of carrying infectious organisms), and eye-seeking flies. Disease clusters in families; the greatest risk factor for infection is sharing a bedroom with an active case. Repeated episodes of infection over many years cause an accumulation of scar tissue in the tarsal plate and tarsal conjunctivae of the upper lids. Contraction of the scar may produce trichiasis and/or entropion, and the resulting corneal abrasion by in-turned lashes leads to corneal scarring. This eventually causes blindness. In paediatric practice in endemic areas, active trachoma is seen frequently. Blinding complications may start to appear in the second and third decades of life.

### Clinical features

These are best presented using the framework of the WHO simplified clinical grading system. Examination for trachoma involves inspection of the lashes and cornea, followed by eversion of the upper eyelids to examine the tarsal conjunctivae (see Figure 6.1.M.1). A ×2.5 magnifying loupe and torch (or daylight) should be used. These tools are sufficient to determine the presence or absence of signs that are considered in this grading scheme. Each eye is graded separately.

**Trachomatous inflammation – follicular (TF):** the presence of five or more follicles at least 0.5 mm in diameter in the central part of the upper tarsal conjunctiva. Follicles appear as white or yellow-grey semitransparent patches or swellings beneath the conjunctiva. Fewer than five follicles, or follicles at the nasal or temporal margin, may be normal.

**Trachomatous inflammation – intense (TI):** pronounced inflammatory thickening of the upper tarsal conjunctiva obscuring more than half of the normal deep tarsal blood vessels.

TF and TI are both forms of ‘active trachoma’; they are associated with infection with *Chlamydia trachomatis*, **although not all infected individuals exhibit these signs, and not all individuals with these signs are infected.** Patients with active trachoma may be asymptomatic or complain of irritable red eyes or a whitish discharge.

**Trachomatous scarring (TS):** the presence of easily visible scars in the tarsal conjunctiva. Scars appear as white bands, lines, or sheets. TS is the result of repeated cycles of inflammation and resolution over many years and itself is virtually asymptomatic, although scarring of eyelid glands may produce symptoms of dry eye.

**Trachomatous trichiasis (TT):** at least one eyelash rubs on the eyeball, or there is evidence of recent removal of in-turned eyelashes. TT is intensely irritating to the sufferer, and they may choose to pull out their eyelashes in an attempt to reduce the discomfort. There may be discharge from superadded bacterial infection of the abraded cornea. Except in hyperendemic areas, it is unusual to observe TT in children.

**Corneal opacity (CO):** easily visible corneal opacity over the pupil, so dense that at least part of the pupil margin is blurred when viewed through the opacity. Such corneal opacities cause significant visual impairment.

It is important to remember that these grades are not mutually exclusive. A patient with active trachoma (TF and/or TI) may also show signs of the late complications of the disease.

There are other signs of trachoma that are not included in the simplified grading scheme:

- Papillae are often visible in individuals with active trachoma, but are not specific for trachoma. These are small elevations of the conjunctival surface that give the conjunctiva a velvety appearance. They are more easily seen using a slit lamp.
- Fibrovascular connective tissue may grow inwards from the limbus to invade the anterior layers of the superior cornea in response to infection. The ingrowth is known as pannus. The new blood vessels may persist after resolution of infection.
- Sometimes follicles are found under the bulbar conjunctiva at the limbus as well as deep to the tarsal conjunctiva. Scarring of limbal follicles may subsequently leave small depressions known as Herbert's pits.

## Treatment

For active trachoma (TF and/or TI), antibiotics are required. Topical tetracycline eye ointment 1% is effective when applied to both eyes twice daily for 6 weeks. A single dose of oral azithromycin (20 mg/kg, up to a maximum dose of 1 gram) is just as effective, is better tolerated than topical tetracycline, and can be directly observed, so is associated with higher compliance rates.

Trichiasis or entropion requires surgical management to restore the margin of the eyelid to its normal position, so that contact between the lashes and globe is interrupted. Bilamellar tarsal rotation is the procedure currently recommended by the World Health Organization; it is performed under local anaesthetic and can be undertaken at the village level by trained ophthalmic nurses or ophthalmic assistants.

Corneal opacity can theoretically be managed by corneal graft. Unfortunately, few endemic countries have the resources to establish a transplant programme, and because of new vessel growth from the limbus and abnormalities of the tear film in the trachomatous eye, the risk of graft rejection or failure is very high.

The identification of signs of trachoma in an individual should prompt screening of other members of that individual's community. Antibiotic treatment of individuals presenting

a *Normal tarsal conjunctiva (x 2 magnification). The dotted line shows the area to be examined.*

b *Trachomatous inflammation – follicular (TF).*

c *Trachomatous inflammation – follicular and intense (TF + TI).*

**FIGURE 6.1.M.1** (a) Normal tarsal conjunctiva (x2 magnification). The dotted line shows the area to be examined. (b) Trachomatous inflammation – follicular (TF). (c) Trachomatous inflammation – follicular and intense (TF + TI).

to healthcare facilities is unlikely to have any impact on the incidence of blindness from trachoma in the communities from which those individuals come. Comprehensive community-based management of trachoma is necessary wherever the prevalence of disease is high.

## Prevention

**Blindness from trachoma is preventable.** The acronym SAFE has been adopted by the WHO and partners to encapsulate the recommended approach to controlling trachoma. It comprises Surgery for trichiasis, Antibiotics to clear infection, and Facial cleanliness and Environmental

improvement (provision of water and acceptable means for disposal of human faeces) to reduce transmission. Surgery should be offered to all individuals with trichiasis. The 'A', 'F' and 'E' components should be implemented district-wide

wherever the prevalence of TF in 1- to 9-year-olds is 10% or higher. The WHO plans to use the 'SAFE' strategy to achieve the elimination of trachoma as a public health problem by the year 2020.

## 6.1.N Tuberculosis

### BOX 6.1.N.1 Minimum standards

- All children with suspected TB should be tested for human immunodeficiency virus (HIV).
- All children with HIV should have a chest X-ray to look for TB.
- Children who cannot expectorate spontaneously should have induced sputum or gastric aspirate.
- Specimens should be sent for both microscopy for acid-fast bacilli and TB culture or Xpert MTB/RIF test.
- Drug-resistant TB needs expert supervision.
- Tracing, screening and prophylaxis of contacts.

### Introduction

The global incidence of tuberculosis (TB) has been falling since 2002. However, in 2009 there were still almost 10 million children who were orphans as a result of parental deaths caused by TB. About 13% of TB cases occur among people living with HIV. India and China accounted for 40% of notified cases and Africa accounted for another 24%. Treatment for smear-positive pulmonary TB was 87% in 2009.

Major factors in the global increase in tuberculosis since the mid-1980s include the HIV pandemic, migration of people from countries with a high prevalence of tuberculosis to industrialised countries (particularly refugees), poverty, overcrowding and failure of investment in tuberculosis control programmes. Multi-drug resistance is a major concern.

### Epidemiology

- In low-income countries, the risk of developing infection is up to 2.5% per annum.
- The age group at highest risk of developing disease is 0–5 years, with risk up to 30–40% (especially under 1 year) and at puberty.
- Spread is by untreated smear-positive adults who may infect up to 10–15 people per year.
- Children are generally non-infectious, except for older children and adolescents with cavitary TB.
- Children with untreated tuberculosis contribute to the pool of adults with reactivated disease.
- The WHO estimates that TB in children contributes to 1.3 million annual cases (or 15%) in low-income countries and 450 000 deaths worldwide.

### Factors that predispose tuberculosis-infected children to develop systemic disease

- Age under 5 years, and especially under 1 year.
- Household contact with smear-positive disease.
- Malnutrition.
- Tuberculosis infection in previous 2 years.
- Immunosuppression, especially HIV infection.

### Tuberculin skin test

- The tuberculin skin test (TST), also called the Mantoux test, is useful for screening contacts. The TST is less useful for diagnosing active TB because a negative result does not exclude TB. If TB is clinically suspected, efforts should be made to collect diagnostic specimens, exclude other causes, and then treat if TB is the most likely diagnosis (do not treat as a diagnostic test).
- Use either 5 TU of tuberculin (PPD-S) or the 2 TU of tuberculin (PPD RT23).
- Inject tuberculin (PPD-S) **intradermally** into the upper third of the flexor surface of the forearm with a 1-mL syringe and a short bevel gauge 25–27 needle producing a wheal of at least 5 mm. Read the transverse diameter of induration at 48–72 hours. Regard induration of 0–5 mm as negative, 6–9 mm as indeterminate, and likely to be associated with environmental mycobacteria, and 10 mm or more as indicative of infection with *Mycobacterium tuberculosis*, except in the child who has had BCG in the previous few years, when induration of 15 mm is required.
- In resource-limited countries where BCG is given at birth, most children will have a negative tuberculin test by 10 years of age, and thus an induration of 10 mm in children this age or older may be regarded as supportive of *M. tuberculosis* infection.
- Negative or reduced response to tuberculin occurs in malnutrition, immunosuppression associated with HIV or other immunodeficiency states, recent viral or some bacterial diseases such as pertussis, overwhelming tuberculosis and non-respiratory tuberculosis. Thus with these conditions an induration of 6–9 mm may be indicative of tuberculosis.
- Remember that a negative tuberculin does not exclude tuberculosis, and additional work-up may be warranted in any suspected child.
- Tuberculin skin test interpretation must be undertaken bearing in mind the age, epidemiology and underlying illness, if any.

### Serology

Antibody tests are inconsistent and imprecise. They do not improve outcomes for patients and should not be used. The WHO recently gave guidelines recommending against the use of serology tests for TB. It is the first negative recommendation to be made by the WHO, describing it as 'inaccurate and useless', after 'overwhelming' evidence that suggested it produced an 'unacceptable level' of false-positive or false-negative results.

## Pathogenesis

- Inhalation of the tubercle bacillus into an alveolus establishes the primary (Ghon) focus. In the 4- to 8-week period before the cell-mediated immune (CMI) response develops, there is spread to regional lymph nodes, and small numbers of bacilli disseminate throughout the body in the lympho-haematogenous system.
- Certain organs favour survival of tubercle bacilli, including regional nodes, epiphyseal lines of bones, cerebral cortex, renal parenchyma and apical regions of the lungs (Simon focus).
- Establishment of an adequate CMI response (which coincides with the appearance of sensitisation to tuberculin) in most cases results in control or eradication of proliferating tubercle bacilli at these sites.
- The primary focus is seldom detected on chest X-ray; enlarged hilar/paratracheal nodes or parenchymal complications are the usual evidence of the primary complex.
- **Primary tuberculosis of the lung** is usually a manifestation of lympho-bronchial disease, with local compression or erosion of the bronchi. **Extrathoracic disease** is due to local spread of disease at metastatic sites (e.g. lymph nodes, brain, bone, kidney and abdomen).
- Dissemination of large numbers of tubercle bacilli may result in acute miliary disease or, less commonly, a chronic disseminated (cryptic) tuberculosis.
- Erythema nodosum and phlyctenular conjunctivitis are hypersensitivity reactions which may occur during primary tuberculosis.
- The risk of developing symptomatic disease following primary tuberculosis is highest (around 50%) in the first 1 to 2 years after infection and the rest in the individual's lifetime.

### Tuberculosis in adolescence

This may result from reactivation of a primary infection, exogenous infection, or both. There is a strong hypersensitivity reaction in the lungs with local infiltration and often cavity formation. Pulmonary lymph node enlargement and extra-thoracic dissemination is uncommon.

### Clinical features

In well-resourced countries, the majority of children with respiratory tuberculosis are asymptomatic and are picked up through contact tracing and will generally have early primary disease. In resource-limited countries, only children with symptomatic disease present, and they are therefore only 'the tip of the iceberg'.

The following are some of the key features of tuberculosis in children:

- Fever, cough, anorexia, weight loss, wheezing, night sweats and malaise are common.
- Extrapulmonary disease may involve other tissues and organs, such as the central nervous system, lymph nodes and gastrointestinal tract.
- Findings can include lung findings (dull resonance) or involvement of other organs in extrapulmonary tuberculosis, such as hepatosplenomegaly, lymphadenopathy, mass, etc. (see Table 6.1.N.1).

### HIV and tuberculosis

Children living with HIV who have poor weight gain, fever or current cough, or contact history with a TB case, may have

**TABLE 6.1.N.1** Typical features of common forms of extrapulmonary TB in children

Type of extrapulmonary TB	Key clinical findings
TB lymphadenitis (most common)	Enlargement and swelling of lymph nodes
Pleural/pericardial TB	Cough and shortness of breath
TB meningitis	Headache, vomiting, fever, neck stiffness, seizures, confusion and coma
Miliary TB	Very sick, respiratory distress, hepatosplenomegaly, diffuse lymphadenopathy
Gastrointestinal TB	Abdominal pain, diarrhoea, mass or ascites
Spinal TB	Backache with or without loss of function in lower limbs
TB arthritis	Pain and swelling of joints (usually monoarthritis)

TB and should be evaluated for TB and other conditions. If the evaluation shows no TB, children should be offered isoniazid preventive therapy (IPT) regardless of their age.

Children living with HIV who do not have poor weight gain, fever or current cough are unlikely to have active TB. Children living with HIV who are more than 12 months of age and who are unlikely to have active TB on symptom-based screening and have no contact with a TB case should receive 6 months of IPT (10 mg/kg/day, maximum 300 mg/day) as part of a comprehensive package of HIV prevention and care services.

With regard to children living with HIV who are less than 12 months of age, only those who have contact with a TB case and who are evaluated for TB (using investigations) should receive 6 months of IPT if the evaluation shows no TB disease. All children living with HIV after successful completion of treatment for TB disease should receive isoniazid for an additional 6 months.

- Features of tuberculosis in children with perinatally acquired HIV infection are not well defined.
- Many HIV-infected infants probably succumb to bacterial infections and *Pneumocystis jirovecii* pneumonia before contracting tuberculous infection.
- In older children, there is difficulty in diagnosis due to the following reasons:
  - The tuberculin reaction is positive in only 20% of cases.
  - There is confusion with HIV-related respiratory disorders, including lymphocytic interstitial pneumonitis (LIP), superimposed viral/bacterial infections, chronic interstitial pneumonitis, Kaposi's sarcoma and bronchiectasis.
  - There is often a lack of facilities for culturing *M. tuberculosis*.
- Atypical clinical and radiological features of TB are much more common in children with HIV with more severe and complicated disease.
- HIV/tuberculosis co-infected children are more likely to develop disseminated tuberculosis and meningitis, have cavitory pulmonary disease and may have a poor response to treatment and a higher mortality if not started on ART.

- Because of the difficulty in confirming tuberculosis in symptomatic HIV-infected children, many children probably receive unnecessary tuberculous chemotherapy.
- Finger clubbing may be seen in chronic tuberculosis, and is common in HIV-related pulmonary disorders.
- Standard 6-month chemotherapy is given in uncomplicated pulmonary tuberculosis.

### Respiratory tuberculosis

- Most respiratory tuberculosis results from complications of lympho-bronchial disease and includes segmental lesions, consolidation, collapse and obstructive emphysema.
- In young children, small cavities may develop during the course of primary (especially progressive) tuberculosis, but they are classically seen in the adolescent period.
- Large pleural effusions usually occur in older children and adolescents.
- Radiological features of pulmonary tuberculosis may be atypical in HIV infection, other immunosuppressed states and/or malnutrition.

### Pericarditis

Tuberculosis should be considered in all cases of pericarditis. *M. tuberculosis* may be cultured from a pericardial tap in over 50% of the cases.

### Lymph node disease

- This may result from a focus in the upper lung fields or from haematogenous spread.
- Diagnosis may be made by biopsy or fine-needle aspiration.
- Swelling and softening of nodes may continue for months after treatment has been completed.
- In well-resourced countries, environmental mycobacteria are now a far commoner cause of chronic granulomatous disease of cervical lymph nodes than tuberculosis in indigenous young children.

### Miliary tuberculosis

- This is commonest in young children and in those who are immunosuppressed, usually occurring within 3–12 months of primary infection.
- Chest X-ray (except in the early stages) will demonstrate a 'snowstorm' or miliary appearance.
- Meningitis is a common complication. Therefore a lumbar puncture should be performed in all cases.
- The WHO advises 9–12 months of anti-TB chemotherapy.

### Meningitis

- This is commonest in children under 5 years, and often occurs within 6 months of infection.
- The onset is usually insidious and the diagnosis is often delayed. Late diagnosis is invariably complicated by neurological dysfunction or death.
- Prolonged fever, irritability, headache, vomiting, mental status changes, visual symptoms, focal neurological deficits or cranial nerve palsies, and seizure are some of the common presentations in children with tuberculous meningitis.
- CSF: cell count is usually less than 500/mm<sup>3</sup> and mainly lymphocytic, but polymorpho-neutrophils may be prominent early on, which may cause confusion with partially treated bacterial meningitis. Protein levels are usually

raised (0.8–4 grams/litre) and glucose levels are low. However, on admission CSF values may be within normal limits and lumbar puncture must be repeated if there is any doubt.

- **Brain imaging, such as CT or MRI (if available)**, should be undertaken at diagnosis and at 3–4 months, and at any time when there is neurological deterioration, to detect complications such as hydrocephalus and tuberculomata.

### Management

- A four-drug regimen in the upper range of drug doses is recommended for 2 months, followed by a two-drug regimen for 10 months in uncomplicated tuberculosis meningitis. It consists of the following four drugs given for first 2 months:
  - H: isoniazid 20mg/kg once daily orally, or by IM or slow IV injection; (maximum 300mg daily) **plus**
  - R: rifampicin 15–20mg/kg once daily orally or by IV infusion over 2–3 hours; (maximum 600mg daily) **plus**
  - Z; pyrazinamide 40mg/kg once daily orally; (maximum 2 grams daily) **plus**
  - E: ethambutol 20mg/kg once daily orally (maximum 1.5 grams daily).

Thereafter, isoniazid **plus** rifampicin alone are continued for 10 months. The WHO also now advises 12 months of therapy, although shorter regimens have been shown to be adequate in some studies.

Corticosteroids must be given in all cases with initiation of therapy. Dexamethasone 0.6mg/kg/day in two divided doses or prednisolone 2–4mg/kg/day is given for 4 weeks and tapered over 2 weeks for a total duration of 6 weeks.

**A ventriculo-peritoneal shunt may be required for obstructive hydrocephalus (if available).**

### Bone and joints

- These are frequently missed in the early stages because of a low index of suspicion.
- The spine is affected in 50% of the cases, followed by knee, hip and ankle. The most serious complication is spinal compression.
- The diagnosis is made by histology, Ziehl–Neelsen (ZN) stain and mycobacterial culture of tissue that may be positive, and **if in doubt specimens should be sent for polymerase chain reaction (PCR).**
- **The WHO advises the standard 12 months of anti-TB chemotherapy, similar to that for TB meningitis.**

### Abdominal tuberculosis

- This may present with ascites, abdominal nodes or masses, or diarrhoea with or without abdominal pain, or as gastrointestinal obstruction.
- The diagnosis is usually made on bacteriological examination of ascitic fluid or a biopsy.
- The standard three- to four-drug regimen is used for therapy for a total of 6–9 months in uncomplicated cases.
- Ultrasound and **CT or MRI (if available) may be required in evaluation and to detect any complications.**

### Perinatal tuberculosis

- Congenital tuberculosis is rare but should always be

considered in sick neonates or infants, especially in areas where HIV/tuberculosis co-infection is common.

- If a mother has completed tuberculosis chemotherapy during pregnancy or has inactive disease, her infant should be given BCG at birth.
- If she has active disease or is still requiring treatment, the infant should be given isoniazid 10 mg/kg once daily for 3–6 months.
- Once the mother and infant are both on appropriate treatment, the infant may breastfeed unless the mother has multi-drug-resistant TB. A tuberculin test and chest X-ray is then performed on the infant. If they are negative, BCG is given; if it is positive, full investigations for tuberculosis are undertaken. If no evidence of disease is detected, isoniazid is continued for another 3–4 months. If tuberculosis is suspected, full treatment with 4 drugs is given at standard doses (see Table 6.1.N.2 and Table 6.1.N.3 on management).

### **Danger signs for TB**

- Suspicion of tuberculous meningitis.
- Extensive pulmonary or miliary TB.
- TB in an infant or a child with HIV.
- Symptoms and signs such as seizures, coma, severe respiratory distress, gastrointestinal obstruction or severe malnutrition.

### **Diagnosis of TB**

Diagnosis depends on eliciting key points that may increase the yield of TB cases. A high index of suspicion in a child who has prolonged or unexplained illness should warrant investigation for TB. Sputum or gastric aspirate for acid-fast bacilli (AFB) stain and culture should always be attempted.

Standard methods for diagnosis are the tuberculin test and a chest X-ray. Even in resource-limited countries, every effort should be made to obtain a diagnostic specimen from gastric aspiration or sputum induction (see below). In poor communities the tuberculin test is often negative (or unavailable) and the chest X-ray might not be available, easy to interpret or have films of good enough quality. Many children are often over-diagnosed, especially in areas with high HIV prevalence.

TB infection is diagnosed using the tuberculin skin test. It is considered positive if there is Mantoux induration of  $\geq 10$  mm in children who have not received BCG vaccination or  $\geq 15$  mm in children who have received BCG recently. Interferon-gamma release assays (IGRA) detect latent and active infection but cannot differentiate between the two. They may be positive in some cases of HIV infection and malnutrition when the tuberculin test is negative, but in these circumstances there is also a higher rate of false-negative IGRA results. However, they are currently too expensive for resource-limited countries, and their routine use is not advised by the WHO.

### **Key features suggestive of pulmonary TB**

**Three or more** of the following should strongly suggest a diagnosis of TB:

- chronic symptoms suggestive of TB (prolonged fever, cough, night sweats weight loss)
- physical signs suggestive of TB (chronic lymphadenopathy, abdominal mass, gibbus or monoarthritis)

- a positive tuberculin skin test (induration  $> 10$  mm)
- chest X-ray suggestive of TB (hilar adenopathy, cavitation, pleural effusion, infiltrate; see below for pictures).

### **Investigations**

- Tuberculin test  $> 10$  mm or  $> 5$  mm in malnutrition or HIV.
- Chest X-ray: lymphadenopathy, collapse/consolidation with or without persistent opacity, cavitation, miliary appearance.
- Histology: lymph node or other tissue biopsy.
- Smear/culture: gastric aspirate, induced sputum, nasopharyngeal aspirate, laryngeal swab, bronchoscopy or body fluids.
- Ultrasound: chest, abdomen, lymph nodes, pericardium and brain.
- **CT or MRI (if available).**
- HIV antibody tests (if relevant).

Except in adolescents with cavitory disease, most tuberculosis in children is paucibacillary (low number of mycobacteria). Young children cannot expectorate.

Tuberculosis may be evident on chest X-ray, especially in older children.

- Gastric aspiration should be undertaken in the early morning while the child is lying down. Ziehl–Neelsen (ZN) staining of gastric aspirate is positive in only about 10% of children with advanced pulmonary tuberculosis, and culture is positive, under optimal conditions, in only 30–50% of cases.
- Alternative methods are sputum induction using nebulised 3% hypertonic saline, nasopharyngeal aspiration and laryngeal swabs. None of these has a sensitivity of more than 25–30%. Sputum induction requires a nebuliser and appropriate equipment, and must be undertaken in a room with adequate ventilation.
- **The polymerase chain reaction (PCR) on histological specimens may be useful if the ZN stain is negative.** In CSF it has similar sensitivity (around 50%) to culture. It is reserved for special cases where an urgent diagnosis is required.
- Young children, especially those who are sick, malnourished or deteriorating, or where tuberculous meningitis is suspected, should be considered for treatment even though investigations are inconclusive. In other cases with pulmonary disease where the diagnosis is not clear, a course of appropriate antibiotics should be given for 7–10 days and the chest X-ray repeated after 2 weeks or so. If there is no improvement or deterioration, a full course of anti-tuberculosis chemotherapy may be given and progress carefully monitored to document the response. If the tuberculin test is negative initially it should be repeated after 3 months, when the patient's immune system has normalised, and it may become reactive at that time.
- Increase in weight (measured daily or weekly) and loss of fever (measured twice daily) indicate a response to treatment. If treatment is given for suspected rather than proven tuberculosis, and no resolution or improvement in symptoms occurs within 4 weeks, this suggests that tuberculosis is unlikely. However, the course should still be completed and an alternative diagnosis sought, such as drug-resistant tuberculosis, fungal infection or malignancy.

### Xpert MTB/RIF test

The Xpert MTB/RIF is a test for rapid diagnosis of TB and drug-resistant TB. It is a TB-specific automated, cartridge-based nucleic acid amplification assay, and it detects *Mycobacterium tuberculosis*, as well as mutations conferring resistance to rifampicin, directly from sputum in an assay that provides results within 100 minutes.

Results from field demonstration studies found that a single Xpert MTB/RIF test can detect TB in 99% of patients with smear-positive pulmonary TB and more than 80% of patients with smear-negative pulmonary TB. The co-existence of HIV does not significantly affect the performance of Xpert MTB/RIF.

Furthermore, Xpert MTB/RIF can detect rifampicin resistance with 95.1% sensitivity and exclude resistance with 98.4% specificity. The WHO endorsed the Xpert MTB/RIF assay in December 2010. It should be used as the initial test in individuals with suspected multi-drug-resistant TB (MDR-TB) or HIV/TB. It may be used as a follow-on test to microscopy where MDR-TB and/or HIV is of lesser concern, especially in smear-negative specimens. It is effective in children where sputum may need to be obtained by induction via nasopharyngeal aspirate after salbutamol and then saline nebuliser.

### Management of TB in children

With the exception of CNS and osteo-articular disease (see below), both pulmonary and extra-pulmonary tuberculosis may be treated with standard 6-month chemotherapy. The standard treatment regimen for all patients with drug-susceptible, uncomplicated TB is made up of an intensive phase lasting 2 months and a continuation phase lasting 4 months. During the intensive phase 4 drugs (isoniazid, rifampicin, pyrazinamide, and ethambutol) are used to rapidly kill the tubercle bacilli. Infectious patients become less infectious within approximately 10–14 days of starting treatment and symptoms abate. In the continuation phase, 2 drugs (isoniazid, rifampicin) are used, over a period of 4 months.

For non-HIV-infected children with a low risk of isoniazid resistance, ethambutol can be omitted. Ethambutol should not be given in a dose higher than 20 mg/kg/day to children under 5 years, as they may be unable to report visual disturbance associated with optic neuritis.

**TABLE 6.1.N.2** Regimens for treatment of uncomplicated susceptible pulmonary tuberculosis

Regimen	Total duration
<i>Standard daily</i>	
Isoniazid, rifampicin, pyrazinamide ethambutol* for 2 months, then isoniazid, rifampicin for 4 months <sup>†</sup>	6 months
<i>Intermittent three times weekly</i>	
Isoniazid, rifampicin, pyrazinamide, ethambutol for 2 months, then isoniazid, rifampicin three times weekly for 4 months	6 months

\* In HIV-uninfected children with a low risk of isoniazid resistance, ethambutol can be omitted.

<sup>†</sup> For central nervous system and osteo-articular disease, the continuation phase should be 10 months (total duration 12 months).

### Thiacetazone is no longer used as a first-line drug. Thiacetazone may cause severe reactions in HIV-infected patients.

Presently DOTS (directly observed treatment, short course) is not generally practised for children, as it is assumed that parents will supervise treatment, but where DOTS is practised in the community it may be appropriate to include children.

During the continuation phase of treatment, thrice-weekly regimens can be considered for children known to be HIV-uninfected and living in an area of low HIV prevalence and settings with well-established directly-observed therapy (DOT). However, our advice is that in low resource settings, all children with TB should be treated with daily regimens (for dosage see Table 6.1.N.4).

For central nervous system and osteo-articular disease, the continuation phase should be 10 months (total duration 12 months).

Adverse reactions to tuberculosis chemotherapy are uncommon and if they occur it is usually within 6–8 weeks of starting treatment. Liver transaminases may increase two- to threefold during treatment with isoniazid and rifampicin, but drug therapy may be continued if there is no jaundice or symptoms of liver toxicity (e.g. nausea, vomiting, malaise or liver tenderness). Viral hepatitis (especially hepatitis A) should be considered if jaundice occurs. Adjunct treatment with corticosteroids in meningitis is indicated at initiation of therapy (see above) and may enhance resolution of disease in lympho-bronchial disease, pericarditis, pleural effusion and severe miliary disease with alveolar capillary block. Prednisolone 1.5–2.0 mg/kg/day is given for 2–3 weeks and then tailed off over 2 weeks (see treatment of meningitis).

### Follow-up

All children who are started on anti-tuberculous therapy must be followed closely, preferably every month. Clinical, radiologic and mycobacteriologic improvement and adverse effects of drugs must be monitored. In children, weight gain and resolution of signs and symptoms are indicators of a good response to treatment. Routine laboratory tests such as liver function tests and X-rays are rarely needed in children. Those children with severe disease, poor response,

**TABLE 6.1.N.3** Summary of treatment of pulmonary or peripheral lymph node TB

Area of low HIV prevalence with low levels of isoniazid resistance and child HIV-negative	<p><i>2-month intensive phase</i></p> <p>Isoniazid Rifampicin Pyrazinamide</p> <p><i>4-month continuation phase</i></p> <p>Isoniazid Rifampicin</p>
Area of high HIV prevalence or high levels of isoniazid resistance or extensive pulmonary disease	<p><i>2-month intensive phase</i></p> <p>Isoniazid Rifampicin Pyrazinamide Ethambutol</p> <p><i>4-month continuation phase</i></p> <p>Isoniazid Rifampicin</p>

**TABLE 6.1.N.4** Daily dosage schedule for anti-tuberculous drugs and side effects

Drug	Children: once daily dose	Adolescents under 50 kg: once daily dose	Adolescents over 50 kg: once daily dose	Side effects
Isoniazid daily	10 mg/kg range 7–15 mg/kg Maximum 300 mg 15–20 mg/kg for meningitis	5 mg/kg Maximum 300 mg	5 mg/kg Maximum 300 mg	Hepatic enzyme elevation, hepatitis, peripheral neuropathy, hypersensitivity
Rifampicin	15 mg/kg range 10–20 mg/kg Maximum 600 mg 15–20 mg/kg in meningitis	10 mg/kg Maximum 600 mg	10 mg/kg Maximum 600 mg	Orange discoloration of urine and secretions (and contact lenses), nausea, vomiting, hepatitis, febrile reactions, thrombocytopenia
Pyrazinamide	35 mg/kg range 30–40 mg/kg 40 mg/kg in meningitis	25 mg/kg Maximum 1.5 gram	25 mg/kg Maximum 2.0 gram	Hepatotoxicity, hyperuricaemia, gastrointestinal upset, arthralgia, skin rash
Ethambutol	20 mg/kg range 15–25 mg/kg 20 mg/kg in meningitis	15 mg/kg Maximum 2.5 grams	15 mg/kg Maximum 2.5 grams	Optic neuritis, skin rash

Higher range of isoniazid applies to young children. Use mean dosage and round up rather than round down when prescribing except when prescribing ethambutol.

**TABLE 6.1.N.5** Three times weekly dosage schedule for anti-tuberculous drugs (from the WHO)

Drug	Children: three times weekly dose given once daily	Adolescents under 50 kg: three times weekly dose given once daily	Adolescents over 50 kg: three times weekly dose given once daily
Isoniazid	20–40 mg/kg Maximum 900 mg	10 mg/kg Maximum 900 mg	10 mg/kg Maximum 900 mg
Rifampicin	10–20 mg/kg Maximum 600 mg	10–20 mg/kg Maximum 600 mg	10 mg/kg Maximum 600 mg
Pyrazinamide	50–70 mg/kg Maximum 3 gram	35 mg/kg Maximum 3 gram	35 mg/kg Maximum 2.5 gram
Ethambutol	25–30 mg/kg	25–30 mg/kg	25–35 mg/kg

unusual presentations or suspected resistant TB must be referred to an expert.

### Multi-drug-resistant TB (MDR-TB) and extreme-drug-resistant TB (XDR-TB)

Rapid drug susceptibility testing of isoniazid and rifampicin should be done at the time of diagnosis (if available). After treatment is started for MDR-TB, further sputum (induced or gastric aspirate) should be obtained monthly to ensure successful treatment. An expert in the management of paediatric TB must be involved in choosing the optimal regimen for a child with drug-resistant TB.

Fluoroquinolones may be used in treatment of MDR-TB in children. Theoretical concerns about cartilage damage from early trials in young dogs have not been evident in children, and these are far outweighed by the benefits in treatment of TB. Later-generation fluoroquinolones (see below) are more effective than earlier ones. Four second-line anti-tuberculous drugs should be used and the intensive phase should include ethionamide or prothionamide, pyrazinamide, a parenteral agent, and cycloserine (or para-aminosalicylic acid (PAS) if cycloserine cannot be used).

The intensive phase should be at least 8 months and the total duration at least 20 months if there was no previous MDR-TB treatment. The continuation phase is usually given as the same oral drugs while stopping the injectable drugs. In children with HIV and MDR-TB, antiretrovirals should be started as soon as possible following initiation

of anti-tuberculous therapy, irrespective of CD4 count. The preferred regimen is zidovudine, lamivudine and efavirenz, but if already on antiretrovirals, continue the same regimen. Co-trimoxazole should be added for pneumocystis prophylaxis.

Treatment should be ambulatory rather than in hospital as much as possible.

### Groups of second-line anti-tuberculosis agents

#### Second-line parenteral agent (injectable anti-tuberculosis drugs)

- Kanamycin (Km), 15–30 mg/kg/day (maximum 1000 mg).
- Capreomycin (Cm), 15–30 mg/kg/day (maximum 1000 mg).
- Streptomycin (S) 15–20 mg/kg/day (maximum 1.0 gram).

#### Fluoroquinolones

- Levofloxacin (Lfx), 15–25 mg/kg/day (maximum 1000 mg).
- Moxifloxacin (Mfx), 7.5–10 mg/kg/day (maximum 400 mg).
- Ofloxacin (Ofx), 15–20 mg/kg/day (maximum 800 mg).

#### Oral bacteriostatic second-line anti-tuberculosis drugs

- Ethionamide (Eto), 15–20 mg/kg/day (maximum 1000 mg).
- Cycloserine (Cs), 10–20 mg/kg/day (maximum 1000 mg).

**TABLE 6.1.N.6 Recommended anti-tuberculous drugs according to resistance pattern of TB culture from list above**

Resistance pattern	Change to:
Pan-susceptible	Category 1 (HREZ) (Isoniazid: H Rifampicin: R Ethambutol: E Pyrazinamide: Z)
H (with or without Streptomycin (S))	R – E – Z (6–9 months)
Polyresistant but not MDR	Continue the empirical second-line regimen. Consult with a specialist. Patient may require a combination of first- and second-line drugs
HR	Z –
HRE	S – Lfx – Eto – Cs – PAS
HREZ	S – Lfx – Eto – Cs – PAS
HRS	Km – Lfx – Eto – Cs – PAS
HRES	
HREZS	
Resistance to any second-line drug	Continue the empirical second-line regimen. Consult with a specialist

- Terizidone (Trd), 10–20 mg/kg/day (maximum 1000 mg).
- *p*-aminosalicylic acid (PAS), 150 mg/kg/day (maximum 8 grams (PASER)).

### Prevention of TB

- Diagnosis and treatment of 'smear-positive' tuberculosis in adults combined with contact tracing is the key to prevention of childhood tuberculosis.
- Tuberculin-positive children with normal chest X-rays should be given prophylaxis, either isoniazid (10 mg/kg/day, maximum dose 300 microgram) alone for 6 months or in low-incidence countries, isoniazid and rifampicin for 3 months. The age limit for prophylactic therapy depends on national policy, for example, under 5 years in low-income countries as per WHO recommendations.
- HIV-infected infants and children exposed to tuberculosis infection but without active disease should

receive isoniazid prophylaxis as described above. The WHO advises that HIV-infected children over 1 year old who are unlikely to have tuberculosis, even in the absence of exposure to tuberculosis, should receive a routine course of isoniazid for 6 months. There must be facilities for investigation of tuberculosis and regular follow-up. However, a recent double-blind, randomised, placebo-controlled trial (see Further reading below) of pre-exposure isoniazid prophylaxis against tuberculosis showed that this does not work for primary prophylaxis. It did not improve tuberculosis-disease-free survival among HIV-infected children or tuberculosis-infection-free survival among HIV-uninfected children immunised with BCG vaccine.

- Neonatal BCG may reduce the risk of tuberculosis meningitis and disseminated disease by 60–80%, especially in children under 5 years of age. However, it has a limited efficacy against pulmonary disease. Because of the increased risk of disseminated BCG infection in HIV-infected infants, the WHO advises that all infants **known to be HIV-infected** should **not** receive BCG. However, this has practical implications in resource-limited countries where PCR is not usually available to detect HIV infection in infants under 18 months of age.

## 6.1.O Typhoid or paratyphoid

### BOX 6.1.0.1 Minimum standards

- Blood culture and full blood count.
- Antibiotics: chloramphenicol, amoxicillin, ceftriaxone, ciprofloxacin.
- Public health measures.
- Sanitation, hygiene and preventive vaccines.

### Typhoid

#### Epidemiology

Despite major advances in public health and hygiene in much of the developed world, typhoid fever continues to plague many resource-limited countries. Although accurate community-based figures are unavailable, it is estimated that over 30 million cases occur annually, with the vast majority of cases in Asia leading to an estimated 200 000

deaths. Population-based incidence rates are estimated at 500–1000 cases per 100 000 population in endemic areas. However, there is a paucity of information from Africa, and preliminary data indicate that the burden in Africa, in urban settings, may also not be far behind that of Asia.

In recent years, typhoid fever has been notable for the emergence of drug resistance. The first cases of chloramphenicol-resistant typhoid emerged in the early 1970s, followed by the emergence of multi-drug-resistant (MDR) typhoid in the mid-1980s. This organism is resistant to ampicillin, chloramphenicol and trimethoprim-sulphamethoxazole (co-trimoxazole). Over the last few years, however, the development of quinolone and third-generation cephalosporin resistance in *Salmonella typhi* from various parts of Asia has raised the extremely worrying prospect of a 'super-resistant' variant of typhoid in addition.

In contrast to classic descriptions of milder disease, because of increasing drug resistance in *Salmonella paratyphi*, paratyphoid fever is now of comparable severity and virulence to typhoid fever. Both types of illness will therefore be described.

FIGURE 6.1.0.1 The pathogenesis of typhoid.

### Pathogenesis

The disease is spread by the ingestion of a Gram-negative flagellar organism, *Salmonella enterica* serovar Typhi (*S. typhi*). A larger infecting dose leads to a shorter incubation period and a more severe infection.

The organism crosses the intestinal mucosal barrier after attachment to the microvilli by an intricate mechanism involving membrane ruffling, actin rearrangement and internalisation in an intracellular vacuole. Once inside the intestinal cells, *S. typhi* bacteria find their way into the circulation and reside within the macrophages of the reticulo-endothelial system.

The clinical syndrome is produced by the release of pro-inflammatory cytokines (the interleukins IL-6 and IL-13 and tumour necrosis factor- $\alpha$ , TNF- $\alpha$ ) from the infected cells, leading to fever, rigors, inanition (the exhausted condition that results from lack of food and water) and anorexia. Local effects such as intestinal haemorrhage and perforation are comparatively rare in childhood, as there is relative lymphoid hyperplasia of the intestinal wall. However, malnourished children, especially adolescents, may be at greater risk of these complications.

### Clinical features

The classic stepladder rise of fever is relatively rare in childhood. Much of the presentation of typhoid fever in

TABLE 6.1.0.1 Common clinical features of typhoid fever in childhood (Karachi, Pakistan)

High-grade fever	95%
Coated tongue	76%
Anorexia	70%
Vomiting	39%
Hepatomegaly	37%
Diarrhoea	36%
Toxicity	29%
Abdominal pain	21%
Pallor	20%
Splenomegaly	17%
Constipation	7%
Headache	4%
Jaundice	2%
Obtundation (reduced alertness)	2%
Ileus	1%
Intestinal perforation	0.5%

various geographical locations and populations is modified by coexisting morbidities and early administration of antibiotics. In malaria-endemic areas and in parts of the world where schistosomiasis is common, the presentation of typhoid may also be atypical. Data in Table 6.1.0.1 from a consecutive series of 2000 cases show the common clinical features of typhoid in endemic areas.

Although data from South America and parts of Africa suggest that typhoid may present as a mild illness in young children, this may vary in different parts of the world. There is emerging evidence from South Asia from both community and health facility settings that the presentation of typhoid may be more dramatic in children under 5 years of age, with comparatively higher rates of complications and hospitalisation. Diarrhoea, toxicity and complications such as disseminated intravascular complications are also more common in infancy, with higher case-fatality rates. However, some of the other features of typhoid fever seen in adults, such as relative bradycardia, are rare, and rose spots may only be visible at an early stage of the illness in fair-skinned children.

It must also be recognised that MDR typhoid appears to be a more severe clinical illness with higher rates of toxicity, complications and case-fatality rates. This appears to be a consistent finding and potentially related to the increased virulence of MDR *S. typhi* as well as higher rates of bacteraemia. In endemic areas, therefore, it may be prudent to treat all severely ill toxic children, especially those requiring hospitalisation, with second-line antibiotics.

Acute perforation of the intestine with haemorrhage and peritonitis can occur. This presents with severe abdominal pain, vomiting, abdominal tenderness, severe pallor and shock. An abscess may form together with enlargement of the liver and spleen. Management of peritonitis is described in Section 5.19.

### Diagnosis of typhoid

The sensitivity of blood cultures in diagnosing typhoid fever in many parts of the developing world is limited, as microbiological facilities may be basic, and widespread antibiotic prescribing may render bacteriological confirmation difficult. Although bone marrow and **duodenal fluid cultures** may increase the likelihood of bacteriological confirmation of typhoid, these are difficult to obtain and they are invasive.

The serological diagnosis of typhoid is also fraught with problems, as a single Widal test may be positive in only 50% of cases in endemic areas, and serial tests may be required in cases presenting in the first week of illness. **Newer serological tests such as a dot-ELISA, co-agglutination and the Tubex® are promising**, but are comparatively expensive, may not be effective in primary care settings and have yet to find widespread acceptability.

The mainstay of diagnosis of typhoid in endemic areas therefore remains clinical. **Thus any high-grade fever of more than 72 hours' duration associated with any of the above-mentioned features, especially with no localising upper respiratory signs or meningitis or malaria, must be suspected as typhoid and managed accordingly.** While leucopenia (white blood cell count  $< 4 \times 10^9$ /litre) with a left shift in neutrophils may be seen in a third of children, young infants may also commonly present with a leucocytosis.

### Typhoid treatment

Making an early diagnosis of typhoid fever and instituting appropriate supportive measures and specific antibiotic therapy is the key to the appropriate management of typhoid fever. The following are the important principles of management:

- Adequate rest, hydration and attention to correction of fluid-electrolyte imbalance.
- Antipyretic therapy (paracetamol) as required if fever is  $> 39^\circ\text{C}$ .
- A soft, easily digestible diet should be continued unless the child has abdominal distension or ileus.
- Regular monitoring for clinical recovery and potential complications.
- Antibiotic therapy: the right choice, dosage and duration are critical to curing typhoid with minimal complications. Traditional therapy with either chloramphenicol or amoxicillin is associated with relapse rates of 5–15% and 4–8%, respectively.
- **If drug resistance is not locally a problem**, start with oral chloramphenicol and/or oral amoxicillin/ampicillin (initially intravenous if vomiting).
- **If drug resistance is prevalent**, use cefixime or ceftriaxone or ciprofloxacin (associated with higher cure rates).

Although epidemics are usually associated with a single dominant clone of *S. typhi*, in endemic situations there may be several coexistent strains of *S. typhi*, and a clinical judgement may need to be made when instituting antibiotic therapy before culture results become available. This is particularly important as delay in the institution of appropriate second-line antibiotic therapy in resistant cases of typhoid leads to a significant increase in morbidity and mortality. Despite the availability of newer orally administrable drugs such as quinolones and third-generation cephalosporins, blanket administration of these agents to all cases of suspected typhoid is expensive and will only lead to the rapid development of further resistance.

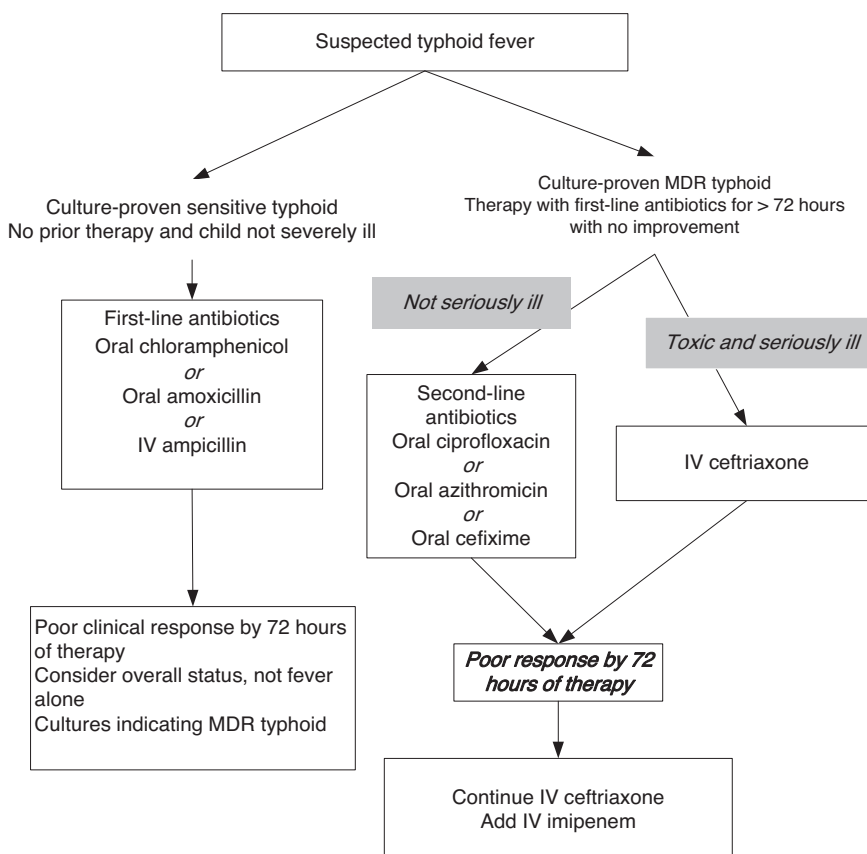

FIGURE 6.1.0.2 Algorithm for the treatment of typhoid. MDR, multi-drug-resistant.

Given the recent evidence that MDR typhoid is a more severe clinical illness from the outset, the algorithm in Figure 6.1.O.2 may be acceptable for selection of antibiotics and management of typhoid.

Table 6.1.O.2 shows the main antibiotics that can be employed for the treatment of both sensitive and MDR infections with *S. typhi*.

### Corticosteroids

In severely ill and toxic children with typhoid requiring hospitalisation, past studies have shown that **dexamethasone IV** (0.5–1 mg/kg/day 8-hourly for up to six doses) **may be life-saving in some contexts**. However, **avoid using steroids in ambulatory settings**, as they mask abdominal complications and peritonitis.

### Preventive measures for typhoid

The continued presence of typhoid in much of the developing world is an indication of the poor state of public health and sanitation. It is important therefore to be aware of the important risk factors for developing typhoid, in order to institute preventive measures during outbreaks.

There is some epidemiological evidence that prior usage of antibiotics is associated with an increased risk of subsequent development of typhoid. The precise reasons for this are unclear, but may be related to alterations in intestinal flora, increasing the predisposition to colonisation and infection with pathogenic strains of *S. typhi*. Thus controlling indiscriminate use of antibiotics may not only reduce the emergence of drug-resistant strains, but also reduce the risk of development of typhoid.

Of the major risk factors for outbreaks of typhoid, contamination of water supplies with sewage is the most important. Therefore during outbreaks a combination of central chlorination and domestic water purification is

important. In endemic situations, consumption of street foods, especially ice cream and cut fruit, has been recognised as an important risk factor. The human-to-human spread by chronic carriers is also important, and attempts should therefore be made to target food handlers and high-risk groups for *S. typhi* carriage screening. There is an urgent need to define the extent of carriage among food handlers in areas of high burden.

Of the available vaccines against typhoid, the classic heat-inactivated whole-cell vaccine is associated with an unacceptably high rate of side effects and is no longer in use. There are two newer vaccines which offer protection in older school-age children, but these are not recommended for use in children under 2 years of age:

- The Vi polysaccharide (Vi-CPS) vaccine can be administered in two doses at any stage, and has a 60–70% protective efficacy for at least 5 years. Recent large-scale demonstration projects in South Asia indicate that the Vi-CPS vaccine has considerable potential for use in school-age populations. The protective efficacy in children under 5 years of age has varied between studies.
- The oral attenuated ty-21a vaccine has also been evaluated and found to be comparably effective. However, it is generally available in capsule form and therefore difficult to administer to young children, especially those of preschool age.

Given the high rates and morbidity of typhoid in young children, there is a clear need for the development of a Vi-conjugate vaccine, which could be potentially employed within the Extended Programme of Immunisation vaccination schedule. Studies in Vietnam confirm the protective efficacy of such candidate vaccines, and several candidates are in an advanced stage of clinical development.

**TABLE 6.1.O.2** Antibiotics in *S. typhi* infections

Drug	Route	Dose (frequency)	Duration (days)
Chloramphenicol	Oral	60–75 mg/kg/day (6-hourly)	14 days
Ampicillin/amoxicillin	IV/oral	100 mg/kg/day (6- to 8-hourly)	14 days
Ciprofloxacin	Oral/IV	20–30 mg/kg/day (12-hourly)	7–10 days
Gatifloxacin	Oral	10 mg/kg/day (once daily)	7 days
Ceftriaxone	IV/IM	65–100 mg/kg/day (once daily)	7–14 days
Cefixime	Oral	8 mg/kg/day (12-hourly)	14 days
Azithromycin	Oral	10–20 mg/kg/day (once daily)	5–7 days

### Non-typhoidal salmonella infections

These infections usually give rise to a self-limiting gastroenteritis. This is manifested as diarrhoea with abdominal cramping pains, nausea and vomiting. There is usually a fever and there may be blood and mucus in the stools (see Section 5.12.A for treatment of this level of infection). A reactive polyarticular arthritis may develop 2 weeks after the diarrhoea.

Occasionally, particularly in the neonate and in the immunosuppressed, the malnourished, or children with sickle-cell disease, these infections can become very serious by spreading to the following sites: meninges (meningitis), bones (osteomyelitis) and joints (septic arthritis), lungs (pneumonia and empyema) and soft tissues (giving

abscesses). This is a particular problem in children with HIV infection.

Treatment for metastatic infections should be urgently given by intravenous or intramuscular injection. Initial treatment should ideally be with the broad-spectrum antibiotics cefotaxime or ceftriaxone, and if later sensitivity tests become available the organisms may be sensitive to amoxicillin (usually resistant now), co-trimoxazole and ciprofloxacin. Chloramphenicol may be effective in the absence of the above.

**Drug dosage schedules**

- Cefotaxime:
  - Neonates less than 7 days old: 50 mg/kg every 12 hours.
  - Neonates over 7 days old: 50 mg/kg every 8 hours.
  - Infants and children: 50 mg/kg every 6 hours.
- Ceftriaxone: All ages 50 mg/kg once daily. In very severe

infections 80–100 mg/kg once daily may be given (maximum dose 4 grams/day).

- Co-trimoxazole: 18 mg/kg by IV infusion 12-hourly. In very severe infections, 27 mg/kg co-trimoxazole IV 12-hourly (maximum dose 1.44 gram).
- Ciprofloxacin: 10–15 mg/kg twice daily by IV infusion.

**6.1.P Rickettsial diseases****BOX 6.1.P.1 Minimum standards**

- Supportive care and hydration.
- Early treatment with doxycycline or chloramphenicol.
- Public health measures and vector control.

**Introduction**

Rickettsial diseases are caused by obligate intracellular Gram-negative coccobacillary forms that multiply within eukaryotic cells. They take on a characteristic red colour when stained by the Giemsa or Gimenez stain.

- Illnesses are restricted by geography to places where both the natural animal host and its insect vector are present, and the vector has contact with humans.
- These diseases affect all ages, including children.

**Aetiology and types**

Rickettsial illnesses can be divided into the following biogroups:

**1 Spotted fever biogroup:**

- Rocky Mountain spotted fever (RMSF), caused by *Rickettsia rickettsia*.
- Rickettsial pox, caused by *Rickettsia akari*.
- Boutonneuse fever (i.e. Kenya tick-bite fever, African tick typhus, Indian tick typhus, etc.).

**2 Typhus group:**

- The causative organisms (*Rickettsia prowazekii* and *Rickettsia typhi*) are similar to those of epidemic typhus.
- Examples include Brill–Zinsser disease (i.e. relapsing louse-borne typhus) and murine (endemic or flea-borne) typhus.

**3 Scrub typhus biogroup (Tsutsugamushi disease):**

- These are a heterogeneous group of organisms that differ strikingly from rickettsial species and have a single taxonomic name, *Orientia tsutsugamushi* (see Section 6.1.Q).

**4 Other rickettsioses and closely related illnesses:**

- New or re-emerging rickettsioses have been described, including tick-borne lymphadenopathy (TIBOLA) and *Dermacentor*-borne-necrosis-eschar-lymphadenopathy (DEBONEL).
- *Ehrlichia* organisms (the cause of human monocytic ehrlichiosis and *Ehrlichia ewingii* infection), *Anaplasma phagocytophilum* (the cause of human granulocytic anaplasmosis), and *Bartonella* species (the cause of catscratch disease, relapsing fever and trench fever) are organisms related to the rickettsiae.
- Q fever is a disease caused by *Coxiella burnetii*, which has recently been removed from the Rickettsiales.

**Clinical presentation**

There are so many clinical similarities among the diseases caused by rickettsiae that certain clinical and epidemiological features should suggest their presence:

- 1 Most of these infections are spread through ticks, mites, fleas or lice.
- 2 All rickettsial infections cause fever, headache and intense myalgias.
- 3 All rickettsial infections are arthropod-borne, so exposure to ticks or mites is an important clue to their early diagnosis.
- 4 Rash and/or a localised eschar occur in most patients.
  - Illnesses are generally characterised by fever, rash and malaise. They are often misdiagnosed as measles, meningococcaemia, typhoid or rheumatic fever, or investigated as pyrexia of unknown origin.
  - Disease is caused by a vasculitis of small blood vessels, which on the skin is seen as a petechial or haemorrhagic rash. The vasculitis may affect many organ systems, and explains the wide range of symptoms seen.
  - There are features specific to individual rickettsia, including meningoencephalitis (in Rocky Mountain spotted fever), myocarditis and cough (in Q fever) or lymphadenopathy and hepatosplenomegaly (in scrub typhus).
  - An eschar at the site of the infecting bite is helpful in the diagnosis of tick-borne and mite-borne rickettsial infections, and is recognised as a necrotic black papule.
  - The severity of illness varies with the organism, and the age of the patient. For example, in Rocky Mountain spotted fever, the untreated acute illness has a case fatality rate of 20%, with two-thirds of cases occurring in children under 15 years of age. In contrast, louse-borne typhus may only cause mild symptoms in children, with deaths occurring mainly in adults.
  - Other manifestations may occur, such as gastrointestinal, conjunctival, hepatic and pulmonary manifestations, that are more common in some illnesses than in others.

**Differential diagnosis**

Depending on local diseases, the combination of clinical manifestations, laboratory data and geographical areas, other causes to consider include the following:

- malaria
- measles
- typhoid

- dengue haemorrhagic fever
- Kawasaki disease
- leptospirosis
- meningococcal infections
- rubella
- group A streptococcal infection
- syphilis
- toxic shock syndrome
- vasculitis and thrombophlebitis.

### Diagnosis

Confirmation of diagnosis of rickettsial infections is usually clinical, with the following methods used for confirmation as appropriate:

#### 1 Isolation:

- Rickettsiae can be isolated following inoculation into animals, such as guinea pigs in special reference laboratories.

#### 2 Serology:

- Serological detection of convalescent antibodies is the mainstay of diagnosis of rickettsial infection. The following serologic tests can be used:
  - the Weil–Felix (WF) agglutination test; **this is not used for rickettsial pox, Q fever or ehrlichiosis, for which specific diagnostic serological tests are available**
  - microimmunofluorescent (MIF) antibody test
  - enzyme-linked immunosorbent assay (ELISA)
  - Western blot immunoassay.

The WF test is neither specific nor sensitive, and is not helpful. None of these methods are normally useful in the initial clinical management of patients with acute illness. A modification of the ELISA test has been developed to serologically confirm the specific species of rickettsiae.

#### 3 Immunologic detection of rickettsiae in tissue:

- Biopsies of skin rash, an eschar, or other tissues can be useful but are rarely performed, as these require specialised laboratories.

#### 4 PCR amplification of rickettsial DNA:

- PCR amplification, especially by the new ‘suicide PCR’ primers from rickettsial genes from blood, skin biopsy samples and other tissues can be performed in reference laboratories for detection of rickettsial DNA. It has estimated sensitivity and specificity of 68% and 100%, respectively.

#### 5 Routine blood examinations:

- These are unhelpful but are required to rule out other diseases, such as malaria, typhoid, dengue haemorrhagic fever and leptospirosis.

### Treatment

- Treatment should not await serological diagnosis, as this is often delayed.
- In children over 8 years of age, give tetracyclines, particularly doxycycline (2.2 mg/kg twice daily up to a maximum of 100 mg twice daily). The use of these drugs is not advised in children under 8 years of age because of dental staining. Under 8 years give co-trimoxazole 24 mg/kg twice daily for 2 weeks.
- Oral chloramphenicol (25 mg/kg four times daily up to a maximum of 3 grams/day) is also effective.
- For scrub typhus (see Section 6.1.Q), rifampicin and azithromycin have been used successfully in areas where the rickettsia is resistant to conventional treatment.
- Treatment should be for 7–14 days.
- Fluoroquinolones (e.g. ciprofloxacin) may be effective and are being evaluated.
- Supportive care for complications affecting the cardiac, renal and pulmonary systems may be necessary in patients with severe disease.

### Control

- Insect vector control is important for human louse-borne typhus, which occurs in cold mountainous areas where people live close together, or in internally displaced or refugee populations. In these situations, delousing of individuals with insecticides prevents and controls epidemic typhus.
- For scrub typhus, mite bites can be prevented by using topical insect repellents.
- A vaccine is also available for Rocky Mountain spotted fever.

### Health education

This may include the following:

- community education on the risks of living in very close proximity to animals
- the need for regular re-facing of mud walls and floors
- for human louse-borne typhus, the importance of washing and sunning clothes and bedding.

TABLE 6.1.P Some major rickettsia and their distribution

Disease	Agent	Vector	Reservoir	Distribution
Rocky Mountain spotted fever	<i>R. rickettsii</i>	Ticks	Rodents, dogs, rabbits	USA, South America, Canada
Rickettsial pox	<i>R. akari</i>	Mite	Mouse	Worldwide
Louse-borne typhus	<i>R. prowazekii</i>	Lice	Human	Worldwide
Murine typhus	<i>R. typhi</i>	Flea	Mouse (urban)	Worldwide
Scrub typhus	<i>Orientia tsutsugamushi</i>	Mite	Rodents	Australia, India, SE Asia
Q fever	<i>Coxiella burnetii</i>	None	Cattle, goats	Worldwide

## 6.1.Q Scrub typhus

### BOX 6.1.Q.1 Minimum standards

- Serology.
- Chest X-ray.
- Doxycycline and tetracycline.

### Epidemiology

- Geographical distribution: Asia, Australia and Pacific Islands.
- Agent: *Orientia tsutsugamushi* (Rickettsia tsutsugamushi).
- Hosts: Rodents are reservoir hosts, and humans are accidental hosts. The most commonly affected age group is 5–14 years, and the disease is more common in boys.
- Vector: Larva of trombiculid mite. Mites live on jungle grass and become infectious by biting and sucking tissue fluid of infected rodent or by transovarian transmission to the next generation of mites.

### Clinical manifestations

- Incubation period is 5–18 days.
- Abrupt onset of fever, severe headache, myalgia, cough, suffused conjunctivae, dark red papular or maculopapular rash (5–7 days after fever) on the trunk, arms and thighs.
- Eschar (19–28% in children, 46–82% in adults) may be seen at the site of the mite bite, especially in the perineum, axilla or trouser-belt region. Eschar is a firmly adherent black scab, 3–6 mm in diameter, with a raised red margin.
- There is regional or generalised lymphadenopathy, hepatomegaly and sometimes a maculopapular rash. Moderate leucocytosis may be seen, and occasionally thrombocytopenia.
- In severe cases, complications include meningoencephalitis, myocarditis, pneumonitis, respiratory distress syndrome or (rarely) renal failure.
- In non-severe cases, fever subsides within 2 weeks. Indigenous people in endemic areas usually have mild illness without rash or eschar.

### Diagnosis

- Diagnosis is based on clinical manifestations, geographical distribution and history of contact with jungle-grass exposure in the bush.
- Confirmation is by serology or polymerase chain

reaction (PCR). Weil–Felix test titres of 1:160 (or a fourfold rise after 2–4 weeks) occur in only 50% of cases. **More sensitive serological tests are the indirect immunoperoxidase test and the indirect immunofluorescent tests. For individuals living in endemic areas the positive titre is  $\geq$  1:400 or a fourfold rise in acute and convalescent sera. The positive titre indicating infection may be lower in non-endogenous children. PCR on the eschar material is more sensitive than on the blood.**

- Routine blood examinations are unhelpful, but are required to rule out other diseases such as dengue haemorrhagic fever, malaria and leptospirosis.
- Blood culture to exclude septicaemia (e.g. typhoid).
- Chest X-ray is indicated if there is cough and dyspnoea to detect pneumonitis, pleural effusion or respiratory distress syndrome.
- Perform lumbar puncture if there is meningism or severe headache to rule out other causes of CNS infection. CSF commonly shows a picture of aseptic meningitis.
- A fall in body temperature usually occurs within 24–48 hours after treatment.

### Management

- The drug of choice is doxycycline orally 2.2 mg/kg initially followed by 2.2 mg/kg 12 hours later, then 1.1 mg/kg every 12 hours until the patient is afebrile for 2–3 days, or continue treatment for 5–7 days.
- Alternative drugs are tetracycline 250 mg orally four times a day for 7 days (in children over 8 years) or chloramphenicol 15–25 mg/kg orally four times a day for 7 days, depending on severity.
- In a few cases, fever returns 5–7 days later. If this happens, repeat the dose of antibiotic.
- Tetracycline should not be given to oliguric patients. Doxycycline is safe in renal impairment.
- Rifampicin and azithromycin have been used successfully in areas where the rickettsia is resistant to conventional treatment.
- In severe cases, the risk of dying outweighs the risk of tooth discoloration from doxycycline or tetracycline.
- **Remember that antimicrobial agents only suppress infection. Cure depends on host immunity.**
- Treatment should not be withheld pending laboratory confirmation for a clinically suspected infection.

## 6.1.R Yaws

### BOX 6.1.R.1 Minimum standards

- Azithromycin.
- Benzathine penicillin.

### Introduction

Yaws is caused by the bacterium *Treponema pallidum* subspecies *pertenue*. It is closely related to the bacterium that causes syphilis, but this disease is not sexually transmitted. Yaws mainly affects children in rural tropical areas, such as the Caribbean Islands, Latin America, West Africa, India,

and South-East Asia. Yaws is transmitted by direct contact with the skin sores of infected people.

### Symptoms

About 2–4 weeks after infection, the child develops a sore called a ‘mother yaw’ where bacteria entered the skin. The sore is reddish and looks like a berry. It is usually painless but does cause itching.

These sores may last for months. More sores may appear shortly before or after the mother yaw heals as the person scratches or spreads the bacteria from the mother yaw to uninfected skin. Eventually the skin sores heal.

Some patients develop destructive ulcerations of the nasopharynx, palate and nose (termed gangosa), painful skeletal deformities, especially in the legs (termed saber shins), and other soft-tissue changes (gummas, inflammatory cell infiltration). In the advanced stage, sores on the skin and bones can lead to severe disfigurement and disability.

### Signs and tests

A sample from a skin sore is examined using a dark-field

microscope. There is no blood test for yaws. However, the blood test for syphilis is usually positive in children with yaws, because the bacteria that cause these two conditions are closely related.

### Treatment

Recently a single dose of oral azithromycin (30 mg/kg) has been shown to be as effective as a single IM injection of benzathine benzylpenicillin 50 000 units/kg (37.5 mg/kg) with less risk of a dangerous anaphylactic response and the need for needles. If the child vomits within 30 minutes of the oral dose of azithromycin, a repeat dose should be given. Benzathine benzylpenicillin must not be given IV.

Anyone who lives in the same house with someone who is infected should be examined for yaws and treated if they are infected. Skin lesions may take several months to heal. By its late stage, yaws may have already caused damage to the skin and bones. It may not be fully reversible, even with treatment for the infection.

## 6.1.S Other bacterial infections

### BOX 6.1.S.1 Minimum standard

- Anthrax: ciprofloxacin, doxycycline, rifampicin, vancomycin, gentamicin, chloramphenicol, penicillin, amoxicillin, imipenem, meropenem and clindamycin.
- Brucellosis: co-trimoxazole.
- *Chlamydia*: erythromycin.
- *Haemophilus influenzae*: amoxicillin, Hib vaccine.
- Plague: streptomycin, tetracycline, chloramphenicol.
- *Staphylococcus*: cloxacillin, flucloxacillin, sodium fusidate.

### Anthrax

This is an infection from animals caused by *Bacillus anthracis*.

#### Cutaneous

Major features:

- surrounded by extensive oedema
- painless and non-tender (although may be pruritic or accompanied by a tingling sensation).

Minor features:

- development of black eschar
- progresses over 2–6 days through papular, vesicular and ulcerated stages before eschar appears
- most commonly affects the hands, forearms, face and neck
- discharge of serous fluid
- local erythema and induration
- local lymphadenopathy
- associated with systemic malaise including headache, chills and sore throat, but afebrile.

#### Take initial diagnostic tests:

- Swab from lesion for stain and culture.
- Blood cultures (prior to antimicrobial use, if possible).

#### Start antibiotic treatment to cover *B. anthracis*.

Ciprofloxacin orally is given under 8 years of age. In children older than 8 years doxycycline can be given. Either drug is combined with one or two other antibiotics (such as amoxicillin, benzylpenicillin, or chloramphenicol). When the condition improves and the sensitivity of the *Bacillus anthracis* strain is known, treatment may be switched to a single antibiotic. Treatment should continue for 60 days because germination may be delayed.

#### Features of inhalation anthrax

- Rapid onset of severe unexplained febrile illness (fever, chills, fatigue, non-productive cough).
- Rapid onset of severe sepsis not due to a predisposing illness.
- Abrupt onset of respiratory failure and the presence of widened mediastinum or pleural effusions on chest X-ray.
- Nausea.
- Sweats (often drenching).
- Confusion or altered mental status.
- Vomiting.
- Pallor or cyanosis.
- Dyspnoea.
- Tachycardia.
- Abdominal pain.
- Pleuritic chest pain.
- Sore throat.

#### Take initial diagnostic tests:

- Chest X-ray: **mediastinal widening**, pleural effusion, pulmonary infiltrate.
- Full blood count: to look for raised haemocrit, raised white cell count, especially neutrophilia.
- Liver function tests: to look for high transaminase activity.
- CT of chest (if available) if high suspicion and normal chest X-ray.

- Blood culture.

#### Start antibiotic treatment to cover *B. anthracis*.

Give ciprofloxacin intravenously in combination with one or two other antibiotics (agents with *in-vitro* activity include rifampicin, vancomycin, gentamicin, chloramphenicol, penicillin, amoxicillin, imipenem, meropenem and clindamycin) until sensitivity testing is available. Treatment should continue for 60 days because germination may be delayed.

It is important to notify public health authorities if such an infection is identified.

### Brucellosis

This is an infection from animals caused by *Brucella* species, usually through infected milk. It causes a chronic illness with fever, pain and swelling of the joints, and anaemia.

Treatment is with co-trimoxazole for 4 weeks: give 18–24 mg co-trimoxazole/kg twice daily.

- Or give paediatric liquid 240 mg/5 mL (200 mg sulfamethoxazole plus 40 mg trimethoprim):
  - Age 6 weeks to 6 months: 2.5 mL twice daily.
  - Age 6 months to 6 years: 5 mL twice daily.
  - Age 6–12 years: 10 mL twice daily.

### Campylobacter infection

This causes acute gastroenteritis with **considerable abdominal pain**, fever and bloody diarrhoea (see Section 5.12.A). Most children recover without treatment with antibiotics, although erythromycin and ciprofloxacin are both effective.

### Chlamydia infections

*Chlamydia trachomatis* causes trachoma (see Section 6.1.M), infections of the genital tract (see Section 6.1.J), and conjunctivitis in the newborn which is less severe than that due to the gonococcus (see Section 3.4).

*Chlamydia pneumoniae* produces a chronic pneumonitis in the infant. It is important not to forget this cause of acute respiratory infection, which responds well to erythromycin.

### Haemophilus influenzae infections

*Haemophilus influenzae* causes serious infections in infants and young children, including:

- pneumonia (see Section 5.3.A)
- middle ear infections (see Section 5.1.C)
- acute epiglottitis (see Section 5.1.A)
- meningitis (see Section 5.16.B).

Infections can be prevented by an extremely effective conjugate vaccine. **Every country should attempt to immunise their infants against this cause of many serious illnesses, deaths and handicap.**

### Plague

*Yersinia pestis* is transmitted to children by the fleas of infected rats. It occurs in epidemics.

It presents with an acute fever and painful tender large

swollen lymph nodes (buboes). It can cause pneumonia and septicaemia.

Prompt treatment on suspicion is essential.

- Streptomycin is the treatment of choice for severe cases (15 mg/kg IM daily, maximum dose 1 gram) for 7 days.
- Tetracycline (in children over 8 years, 250–500 mg 6-hourly) and chloramphenicol (15–25 mg/kg 6-hourly) are alternative drugs, which are also given for 7 days.

### Shigellosis

- This causes an acute gastroenteritis, which particularly affects the large bowel. There is blood and mucus in the diarrhoea.
- There is often a high fever.
- Shigellosis may cause seizures.
- There may be tenesmus (a continuous feeling of wanting to defecate).
- Septicaemia may occur.

See Section 5.12.A for advice on treatment.

### Staphylococcal infections

The most common presentation is with a pus-forming skin infection (impetigo) (see Section 5.18).

However, this bacterium can be transported in the blood to other parts of the body, where it produces serious infections:

- Pneumonia is particularly dangerous (see Section 5.3.A).
- Osteomyelitis is also dangerous and difficult to diagnose (see Section 5.17).
- Pyomyositis can occur.
- Occasionally staphylococcal infections cause mastoiditis (see Section 5.1.C) and laryngotracheitis (see Section 5.1.A).

The two groups of antibiotics most effective against this organism are flucloxacillin or cloxacillin and sodium fusidate (fucidin).

#### Treatment with sodium fusidate/fusidic acid

Use in combination with another antistaphylococcal agent if possible, to avoid the development of resistance.

#### Oral route

Absorption is not as good as with the IV route, but the oral route should be used when possible. Doses as fusidic acid:

Neonate to 1 year	15 mg/kg	3 times daily
1 year to 5 years	250 mg	3 times daily
5 years to 12 years	500 mg	3 times daily
12 years to 18 years	750 mg	3 times daily

The suspension usually contains 250 mg of fusidic acid in 5 mL.

#### Intravenous infusion

Give 6–7 mg/kg of sodium fusidate 8-hourly (for children over 50 kg in weight, give 500 mg IV 8-hourly).

The dose may be doubled in severe infections.

Dilute in 5% glucose to a concentration of 1 mg/mL, and give slowly over at least 6 hours.

See Section 5.12.A for further information on *Campylobacter* and cholera infections.

## 6.2 Viral infections

### 6.2.A Chickenpox

#### BOX 6.2.A.1 Minimum standards

- Antipyretics and antipruritus treatment (e.g. chlorpheniramine/promethazine).
- Antibiotics for secondary infection.
- Aciclovir in immunosuppressed, neonates and other at-risk groups.
- VZIG IM (if available) for immunocompromised patients.
- Live attenuated varicella vaccine (for susceptible groups when in remission).

#### Introduction

Chickenpox is caused by varicella zoster virus (VZV), a member of the herpesvirus family. It is spread by direct contact, droplet or airborne transmission, and is very contagious.

Chickenpox manifests as a generalised pruritic vesicular rash typically consisting of crops of lesions in varying stages of development and resolution (crusting), mild fever, and other systemic symptoms. Varicella tends to be more severe in adolescents and adults than in young children.

The peak age for infection is 5 to 9 years. In immunocompetent children it is usually a mild disease, and lifelong immunity follows an infection.

Groups at increased risk include those with immunodeficiency (mainly those with HIV infection), those on chemotherapy or long-term steroids (defined as those who within the previous 3 months received prednisolone, or its equivalent, at a daily dose of 2 mg/kg/day or more than 40 mg/day for at least 1 week or 1 mg/kg/day for 1 month), and neonates whose mothers have had chickenpox just before or just after the birth. Patients on lower doses of steroids plus another immunosuppressant drug and patients with an additional medical problem (e.g. nephrotic syndrome) should be included, plus those on salicylate therapy or with chronic lung or skin problems, including eczema. Acyclovir should be used in these groups.

Children with chickenpox are at increased risk of developing Reye's syndrome if given aspirin and other non-steroidal anti-inflammatory drugs.

#### Clinical presentation

- The incubation period is 14–21 days. There is low-grade fever and headache, followed by the rash, which is mostly on the trunk and face. The rash develops into successive small single oval vesicles with an erythematous base which break within 2 days to develop into scabs and heal. It is very itchy, and scratching may result in secondary bacterial infection and scar formation.
- The course of the disease is about 1 week. Children are

infectious from 1 or 2 days before the rash appears until 1 or 2 days after all of the lesions have formed scabs.

- Complications include septicaemia, bronchopneumonia, hepatitis, thrombocytopenia, purpura, pericarditis, myocarditis, endocarditis, arthritis, myositis, glomerulonephritis, ascending mediastinitis and post-infectious encephalitis, especially with cerebellar involvement. Any fever or other symptom occurring within a few days of apparently resolving chickenpox must be taken seriously.
- Guillain–Barré syndrome, facial nerve palsy, transverse myelitis, hypothalamic involvement, optic neuritis and transient loss of vision have been reported.
- Intrauterine infection, especially in the first two trimesters, may result in a congenital varicella syndrome (i.e. intrauterine growth retardation, scarred skin, limb atrophy, mental retardation, CNS and eye complications). Only 1–2% of infants with intrauterine exposure develop complications.
- In mothers, chickenpox but not shingles, occurring between 5 days before and 2 days after delivery, may result in a **severe infection in the neonate**. This is probably due to lack of formation of VZV IgG antibodies that would have crossed the placenta and would be protective for the newborn baby. The infant should be treated as soon as possible with **varicella-zoster immunoglobulin** (if available) and with **IV aciclovir** as well if infection manifests (see below and Section 2.8.1).

#### Management

- Keep the child clean, and cut and clean under their nails to discourage scratching and prevent secondary skin infection.
- Baking soda baths or calamine lotion may relieve the itching.
- Antihistamines, such as chlorpheniramine 1 mg twice daily (1 month to 2 years of age), 1 mg three to six times a day; maximum 6 mg daily (2–6 years), 2 mg three to four times a day; maximum 12 mg daily (6–12 years), or 4 mg three to six times a day; maximum 24 mg daily (over 12 years) may reduce scratching.
- Give paracetamol for fever.
- Appropriate antibiotics should be given for secondary bacterial infection, which is mostly due to *Staphylococcus aureus* or *Streptococcus pyogenes*.
- Aciclovir IV 10 mg/kg 8-hourly or 250 mg/m<sup>2</sup> 8-hourly for 7–10 days is recommended for immunocompromised children who develop chickenpox. Oral aciclovir (20 mg/kg four times a day) is given for HIV-infected patients whose **CD4+ counts** are relatively normal. It should

be considered for HIV-infected children with a CD4+ T-lymphocyte percentage of 15% or greater.

- If available, IM varicella-zoster immunoglobulin (VZIG) should be given at the following doses: birth to 5 years, 250 mg (one vial); 6–10 years, 500 mg (two vials); 10–15 years, 750 mg (three vials) and 15–18 years, 1 gram. This may modify the disease if given shortly (not more than 4 days) after exposure. Indications include immunocompromised children, such as HIV-infected pregnant women and premature infants born at less than 28 weeks' gestation, who have had intimate contact (face to face) with chickenpox or herpes zoster. Neonates whose mothers develop varicella between 7 days before and 28 days after delivery are offered VZIG 250 mg as a single IM injection.
- If VZIG is not available, oral or IV aciclovir (at the above doses) may be given.
- In addition to standard precautions, airborne and contact precautions are recommended for patients with varicella for a minimum of 5 days after the onset of rash and until all lesions are crusted, which in immunocompromised patients can be 1 week or longer.

### Prevention

- Live attenuated varicella vaccine (monovalent varicella vaccine or measles, mumps, rubella, varicella: MMRV) given as two subcutaneous or intramuscular injections confers over 95% protection against severe disease. Both have been licensed for use in healthy children from 12 months to 12 years of age. Children in this age group should receive two 0.5-mL doses of varicella vaccine administered subcutaneously, separated by at least 3 months.
- Susceptible children aged 13 years or older without immunocompromise should receive two 0.5-mL doses of varicella vaccine separated by at least 28 days.
- Patients in whom vaccine is contraindicated include those who are immunocompromised children and those receiving aspirin.
- Patients who are receiving immunosuppressive treatment (including steroid therapy) are generally immunised when in complete remission. The total lymphocyte count should be  $> 1.2 \times 10^9$ /litre and there should be no other evidence of a lack of cellular immune competence.
- The vaccine should not be given within 3 months of VZIG.

## 6.2.B Dengue

### BOX 6.2.B.1 Minimum standards

- Airway, Breathing and Circulation assessment and management.
- Recognition and treatment of shock.
- Blood transfusion and replacement of clotting factors and platelets.
- High-dependency/intensive care.
- Vector control.

### Introduction

Dengue infection is caused by an RNA virus of the Flaviviridae family. The disease first appeared in an epidemic in the Philippines in 1957, subsequently in Thailand,

and then in other South-East Asian countries. It is now an important health threat in most Asian and South American countries, with an estimated 50–100 million dengue infections worldwide every year and a fatality rate of about 2.5% in hospitalised cases, although this could be reduced by earlier detection and access to good medical care.

Epidemics occur every year during the rainy season, and the mosquitoes *Aedes aegypti* and *Aedes albopictus* are the main vectors.

The dengue virus comprises four serotypes (type 1, 2, 3 and 4) which cause lifelong specific antibody responses. Unusually, a second infection with a different serotype of the virus puts the sufferer at greater risk of more severe illness.

Dengue hemorrhagic fever or severe dengue is the

TABLE 6.2.B.1 Increasing signs of severity in dengue

Dengue: diagnosis	Warning signs of severity	Severe dengue
<i>Probable dengue</i>	<i>Require close observation and medical care</i>	<i>Any of the following:</i>
Live in or travel to dengue endemic area	Persistent vomiting Clinical fluid accumulation	Severe plasma leakage showing as shock or respiratory distress
Fever and two of the following: Nausea, vomiting Rash Aches and pains Tourniquet test positive	Mucosal bleed Lethargy, restlessness Liver enlargement > 2 cm Laboratory: increase in haematocrit concurrent with rapid decrease in platelet count	Severe bleeding as evaluated by clinicians Severe organ involvement: ● liver (AST, ALT $\geq 1000$ ) ● CNS: impaired consciousness ● heart and other organ failure
Supportive serology <b>or</b> Occurrence at the same location and time as other confirmed dengue cases	Abdominal pain and tenderness	

AST, aspartate aminotransferase; ALT, alanine aminotransferase; CNS, central nervous system.

severe clinical illness, and involves plasma leakage, significant bleeding and shock with a significant fatality rate, especially where intensive-care facilities are lacking. There are no available vaccines for dengue and no specific antiviral treatment. Treatment is supportive. Control is currently by control of the vectors.

### Diagnosis

In 2009, the WHO classification of dengue infection was revised to simplify diagnosis and management. Table 6.2.B.1 shows the warning signs that severe dengue may develop.

This new WHO guideline classifies the infection either as dengue or as severe dengue. The old definition of (non-severe) dengue is the same as that of dengue fever (A90 according to the ICD code) and severe dengue means dengue hemorrhagic fever (A91 according to the ICD code).

The alternative differential diagnosis of acute febrile illness with non-specific symptoms is as follows:

- septicaemia
- scrub typhus
- viral infection

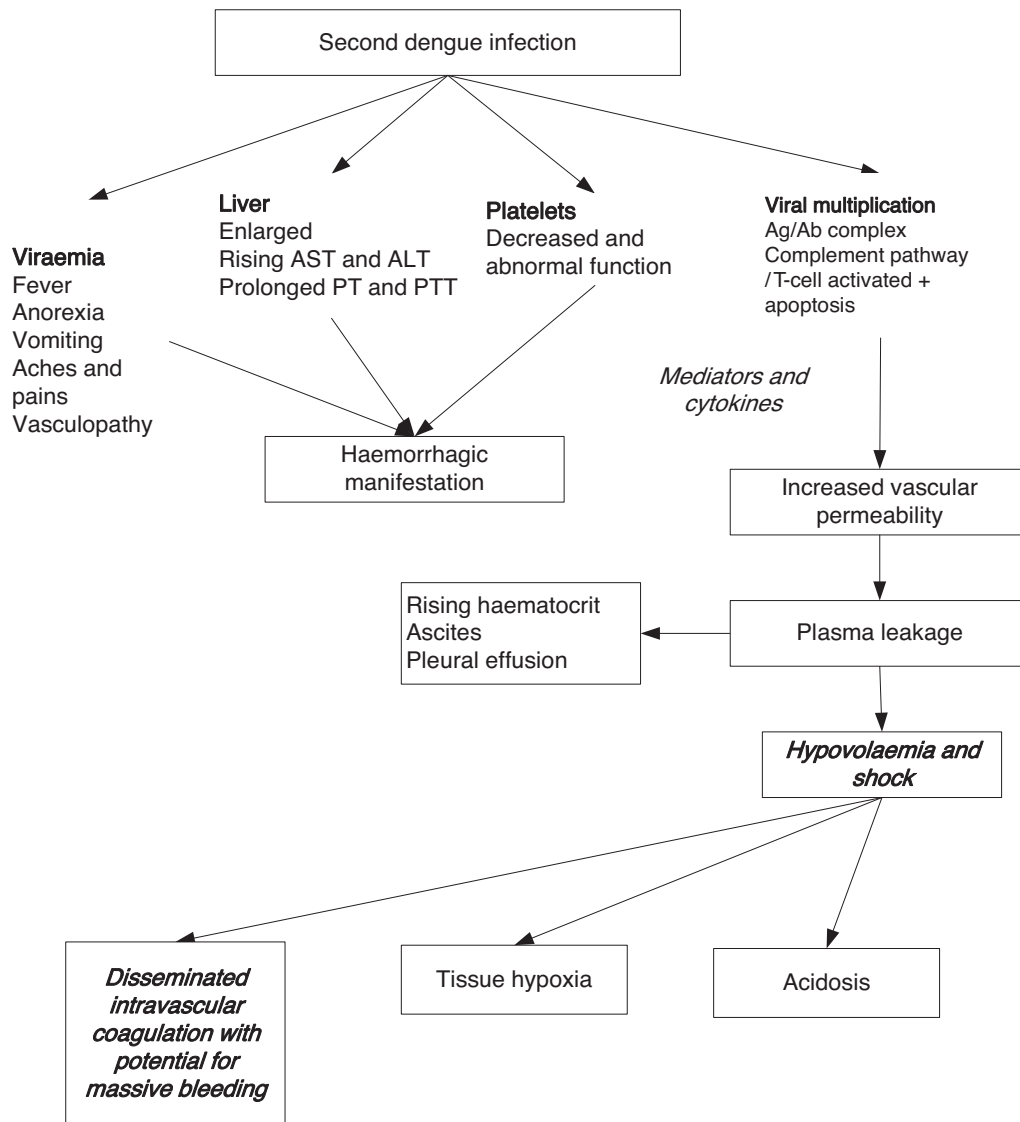

- enteric fever
- leptospirosis.

### Pathogenesis of severe dengue or dengue haemorrhagic fever (DHF)

Infection with one dengue serotype gives specific lifelong antibody with only partial protection against other serotypes. Therefore, unusually, severe dengue or DHF occurs predominantly in patients with second infections who have a different serotype in their second infection from their first (previous dengue fever). Antibody-dependent enhancement, immune enhancement and T-cell (T8) proliferation and apoptosis are important in the development of disease.

Hypotheses for severe dengue or DHF include the following:

- Non-neutralising antibodies to dengue virus enhance viral uptake and replication in target cells (monocytes).
- Enhanced viral replication in the presence of T-cell apoptosis, resulting in large antigen load in the face of massive T-cell activation, releasing cytokines that lead to tissue damage and vascular leakage.

**FIGURE 6.2.B.1** Pathophysiology of severe dengue or dengue haemorrhagic fever. AST, aspartate aminotransferase; ALT, alanine aminotransferase; PT, prothrombin time; PTT, partial thromboplastin time.

TABLE 6.2.B.2 Clinical course of severe dengue or DHF

Phase	Symptoms	Signs	Laboratory test
1. Febrile phase duration 3–5 days (days 1–5)	High continuous fever (39–40°C), headache, anorexia, nausea, vomiting, myalgia, arthralgia, epigastric discomfort, right upper quadrant pain, fine rubelliform maculopapular rash, mucosal bleeding	Facial flushing, injected conjunctivae Tourniquet test positive ( <i>see</i> Figure 6.2.B.2), tenderness at right upper quadrant, hepatomegaly, lymphadenopathy, dry lips and mucosa	Not significant
2. Haemorrhagic shock or toxic phase duration 1–2 days (days 4–6)	Fever declines, abdominal pain especially in the right upper quadrant, bleeding in skin and mucosa (nose, gums, gastrointestinal tract) About 30% of cases will develop shock (irritability, restlessness, severe abdominal pain, sweating) Shock is less common when IV fluids have been given early	Right upper quadrant tenderness, hepatomegaly, tourniquet test positive, bleeding of mucosa, signs of dehydration (dry lips and mucosa, dark yellowish urine) Cold clammy skin (prolonged capillary refill time > 2 seconds) Thready pulse, tachycardia, narrow pulse pressure ( $\leq 20$ mmHg, e.g. 90/70, 100/80)	Blood count: rising haematocrit, decreased platelet count ( $< 100 \times 10^9/\text{litre}$ ), leucopenia Abnormal liver function test (albumin, liver enzyme: AST, ALT), renal function, calcium, electrolyte, blood gas in severe dengue with intractable and prolonged shock
3. Convalescence phase Duration 2–3 days	No fever or low-grade biphasic fever Increased appetite Diuresis	Convalescence rash on extremities with itching Widespread petechial rash with scattered round pale areas Sinus bradycardia	Stable haematocrit (or slowly increasing is a good clinical sign due to diuresis in some cases) Rising platelet count

Dengue or dengue fever (non-severe dengue) has only phases 1 and 3.

- Antibodies against dengue virus bind to complement pathway, releasing mediators that lead to vascular leakage as well.

Figure 6.2.B.1 shows a proposed pathophysiological pathway for severe dengue.

FIGURE 6.2.B.2 Tourniquet test showing petechiae.

Tourniquet test:

- Apply an appropriate blood pressure cuff (it should be two-thirds of upper arm length)
- Inflate to the level of mean arterial pressure (systolic plus diastolic blood pressure, divided by 2) for 5 minutes.
- Positive test: petechiae > 10/square inch after removing the cuff for 2 minutes or longer.

### Management of dengue and severe dengue (dengue haemorrhagic fever, DHF)

The aim of management of dengue and severe dengue is supportive, aiming to maintain adequate intravascular volume to prevent shock and to use blood and blood products to combat severe bleeding.

### Management of severe dengue with shock and respiratory distress

#### Initial management of shock

- Give high-flow oxygen with a mask with reservoir or nasal cannulae.
- Give a bolus of Ringer-lactate or Hartmann's or 0.9% saline solution (20 mL/kg).
- If the child shows improvement, give 10 mL/kg of Ringer-lactate or Hartmann's solution or 0.9% saline with 5% dextrose over 1 hour (add 50 mL of 50% dextrose to each 500-mL bag).
- Reduce IV fluids (Ringer-lactate or Hartmann's solution or 0.9% saline plus 5% dextrose) to 7 mL/kg/hour for 6 hours if vital signs improve.
- Check vital signs every 15 minutes until stable, then every hour for 4 hours, then every 2–4 hours.
- Check haematocrit every 4 hours.
- If vital signs are stable, haematocrit declines to 36–40% and no warning signs appear, then reduce IV fluid to 5 mL/kg/hour for 6 hours followed by maintenance fluids (2–3 mL/kg/hour).
- Stop IV fluid when the child drinks more than half of the required intake or there is a diuresis.

**TABLE 6.2.B.3 Management of dengue and severe dengue without shock**

Day of illness	Assessment	Management
Days 1–3 (febrile phase)	<p><b>Monitor</b> temperature, blood pressure and pulse rate at least every 4–6 hours</p> <p><b>Do</b> tourniquet test</p> <p><b>Look for</b> signs of dehydration (dry lips and mucosae, low urine output)</p> <p><b>Look for</b> warning signs (<i>see</i> Table 6.2.B.1)</p>	<ol style="list-style-type: none"> <li>1 Tepid sponge, paracetamol (do not give salicylate or other non-steroidal anti-inflammatory drugs, as they may cause bleeding, acidosis, hepatotoxicity and Reye's syndrome)</li> <li>2 Give ORS/fruit juice/water frequently and in small amounts</li> <li>3 If the child is vomiting, try domperidone 0.2 mg/kg 6- to 8-hourly</li> <li>4 Admit if the child has signs of dehydration, gastrointestinal bleeding or cannot drink</li> <li>5 Give IV fluid: 5% dextrose in Ringer-lactate or Hartmann's or 0.9% saline 1–3 mL/kg/hour depending on oral intake and haematocrit</li> </ol>
Days 4–6 (toxic phase)	<p><b>Monitor</b> vital signs every 2–4 hours</p> <p><b>Do:</b></p> <ul style="list-style-type: none"> <li>• tourniquet test if previously negative</li> <li>• complete blood count (CBC)</li> <li>• serial haematocrit every 4 hours</li> <li>• palpate liver</li> <li>• record intake and output</li> </ul> <p><b>Look for</b> warning signs (<i>see</i> Table 6.2.B.1)</p>	<ol style="list-style-type: none"> <li>1 Admit if the child has signs of dehydration or warning signs</li> <li>2 Give IV fluid: 5% dextrose in Ringer-lactate or Hartmann's or 0.9% saline = maintenance + 3–5% deficit depends on haematocrit (maintain latter at 36–43 vol%)</li> <li>3 If haematocrit is rising above 44% (or above 5% of previous value) increase rate of IV fluid to 6–7 mL/kg/hour (or 7% deficit) to prevent shock</li> <li>4 If haematocrit is still high (&gt; 45%), change IV fluid to low dose of colloid, e.g. Dextran 40 (maintenance + 3% deficit) or 2–4 mL/kg/hour (maximum dose of 30/kg/day)</li> <li>5 Decrease IV fluid when vital signs are stable, haematocrit declines and urine is clear</li> <li>6 Stop IV fluid when the child can drink more than half of normal or there is a diuresis</li> </ol>

Haematocrit of normal child is usually 35–36%, so if a child has haematocrit > 42% this means that it has risen to 20% or more above normal level.

#### **Shock that does not improve with the first 20 mL/kg bolus of Ringer-lactate or Hartmann's or 0.9% saline solution**

- 1 Continue high-flow oxygen.
- 2 Give a bolus of Dextran 40 (especially if the haematocrit is very high (> 50%) or the child has a puffy face or distended abdomen), 10 mL/kg over 15–30 minutes.
- 3 If the haematocrit is < 42% or has decreased by more than 5% consider careful transfusion of packed red cells, 5–10 mL/kg over 30 minutes to 1 hour.
- 4 If the child improves, revert to Ringer-lactate or Hartmann's solution or 0.9% saline plus 5% dextrose, 5–7 mL/kg/hour for 6 hours and follow management in steps (7) and (8) above, 5 mL/kg/hour for 6 hours.
- 5 Check vital signs every 15 minutes until the child is stable, then every hour.
- 6 Check haematocrit every 4 hours and aim to maintain it at 40–45%.
- 7 Measure fluid intake and output every 4–8 hours.

#### **Shock that does not improve with Dextran 40 bolus**

- 1 Consider giving 4.2% sodium bicarbonate, 1–2 mL/kg IV slowly over 10 minutes.
- 2 Continue giving Dextran 40 at 7 mL/kg/hour.
- 3 Consider using an inotropic drug, such as dopamine or dobutamine 5–15 micrograms/kg/minute, if the child is still shocked or not improving.
- 4 Consider transfusion with packed red cells if the child is shocked with haematocrit < 42% or haematocrit declines by more than 5% of previous value.

#### **Intractable shock with respiratory distress**

- 1 Continue high-flow oxygen.

- 2 If calculated total intake is maximum ( $\geq 7$  mL/kg/hour), haematocrit is > 40%, and shock has been present for > 24 hours, try furosemide 200–500 microgram/kg IV or 5–10 mg per dose for most children > 1 year of age.
- 3 If total intake is maximum ( $\geq 7$  mL/kg/hour), haematocrit is > 40% and duration since first shock is < 24 hours **consider giving sodium bicarbonate, give inotropic drugs and consider positive pressure ventilation with PEEP** (if available).
- 4 Drain pleural effusion if it is interfering with ventilation (and if high pressure settings are needed on the ventilator); diagnose from chest X-ray or ultrasound.
- 5 Monitor electrolytes, calcium, albumin, renal function, blood gas and blood clotting according to clinical severity.

**Blood and blood components should be given only in cases of suspected or severe bleeding or intractable shock.**

#### **Fluid management**

##### **Plasma expanders**

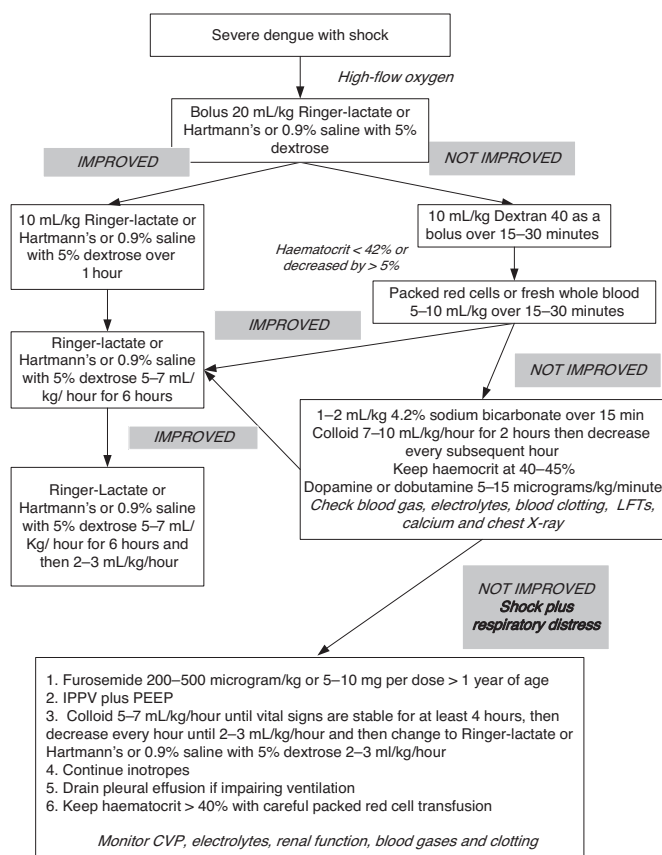

**Colloid solutions** to expand the intravascular volume:

- Dextran 40 (osmolarity = 600 mOsmol/litre), maximum 30 mL/kg/day
- 6% hydroxyethyl starch (osmolarity = 308 mOsmol/litre)
- 4.5% albumin in severe hypoalbuminaemia with moderate to massive effusion/ascites and respiratory distress.

**Blood products** to combat bleeding:

- fresh frozen plasma (FFP), 10 mL/kg/dose
- packed red cells (PRC), 5–10 mL/kg/dose
- platelet transfusion, 0.2 units/kg/dose.

**FIGURE 6.2.B.3** Management of severe dengue with shock. LFTs, liver function tests; IPPV, intermittent positive pressure ventilation; PEEP, positive end-expiratory pressure; CVP, central venous pressure.

### Crystalloids

Normal maintenance fluids are 5% dextrose in Ringer-lactate or Hartmann's or 0.9% saline solution, about 2–3 mL/kg/hour or:

Up to 10kg	= 100 mL/kg/day
From 11–20kg	= 100 mL/kg/day + 10 kg for the first 10 kg, PLUS 50 mL/kg/day × body weight in kg above 10 kg
> 20kg	= 1500 mL PLUS 20 mL/kg/day × body weight in kg > 20 kg

Example: body weight of 14 kg = 1000 mL + (4 × 50) = 1200 mL.

Example body weight of 30 kg = 1500 mL + (10 × 20) = 1700 mL.

In an obese child, use ideal body weight to calculate IV fluids. For example, for an obese 7-year-old girl with body weight 40 kg, IV fluids should be calculated from her age multiplied by 2 plus 8 (7 × 2 + 8 = 22 kg).

In practice, based on the above we can calculate IV fluids easily and rapidly as follows:

- 5 mL/kg/hour is equal to a 5% deficit if body weight < 40 kg
- 4 mL/kg/hour is equal to a 5% deficit if body weight > 40 kg

The maximum fluid that should be given in 24 hours (maximum fluid = resuscitation [20 mL/kg] + 10% deficit + maintenance) is 7 mL/kg/hour.

### Inotropic drugs

- Dopamine will increase renal blood flow: dose is 5–15 micrograms/kg/minute.
- Dobutamine is usually used in patients with poor peripheral circulation: dose is 5–15 micrograms/kg/minute.

### Severe dengue with organ involvement

Vital organs are not primarily involved in severe dengue, but are affected secondarily to plasma leakage, shock, haemorrhage and hypoxia. Notably, hepatic dysfunction and renal failure may occur especially in cases with prolonged shock.

Central nervous system involvement may be manifested by convulsions, spasticity and/or change in consciousness. Some cases have reported dengue virus in cerebrospinal fluid as in encephalitis.

### Prevention and control

There is no vaccine to protect against dengue. Development of a vaccine against dengue infection has been challenging, although there has been recent progress.

At present, the only method for controlling or preventing the transmission of dengue virus is to combat vector mosquitoes by preventing them from accessing egg-laying habitats. This is achieved by environmental management and modification, with community participation and active monitoring.

## 6.2.C Acute hepatitis

### BOX 6.2.C.1 Minimum standards

- Liver function tests.
- International normalised ratio (INR) or prothrombin time.
- Blood glucose measurement.
- Vitamin K.
- Immunisation against hepatitis B: population vaccination.

### Introduction

- Acute hepatitis results in liver dysfunction of duration less than 6 months.
- Transaminases (AST and ALT) are abnormal, but patients are not necessarily jaundiced.
- Acute hepatitis may be cholestatic, and may be complicated by acute liver failure as described in Section 5.7.A.
- Hepatitis A is common and usually self-limiting, but other important diseases may occur at the same time or appear similar and be overlooked (see Table 6.2.C.1).

TABLE 6.2.C.1 Causes of acute hepatitis-like presentation

Aetiological group	Examples	Possible cholestasis
Viral	Hepatitis A virus, hepatitis B virus, hepatitis C virus, hepatitis E virus, delta superinfection, cytomegalovirus, Epstein–Barr virus, herpes simplex, parvovirus, measles, mumps, varicella, rubella, adenovirus, ECHO, coxsackie, flaviviruses (e.g. yellow fever, dengue, Lassa, Ebola, Rift Valley fever).	Hepatitis A virus, hepatitis B virus, hepatitis E virus
Bacterial/fungal	<i>Salmonella</i> , <i>Leptospira</i> , any septicaemia	Not usually
Protozoal + parasitic	See Section 6.3.A.d and 6.3.C	Not usually
Drugs and toxins	See Section 7.4	Drug cholestasis
Shock	Cardiac arrest, post surgery, heat stroke, radiation	Occurs 7–10 days after injury
Immune	Autoimmune, lupus, Kawasaki disease	Autoimmune, lupus, Kawasaki disease
Infiltrative	Leukaemias, haemophagocytic syndromes, Hodgkin's disease	Leukaemias, Hodgkin's disease
Metabolic	Urea cycle disorders Wilson's disease	Usually not Yes

### Management of acute hepatitis

- Exclude hepatitis A with HAV IgM and attempt diagnosis with tests (if available).
- Monitor hepatic synthetic function for liver failure using prothrombin time or INR, having given IV vitamin K.
- Monitor for complications, including hypoglycaemia, encephalopathy, bone-marrow aplasia, secondary sepsis and pancreatitis (see Section 5.7.A).
- Treat complications when possible.
- Give vitamin K, 300 micrograms/kg.
- Give anti-emetics if there is severe nausea and vomiting.
- Give intravenous fluids **only if oral or nasogastric rehydration is not possible**.
- See Section 5.7.A for the management of acute liver failure if this develops.
- If available, immunise all family contacts for HAV and HBB (HAV A, two doses 2 weeks apart; HAV B, three doses, the first being given immediately, the second 1 month later, and the third 3–6 months later).

#### Hepatitis A

- Hepatitis A (HAV) is a picornavirus spread by the faecal–oral route.
- The incubation period from infection to raised transaminases is 10–20 days.
- Before jaundice is seen there may be anorexia, nausea, vomiting, fever and liver tenderness.

- Jaundice is related to age, with more than 90% of children under 2 years being asymptomatic, and only 76% of teenagers jaundiced.
- A minority of cholestatic cases have a relapsing course, and 0.1–0.2% develop acute liver failure. The prognosis for almost all is excellent with symptomatic treatment.
- Chronic liver disease does not develop, but occasional patients have a transient nodular regenerative phase with evidence of portal hypertension lasting up to 1 year. Aplastic anaemia is a rare complication.
- HAV vaccine is highly efficacious and without side effects.

#### Hepatitis B

**Acute hepatitis B** (see also section on chronic hepatitis)

- This is spread by blood and body fluid products, vertical transmission from mother to baby, and sexual contact. The risk of all such spread is much greater than for HIV infection.
- The incubation period is 60–90 days, but rarely up to 7 months.
- The risk of acute liver failure is less than 1%, and the risk of chronic liver disease depends on the patient's age: it is approximately 90% at birth, 25% in childhood and less than 10% in adults.
- Hepatitis B vaccine is usually given by three injections over 6 months, but an accelerated course can be given

over 21 days, and post-exposure vaccination is usually given in combination with immunoglobulin in a different site. All healthcare workers should be immunised against HBV and their immunity status checked.

### Hepatitis C

- The mechanisms of spread are the same as for hepatitis B, but vertical spread is rare (around 4%).
- The incubation period is 2–26 weeks, followed by acute hepatitis that is almost always asymptomatic.
- Chronic hepatitis ensues in 30–90% of cases.
- Symptomatic liver disease is almost never seen in childhood.
- Treatment with a combination of pegylated interferon and ribavirin is becoming progressively more successful (if available).

### Hepatitis E

- Spread is by the faecal–oral route and is endemic in Southern Europe, the Middle East and Asia.

- It is rare in children, and the highest rate in adolescents is 3%.
- A relapsing course is seen.
- The prognosis is usually good, but mortality is recognised in pregnant women.

### Epstein–Barr virus (EBV)

- EBV infection is accompanied by hepatosplenomegaly and hepatitis.
- The prognosis is usually good, but rare cases are complicated by lymphoproliferative disease or haemophagocytic syndrome in immune-deficient individuals.

### Cytomegalovirus (CMV)

- Spread is the same as for EBV and hepatitis, but symptoms are usually only seen in the newborn and immunocompromised.

### Parvovirus B19

- This infection can be accompanied by acute liver failure and aplastic anaemia.

## 6.2.D Human immunodeficiency virus (HIV) infection

### BOX 6.2.D.1 Minimum standards

- Preventive campaigns.
- Antenatal HIV screening.
- Antenatal and postnatal antiretroviral (ARV) drugs.
- Paediatric HIV testing.
- Antiretroviral drugs (triple drug regimes for all), including those to prevent vertical transmission guaranteed.
- Health system strengthening to provide a capacity to treat all with ARV and give supportive treatment.
- Correction of nutritional deficiencies.
- Antibacterial drugs, including anti-TB and antifungal drugs.
- Analgesia and palliative care.
- Counselling and family support.

### Introduction

The human immunodeficiency virus (HIV) epidemic has spread to all corners of the world, affecting millions of infants, children and adults. It is the most common cause of acquired immune deficiency in children. The timely and early diagnosis of neonates, infants and children with HIV is vital. However, the healthcare system of resource-limited countries has its own strengths and limitations. Pitfalls in accurate testing, poor access to health, and high financial costs are a few of the many factors that hamper efforts to limit the spread of diseases such as HIV. In addition, the management of HIV is complex and intricate. Many factors, including proper assessment and indication, counselling, availability and choice of antiretroviral drugs, toxicity, monitoring, financial burden, and social and psychosocial support have to be addressed for HIV care to be successful. Education, evaluation, building expertise, establishing HIV referral centres with diagnostic testing (including virological testing), ensuring availability of antiretroviral drugs,

monitoring and follow-up are some of the key elements necessary for programmes to have adequate impact.

### Epidemiology

- There are two major strains of the human immunodeficiency virus: HIV1 and HIV2. HIV1 is the more pathogenic, and is responsible for the global epidemic. HIV2 is largely confined to West Africa. This subsection reflects current management of HIV1, but the principles apply to both strains.
- Infection with HIV leads to progressive destruction of the cellular immune system, ultimately resulting in an acquired immune deficiency syndrome (AIDS) in the vast majority of infected individuals.
- HIV/AIDS is now one of the leading causes of death in children.
- Mother-to-child transmission results in approximately 1000 children becoming infected with HIV each day worldwide. There were 2.5 million children under 15 years old living with HIV in 2009.
- Around 97% of the world's new HIV infections occur in people living in low- and middle-income countries. About 92% of children living with HIV are from sub-Saharan Africa.
- The number of new infections fell from a peak in the late 1990s, but has now plateaued at a high incidence of 2.6 million new infections per year, just below the maximum level reached previously.
- Deaths from AIDS have decreased by 19% between 2004 and 2009 with increasing access to antiretroviral therapy.
- Around 95% of the world's HIV-infected children have been from resource-limited countries. About 90% have been from sub-Saharan Africa, but the prevalence elsewhere is rising, particularly in India, South-East Asia, and countries of the former Soviet Union.

- More than 90% of children acquire HIV perinatally (vertically) from their mothers. The rest are infected through transfusion of infected blood products or via unsterilised needles (extent unknown but probably small), or via sexual transmission among adolescents, or in younger children through child sexual abuse.
- In non-breastfed infants, vertical transmission occurs mainly around the time of delivery, with transmission rates in resource-limited countries ranging from 17% to 24%. Breastfeeding roughly doubles the risk of transmission. In breastfed cohorts from resource-limited countries the rates of transmission are 25–45%.
- Management ideally begins before birth, with counselling and voluntary testing of HIV-infected women during pregnancy, and institution of measures to reduce transmission. In almost all countries, antiretroviral therapy for mothers and infants, elective (pre-labour) Caesarean section and avoidance of breastfeeding have reduced transmission rates to less than 2%.
- Without prenatal counselling and screening, as is frequently the case in resource-limited countries, management begins only when the child becomes symptomatic, with subsequent identification of the HIV infection in the mother.
- Treatment may not be successful if presentation is at an advanced stage of immunosuppression.
- In all societies, even those with a high prevalence, HIV is a potentially stigmatising condition, and the mother or both parents may be reluctant to undergo testing. Confidentiality is essential.
- Counselling must be confidential, requires time and should be undertaken by trained staff.
- Even if a child born to an infected mother is uninfected, he or she will inevitably be affected. Between 14.4 and 18.8 million children were estimated to have lost one or both parents to AIDS in 2010 (UNAIDS data). These children may be abandoned by relatives, ostracised by the community, poorly educated and highly vulnerable. Many support themselves and surviving siblings by commercial sex work, and may acquire HIV infection as a result.

#### Natural history data

- Before the advent of **highly active antiretroviral therapy (HAART)**, infant mortality doubled and mortality

in children aged 1–5 years increased from 8 to 20 per 1000 in Harare between 1990 and 1996.

- However, even in resource-limited countries, some children may be symptom-free into the second decade of life. There is no upper age limit at which it is appropriate to test for HIV if the mother does not have a negative test after the child's birth.
- Data from large long-term prospective perinatally recruited cohort studies are limited in resource-limited countries.
- Growth failure, generalised lymphadenopathy, hepatosplenomegaly, persistent diarrhoea, pulmonary infections, chronic cough and recurrent fevers are the most frequent clinical manifestations.
- The most common causes of death are pneumonia, diarrhoea and malnutrition. Post-mortem studies from the Cote d'Ivoire and clinical studies in Malawi and South Africa showed that *Pneumocystis jiroveci* pneumonia (PCP) is a frequent cause of death in children under 15 months of age.
- Malignancy is a relatively rare AIDS-defining illness in children, compared with HIV-infected adults. However, substantial increases in Kaposi's sarcoma in children have been reported from East and Central Africa. Co-infection with the human herpes virus (HHV8) is a crucial aetiological factor. Kaposi's sarcoma typically presents with large non-tender firm mobile lymph nodes in the head and neck region, and there may be skin lesions and pulmonary disorders. Median survival in one series was only 3 months.

#### Diagnostic issues

Confirming a diagnosis of HIV infection in young children can be difficult in resource-limited settings.

**Early infant diagnosis of HIV:** exposed infants should be tested at 6 weeks or as soon as possible thereafter. Infant blood samples are sent as dried blood spots to a laboratory that has the required equipment for HIV PCR testing. This laboratory may be close by, but could also be far from the site. The results then need to be sent back to sites and returned to caregivers in a timely manner. Finally, infants who have tested positive must be started on ART.

In areas of high HIV prevalence, WHO *Integrated Management of the Child* recommends that, when

**TABLE 6.2.D.1** Signs and symptoms for use in endemic areas with limited access to diagnostic laboratories

Signs or illness specific to HIV infection	Signs or illness uncommon in HIV-negative children	Signs common in both HIV-positive and ill non-HIV-infected children
Pneumocystis pneumonia	Molluscum contagiosum with multiple lesions	Persistent diarrhoea (> 14 days)
Oesophageal candidiasis	Oral thrush (especially after the neonatal period) without antibiotic treatment and lasting > 1 month or recurrent	Failure to thrive
Herpes zoster	Generalised pruritic dermatitis	Persistent cough > 1 month
Lymphoid interstitial pneumonia	Recurrent severe infections (three or more per year)	Generalised lymphadenopathy
Kaposi's sarcoma	Persistent and/or recurrent fever lasting > 1 week	Hepatosplenomegaly
Chronic parotid enlargement	Neurological dysfunction (progressive neurological impairment, delayed development, intellectual impairment, hypertonia)	Chronic otitis media
Recto-vaginal fistula (rare)	Failure to thrive in a fully breastfed infant < 6 months of age	Moderate or severe malnutrition

assessing sick children aged 2 months to 5 years, health-care workers ask about a history of pneumonia, persistent diarrhoea, ear discharge or very low weight, and look for oral thrush, parotid enlargement and generalised persistent lymphadenopathy. If there are two or more of the above, HIV infection should be suspected and an HIV antibody test performed.

### Clinical diagnosis

- The symptoms and signs are often non-specific. The most recent modified WHO clinical case definition for paediatric AIDS is a useful tool for epidemiological surveillance, but lacks sensitivity and has a low positive predictive value (PPV). It is therefore not useful for confirming a diagnosis of HIV infection in an individual child.
- The presence of oral candidiasis does not distinguish HIV-infected from HIV-uninfected children. However, failure of oral candidiasis to respond to treatment or rapid relapse is a highly specific sign of HIV infection. After the neonatal period, the presence of oral thrush without antibiotic treatment, or lasting over 30 days despite treatment, or recurring, or extending beyond the tongue, is highly suggestive of HIV infection. Also typical is extension to the back of the throat, which indicates oesophageal candidiasis.
- Chronic parotitis, the presence of unilateral or bilateral parotid swelling (just in front of the ear) for 14 or more days, with or without associated pain or fever or shingles, is highly suggestive of HIV infection.
- Shingles is unusual in healthy children. Herpes zoster ophthalmicus (i.e. shingles around one eye) is said to have greater than 95% PPV for HIV infection in African children.
- Geographical variation in patterns of disease must be recognised. *Penicillium marneffei* infection, an opportunistic fungal disease that presents with nodular skin lesions, is an AIDS-defining illness that has been reported in South-East Asia. Giant molluscum contagiosum has been a presenting sign in children in Eastern Europe.
- None of these clinical features is a sensitive marker of HIV infection in childhood populations, in that a minority of HIV-infected children manifest them.

There are many clinical signs or conditions that are quite specific to HIV infection, which should be strongly suspected if these conditions are present (see Table 6.2.D.1). Some of these features are listed below.

- 1 Signs or conditions that are very specific to HIV-infected children:
  - Pneumocystis pneumonia (PCP).
  - Oesophageal candidiasis.
  - Lymphoid interstitial pneumonia (LIP).
  - Kaposi's sarcoma.
- 2 Signs that may indicate possible HIV infection:
  - **Recurrent infection:** three or more severe episodes of a bacterial infection (e.g. pneumonia, meningitis, sepsis, cellulitis) in the past 12 months.
  - **Oral thrush:** after the neonatal period, the presence of oral thrush in the absence of antibiotic treatment, or lasting over 30 days despite treatment, or recurring, or extending beyond the tongue.
  - **Chronic parotitis:** the presence of unilateral or bilateral parotid swelling for 14 or more days.

- **Generalised lymphadenopathy:** the presence of enlarged lymph nodes in two or more non-inguinal regions without any apparent underlying cause.
  - **Hepatomegaly** with no apparent cause.
  - **Persistent and/or recurrent fever.**
  - **Neurological dysfunction:** progressive neurological impairment, microcephaly, developmental delay, hypertonia, encephalopathy.
  - **Herpes zoster.**
  - **HIV dermatitis:** typical skin rashes include erythematous papular rashes, extensive fungal infections of the skin, scalp and nails, and extensive molluscum contagiosum.
  - **Chronic suppurative lung disease.**
- 3 Signs that are common in HIV-infected and non-HIV-infected children:
    - Chronic otitis media.
    - Persistent diarrhoea.
    - Moderate or severe malnutrition.

### Counselling and testing

If there are reasons to suspect HIV infection, and the child's HIV status is not known, the family should be offered diagnostic testing for HIV.

Counselling used to be more complex when there was no treatment available. There is now no question that it is in the child's best interest to be tested so that treatment can be given to prolong life if they are HIV-positive. The lessons of obtaining informed consent still apply, just as with any other important investigation. If the mother has not already been tested, a positive result in a child is most likely to mean that the mother is infected, too. However, if the mother is not present when the child presents, the onus of responsibility of the paediatrician is to the child, and testing should not be delayed.

The additional consideration with testing for HIV is the stigma associated with the diagnosis. When HIV meant inevitable death, there was enormous fear of the diagnosis. The potentially better prognosis has been hard to accept when so many present too late. Stigma is also associated with the fact that it is a sexually transmitted disease. This raises issues of where the infection was acquired and contact tracing. The fear of domestic violence and social ostracisation sometimes creates reluctance to allow children to be tested.

The process of counselling starts with always ensuring that the test is done with consent. The person giving consent should be the carer at the time when the test is indicated. If the child is of an age at which they can be responsible for taking their own medicines, they can give their own consent for testing. There are no surrogate tests for HIV, such as lymphocyte counts; the appropriate test according to what is available should always be done. If there is delay in getting a result it may be necessary to start appropriate treatment – for example, for suspected PCP pneumonia with IV co-trimoxazole.

If there is refusal to allow testing, the test cannot be carried out. If the test is positive, the family need to have confidence in the healthcare professionals to ensure adherence to treatment. Counselling requires time, and must be done by trained staff. If staff at the first referral level have not been trained, assistance should be sought from other sources, such as local community AIDS support organisations. A time limit should be set to prevent repeated

procrastination and the risk of death from opportunistic infection.

HIV counselling should take account of the child as part of a family. This should include the psychological implications of HIV infection for the child, mother, father and other family members. Counselling should stress that, although cure is currently not possible, there is much that can be done to improve the quality and duration of the child's life. Antiretroviral treatment (ART) is available and greatly improves survival and the quality of life of the child and the parents. Counselling should make it clear that the hospital staff want to help, and that the mother should not be frightened of going to a health centre or hospital early in an illness, even if this is only to ask questions.

HIV is talked about much more openly now than was the case at the start of the epidemic, and testing is seen as an expected part of routine healthcare. The request for testing should not be built up as a major event, but included as part of the diagnostic work-up along with malaria, TB and other investigations.

As mentioned above, counselling requires time, and must be done by trained staff.

### Indications for HIV counselling

HIV counselling is indicated in the following situations.

#### Child with unknown HIV status presenting with clinical signs of HIV infection and/or risk factors (e.g. a mother or sibling with HIV/AIDS)

- Make time for the counselling session.
- Take advice from local people experienced in offering testing, so that any advice given is consistent with what the mother will receive from professional counsellors at a later stage.
- Where available, arrange an HIV test, according to national guidelines, to confirm the clinical diagnosis, alert the mother to HIV-related problems, and discuss prevention of future mother-to-child transmission.

Note the following:

- 1 If HIV testing is not available, discuss the presumptive diagnosis of HIV infection in the light of the existing signs and symptoms and risk factors.
- 2 In countries with generalised HIV epidemics, routine healthcare provider-initiated testing and counselling (PITC) is recommended for all children seen in paediatric health services (World Health Organization, 2007).

#### Child known to be HIV-infected but responding poorly to treatment, or needing further investigations

Discuss the following:

- the parents' understanding of HIV infection
- management of current problems
- the role of ART and adherence to regular drug administration
- the need to refer to a higher level, if necessary
- support from community-based groups (if available).

#### Child known to be HIV-infected who has responded well to treatment and is to be discharged (or referred to a community-based care programme)

Discuss the following:

- the reason for referral to a community-based care programme, if appropriate
- follow-up care

- risk factors for future illness
- immunisation and HIV
- adherence and ART treatment support.

### Laboratory diagnosis

The definitive diagnosis of HIV requires laboratory confirmatory testing. The HIV antibody test is commonly used as a screening test. However, in the neonatal and infantile period, the antibody test is not recommended. This is because the maternal HIV antibodies readily cross the placenta and persist in the neonate for up to 18 months. Also, all screening tests should be confirmed by a second test. The following are some of the tests used for laboratory diagnosis of HIV in children:

- Antibody tests:
  - HIV IgG antibody tests.
  - Rapid Test.
- Virological tests:
  - HIV DNA polymerase chain reaction (PCR).
  - HIV RNA PCR.
  - HIV culture.
- P24 antigen assay:
  - Direct.
  - Acid hydrolysis.

DNA-based assays are the most reliable for diagnosis, and are recommended for diagnosis in infants. However, the cost and availability of tests may be an issue in resource-limited countries. The simplest laboratory test is an HIV antibody test, usually done by enzyme-linked immunosorbent assay (ELISA). However, even this may not be affordable or available in many settings.

The WHO recommends the use of a presumptive clinical diagnosis of severe HIV disease in the **absence** of virologic testing **if**:

- an infant's HIV exposure is confirmed by antibody testing **and** if either:
  - clinical stage 3 or 4 or AIDS-indicator condition(s) are present **or**
  - the child has two or more of the following: oral thrush, severe pneumonia, severe sepsis.

A **presumptive** diagnosis of AIDS can also be made in an antibody-positive infant **if** CD4 percentages are below 20% **or** other factors are present, including recent HIV-related maternal death or advanced HIV disease in the mother.

Infants acquire maternal HIV IgG transplacentally, and this can be detected by ELISA up to 18 months of age. Thus antibody tests cannot reliably distinguish infected from uninfected children until they are 18 months old. Additional diagnostic challenges arise if the child is still breastfeeding or has been breastfed. Although HIV infection cannot be ruled out until 18 months for some children, many children will have lost HIV antibodies between 9 and 18 months of age. The importance of this is that a rapid antibody test can be done if the mother is unwilling or unavailable to be tested herself. If the antibody test is negative and the child has not been breastfed in the last 6 weeks, there is then no need for further testing unless there is ongoing exposure (e.g. through breastfeeding). If the antibody is positive, this does not mean that the child is infected, but if other signs of immune deficiency are present it may warrant empirical treatment according to WHO guidelines if PCR testing is not available.

**FIGURE 6.2.D.1** Algorithm for diagnosing HIV infection in infants and children less than 18 months of age.

Many children born to HIV-infected mothers may die before this age, and a diagnosis of HIV infection may be presumptive, dependent on signs and symptoms. Thus,

based on age, the clinical, serological and virological tests and status of breastfeeding will determine the diagnosis of a child undergoing evaluation (see Table 6.2.D.2).

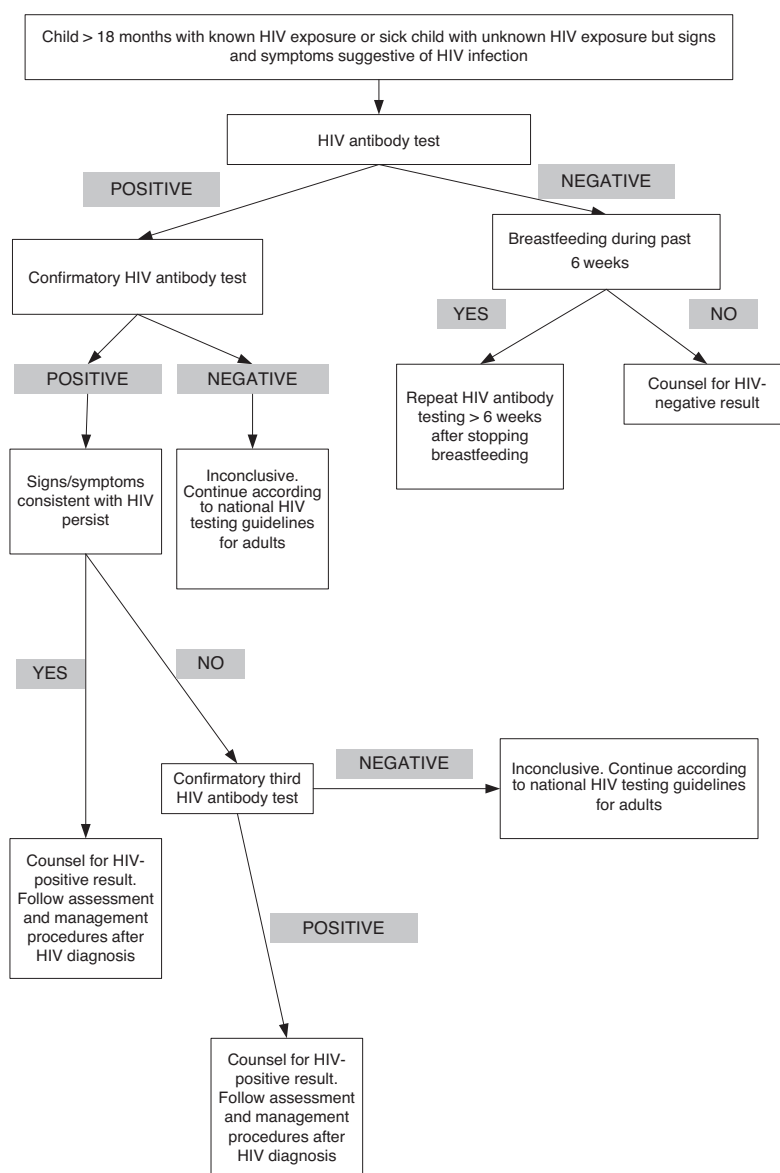

**TABLE 6.2.D.2** Proposed methods for diagnosing HIV in children (born to mothers identified as HIV-positive or with unknown HIV status) in resource-limited settings\* (see Figure 6.2.D.1)

Diagnostic method	Age of child		
	< 12 months	12–18 months	> 18 months
Clinical staging	Yes	Yes	Yes
Serological (antibody)	May be helpful <sup>†</sup>	Yes <sup>‡</sup>	Yes
Virological	Yes	Yes, if serology is positive	No, serology is definitive

\*If the child is breastfeeding, a negative diagnostic test, either serological or virological, would have to be repeated 6 weeks after cessation of all breastfeeding.

<sup>†</sup> A positive antibody test in a child under 12 months of age defines the exposure status of the child and may be helpful when the mother's HIV status is unknown.

<sup>‡</sup> By the age of 12 months, HIV antibody-positive testing can be considered indicative of probable HIV infection, and should be confirmed by a second antibody test after 18 months.

**FIGURE 6.2.D.2** Algorithm for diagnosing HIV infection in infants and children aged 18 months or older.

Algorithms for diagnosis are shown in Figures 6.2.D.1 and 6.2.D.2.

**Notes to Figure 6.2.D.1.**

- 1 If HIV exposure is not certain, consider testing the mother first before doing a virological test on the child. If the mother tests negative for HIV, explore other risk factors for HIV transmission.
- 2 In infants and children under 18 months of age considered to be HIV-uninfected who develop signs or symptoms suggestive of HIV, virological testing should be performed.
- 3 If virological testing is not available, antibody testing can be performed. By the age of 12 months most uninfected children will have lost maternal antibody, and positive antibody testing at this time usually indicates HIV infection in the child (96% specificity). In infants younger than 12 months where antibody testing is still positive, a presumptive clinical diagnosis of severe HIV disease may need to be made, as it is not possible to reliably establish HIV infection with antibody testing before the

age of 12 months (i.e. specificity at age 9–12 months is 74–96%). In this situation, confirmation of the presumptive clinical diagnosis of HIV infection by virological testing should be sought as soon as possible.

- 4 Antibody testing can be performed at the age of 12 months (see above).
- 5 Where the infant is being considered to be HIV-infected based upon a positive antibody test performed at 12 months of age or older, the result should be confirmed by virological testing (in children less than 18 months of age) or by antibody testing (once they are over 18 months of age).

**Notes to Figure 6.2.D.2.**

- 1 A definitive diagnosis of HIV infection in children aged  $\geq 18$  months can be made with antibody testing. HIV testing procedures for children aged  $\geq 18$  months follow the national HIV testing guidelines for adults. Virological testing can be used to diagnose HIV infection at any age.
- 2 One positive HIV antibody test (rapid test or ELISA) should be confirmed by a second HIV antibody test

(rapid test or ELISA) using an assay that relies on a different antigen or has different operating characteristics. In low-HIV-prevalence settings, a third confirmatory test may be required.

- 3 Children who are breastfed have an ongoing risk of acquiring HIV infection. Therefore HIV infection can be excluded only after stopping breastfeeding for more than 6 weeks.

### **HIV antibody test (ELISA or rapid tests)**

Rapid tests are widely available and are safe, effective, sensitive and reliable for diagnosing HIV infection in children above the age of 18 months. For those under 18 months, HIV antibody tests are a sensitive reliable way to exclude HIV infection in non-breastfeeding children. For those children under 18 months, confirm all positive HIV antibody tests by virological tests as soon as possible (see below). Where this is not possible, repeat antibody testing at 18 months.

Rapid HIV tests can be used to exclude HIV infection in a child presenting with malnutrition or other serious clinical events in areas with high HIV prevalence.

To confirm the diagnosis, it is necessary to use assays that detect the virus itself or viral components. Such tests include **antigen detection tests, viral culture, amplification techniques and HIV-specific IgA tests.**

### **Virological testing**

Virological testing for HIV-specific RNA or DNA is the most reliable method of diagnosing HIV infection in children under 18 months of age. This requires sending a blood sample to a specialised laboratory that can perform this test, and these are becoming increasingly available in large centres in many countries. It is relatively inexpensive, easy to standardise, and can be done using dried blood spots. In infants and children undergoing virological testing, the following assays (and respective specimen types) are potentially available:

- HIV DNA on whole blood specimens or dried blood spots (DBS)
- HIV RNA on plasma or DBS
- ultrasensitive p24 antigen (Up24 Ag) on plasma or DBS.

The new ultrasensitive p24 assay is as accurate as PCR virology, significantly less expensive, and less resource demanding when used to diagnose HIV. It is particularly valuable in infants under 12 months old.

A test at birth will only detect *in-utero* infection, whereas most infection occurs at delivery. Infected infants can suffer life-threatening infections in the first weeks of life. Where there is a high risk of infection (e.g. a mother who seroconverts in pregnancy, has a low CD4 count or other genital lesions and has had no antiretrovirals), testing should be done at 2 weeks of age. Where the risk is low (e.g. a mother who has been on HAART throughout pregnancy), the test can be delayed until 6 weeks of age. At the first DTP immunisation of all infants, the maternal HIV status should be checked from records or rapid testing. If it is positive or unavailable, the child should be tested. All HIV-exposed infants should have HIV virological testing at 4–6 weeks of age or at the earliest opportunity thereafter.

If the child has had zidovudine (ZDV) prophylaxis during and after delivery, virological testing is not recommended until 4–8 weeks after delivery, as ZDV interferes with the reliability of the test.

One virological test that is positive at 4–8 weeks is

sufficient to diagnose infection in a young infant. If the young infant is still breastfeeding, and the DNA virological test is negative, it needs to be repeated 6 weeks after the complete cessation of breastfeeding to confirm that the child is not HIV infected.

Infants with signs or symptoms suggestive of HIV infection must undergo HIV serological testing and, if this is positive, virological testing. In breastfeeding infants or children it is strongly recommended that breastfeeding is not discontinued in order to perform any kind of diagnostic HIV test. In sick infants in whom HIV infection is being considered as an underlying cause of symptoms and signs, and virological testing is not available, HIV serological testing and the use of a clinical algorithm for presumptive clinical diagnosis of HIV infection are strongly recommended.

In infants with an initial positive virological test result, it is strongly recommended that ART be started without delay and, at the same time, a second specimen be collected to confirm the initial positive virological test result. **Do not delay ART. In infected infants, immediate initiation of ART saves lives, and commencement of ART should not be delayed while waiting for the results of the confirmatory test. Results from the CHER trial suggest initiation of ART before 12 weeks of age results in a 75% reduction in early mortality.**

**(Cotton MF, Violari A, Otwombe K, *et al.* (2013) Early time-limited antiretroviral therapy versus deferred therapy in South African infants infected with HIV: results from children with HIV early antiretroviral (CHER) randomised trial. *Lancet* 382: 1555–63.)**

Test results from virological testing in infants should be returned to the clinic and the child and their mother or carer as soon as possible, but at the very latest within 4 weeks of specimen collection. Positive test results should be fast-tracked to the mother–baby pair as soon as possible to enable prompt initiation of ART.

All infants with unknown or uncertain HIV exposure who are being seen in healthcare facilities at or around the time of birth or at the first postnatal visit (usually 4–6 weeks), or at another child health visit, should have their HIV exposure status ascertained.

Clinically well, HIV-exposed infants should undergo HIV serological testing at around 9 months of age (or at the time of the last immunisation visit). Those who have positive serological assays at 9 months should have a virological test to identify whether they need ART.

Recently the WHO Technical Reference Group for Paediatric HIV/ART and Care made the following key recommendations with regard to when and how to test for HIV in children:

- 1 Infants known to have been exposed to HIV should have a virological test (HIV nucleic acid test) at 4–6 weeks of age, or at the earliest opportunity for infants seen after 4–6 weeks.
- 2 Urgent HIV testing is recommended for any infant presenting to healthcare facilities with signs, symptoms or medical conditions that could indicate HIV.
- 3 All infants should have their HIV exposure status established at their first contact with the healthcare system, ideally before 6 weeks of age.
- 4 Infants under 6 weeks of age, of unknown HIV exposure status and in settings where local or national antenatal HIV seroprevalence is greater than 1%, should be offered maternal or infant HIV antibody testing and counselling in order to establish their exposure status.

**Other laboratory tests**

- A low CD4 count or CD4:CD8 ratio suggests HIV infection, but requires specialised equipment. A low total lymphocyte count is a much less expensive though less specific surrogate marker of HIV infection and immunosuppression.
- HIV infection can also cause anaemia or thrombocytopaenia. It is appropriate to test for HIV in children who present with low platelet counts.
- Lack of thymic shadow on chest X-ray is a feature of advanced disease, but is clearly not specific, as the thymus tends to shrink in volume in response to a variety of acute infections in childhood.

**Assessment of HIV-infected and HIV-exposed children**

Any child with an illness compatible with HIV infection should be properly evaluated irrespective of HIV exposure. This includes neonates, infants and children with perinatal

exposure, and those with specific signs and symptoms suggestive of HIV infection, chronic or unexplained illness, or known exposure during childhood. Figure 6.2.D.3 shows a useful algorithm that can be used by paediatricians and other clinical care providers for the initial evaluation and management of children with known exposure to HIV, or sick children with symptoms suggestive of HIV infection but unknown history of exposure.

**Notes to Figure 6.2.D.3.**

- 1 An expert in the management of children with HIV should be consulted wherever this is feasible.
- 2 If HIV is suspected, compassionate counselling before HIV testing should be arranged.
- 3 Maternal advanced HIV disease and low CD4 are risk factors for HIV transmission.
- 4 Successful treatment with ART in mothers reduces the risk of transmission.
- 5 PMTCT using ZDV monotherapy alone, ZDV plus NVP single dose, and NVP single dose alone is associated

**FIGURE 6.2.D.3** Initial assessment of a child with known HIV exposure or a sick child with unknown HIV exposure but with suspected HIV infection. MTCT, mother-to-child transmission; ART, antiretroviral therapy; PCP, pneumocystis pneumonia.

with transmission rates of approximately 5–10%, 3–5% and 10–20%, respectively.

- 6 An infant remains at risk of acquiring HIV for as long as he or she is breastfed.

### Perinatally acquired HIV infection

HIV1 transmission occurs more frequently than that of HIV2. It occurs in late pregnancy, during delivery and through breastfeeding, and transmission is more likely if any of the following factors are present:

- advanced maternal HIV disease
- premature labour
- prolonged rupture of membranes
- contact with maternal blood
- in the first twin
- maternal genital infection.

### Prevention of mother-to-child transmission (PMTCT) of HIV and infant feeding in the context of HIV

HIV transmission may occur during pregnancy, labour and delivery, or through breastfeeding. The best way to prevent transmission is to prevent sexually acquired HIV infection, especially in pregnant women, and to prevent unintended pregnancies in HIV-positive women. If an HIV-infected woman becomes pregnant, she should be provided with services including antiretroviral drugs, safe obstetric practices, and infant feeding counselling and support (see Section 2.8.C).

The key recommendations of the 2010 WHO guidance on ARV drugs for treatment of pregnant women and prevention of HIV in infants are as follows:

#### Women who are immunocompromised

As early as possible, provide ART for all HIV-positive pregnant women both to benefit the health of the mother and to prevent HIV transmission to her child during pregnancy and breastfeeding.

Start lifelong ART for all pregnant women with severe or advanced clinical disease (stage 3 or 4), or with a CD4 count of  $\leq 350$  cells/mm<sup>3</sup>, regardless of symptoms. HIV-positive pregnant women in need of treatment for their own health (i.e. as soon as the eligibility criteria are met) should start ART irrespective of gestational age, and should continue with it throughout pregnancy, delivery, during breastfeeding and thereafter.

The recommended first-line regimens for pregnant women are as follows:

- AZT + 3TC + NVP **or**
- AZT + 3TC + EFV **or**
- TDF + 3TC (or FTC) + NVP **or**
- TDF + 3TC (or FTC) + EFV.

The infant is given NVP or AZT starting as soon as possible after birth (aim for less than 6 hours postpartum) and continued for 4–6 weeks.

#### Women who are not immunocompromised

Antiretroviral (ARV) prophylaxis is indicated for HIV-positive pregnant women with relatively strong immune systems who do not need ART for their own health. This would reduce the risk of HIV transmission from mother to child. There are two options, both of which should start early in pregnancy, at 14 weeks or as soon as possible thereafter.

The two options provide a significant reduction in MTCT with equal efficacy in this group of women who are not eligible for ART.

**Option A:** Twice daily AZT for the mother during pregnancy; if the mother has less than 4 weeks of AZT, give single-dose nevirapine during labour, and AZT and lamivudine during labour and for 7 days postpartum. Give the infant prophylaxis with either AZT or NVP for 6 weeks after birth if he or she is not breastfeeding. If the infant is breastfeeding, daily NVP infant prophylaxis should be continued for 1 week after the end of the breastfeeding period.

**or**

**Option B:** a three-drug prophylactic regimen for the mother, taken during pregnancy and throughout the breastfeeding period, as well as infant prophylaxis for 6 weeks after birth, whether or not the infant is breastfeeding.

**Option B+:** all pregnant and breastfeeding women infected with HIV should initiate ART as lifelong treatment.

### Breastfeeding

The global availability of ART means that there is enough evidence for the WHO to recommend breastfeeding for mothers with HIV.

Even with ART there is still a small risk of HIV transmission, particularly if there is any interruption to treatment, either in supply or absorption (due to diarrhoea or vomiting). HIV can be transmitted through breast milk at any point during lactation, so the rate of infection in breastfed infants increases with duration of breastfeeding.

In many countries, public health services where there is poor access to clean drinking water and alternatives to breastfeeding have not been able to adequately support and provide safe replacement feeding. HIV-positive mothers have faced the dilemma of whether to give their babies all the benefits of breastfeeding but expose them to the risk of HIV infection, or avoid all breastfeeding and increase the risk of their baby's death from diarrhoea and malnutrition.

The effectiveness of ART in reducing transmission through breastfeeding has resulted in two major changes in 2012 from previous guidelines:

- 1 National health authorities should decide whether health services will principally counsel and support HIV-positive mothers to either:
  - breastfeed and receive ARV interventions **or**
  - avoid all breastfeeding, as the strategy that is most likely to give infants the greatest chance of HIV-free survival.
- 2 In settings where national authorities recommend that HIV-positive mothers should breastfeed, and provide ARVs to prevent transmission, mothers should exclusively breastfeed their infants for the first 6 months of life, introducing appropriate complementary foods thereafter, and should continue breastfeeding for the first 12 months of life.

Mothers who are known to be HIV infected and who decide to stop breastfeeding at any time should stop gradually over 1 month. Stopping breastfeeding abruptly is not advisable (World Health Organization, 2010).

These new guidelines have great potential to improve the mother's own health and to reduce the mother-to-child HIV transmission risk to 5% or lower in a breastfeeding population in the absence of any interventions and with continued breastfeeding. With ART the WHO is aiming

for complete prevention of mother-to-child transmission worldwide by 2015.

Where a decision has been made to continue breastfeeding because the child is already infected, infant feeding options should be discussed for future pregnancies. This should be carried out by a trained and experienced counsellor.

If a child is known to be HIV-infected and is being breastfed, encourage the mother to continue breastfeeding if living in a resource-limited country, as there is usually a high risk of gastroenteritis in such regions.

If the mother is known to be HIV-positive and the child's HIV status is unknown, the mother should be counselled about the benefits of breastfeeding as well as the risk of HIV transmission through breastfeeding. If replacement feeding is acceptable, feasible, affordable, sustainable and safe, avoidance of further breastfeeding is recommended. Otherwise, exclusive breastfeeding should be practised if the child is less than 6 months of age, and breastfeeding should be discontinued as soon as these conditions are in place.

Infants born to HIV-positive mothers who have escaped perinatal infection have a lower risk of acquiring HIV if they are not breastfed. However, their risk of death may be increased if they are not breastfed in situations where there is no regular access to nutritionally adequate, safely prepared breast milk substitutes, and there is a high risk of gastroenteritis.

Counselling should be provided by a trained and experienced counsellor. Take advice from local people experienced in counselling so that any advice given is consistent with what the mother will receive from professional counsellors at a later stage.

If the mother decides to use breast milk substitutes, counsel her about their correct use and demonstrate their safe preparation.

### Management of the child with a suspected or proven HIV infection

- The aim of treatment should be to maintain the best possible quality of life for the child for as long as possible, without bankrupting the family. This disease affects the whole family, and the child must be treated in the context of the needs of all of the family.
- Currently there are far more questions than evidence-based answers; published data on many management issues in the context of resource-limited countries are not available.
- Much can be achieved with compassionate supportive care, by applying existing guidelines (such as Integrated Management of Childhood Illness algorithms) with an awareness of the need for early diagnosis and intervention in the HIV-infected child.
- Diagnosis of infections such as tuberculosis, lower respiratory infections, bacteraemia (particularly with non-typhoid salmonellae, staphylococci or streptococci) and opportunistic infections can be difficult, and often relies on empirical trials of therapy.

A low threshold for antibiotic use is appropriate, but may exacerbate diarrhoea and candidiasis, and may only be effective if given IV or IM, in the presence of diarrhoea and malabsorption.

Most infections in HIV-positive children are caused by the same pathogens as in HIV-negative children, although they may be more frequent, more severe and occur repeatedly. There is recent evidence that *Staphylococcus aureus* may be more invasive in children with HIV.

### Clinical staging of HIV infection

In a child with diagnosed or highly suspected HIV infection, a clinical staging system helps to identify the degree of damage to the immune system and to plan treatment and care options. The stages determine the likely prognosis of HIV, and are a guide as to when to start, stop or substitute ARV therapy in HIV-infected children.

The clinical stages identify a progressive sequence from least to most severe, such that the higher the clinical stage the poorer the prognosis. For classification purposes, once a stage 3 clinical condition has occurred, the child's prognosis will probably remain that of stage 3, and will not improve to that of stage 2, even with resolution of the original condition, or the appearance of a new stage 2 clinical event. ART with good adherence dramatically improves the prognosis.

The clinical staging events can also be used to identify the response to ARV treatment if there is no easy or affordable access to viral load or CD4 testing.

**TABLE 6.2.D.3 WHO paediatric clinical staging system for use in children under 13 years with confirmed laboratory evidence of HIV infection (HIV antibody where age is > 18 months, DNA or RNA virological testing where age is < 18 months)**

Stage 1	<ul style="list-style-type: none"> <li>• Asymptomatic</li> <li>• Persistent generalised lymphadenopathy (PGL)</li> </ul>
Stage 2	<ul style="list-style-type: none"> <li>• Unexplained persistent hepatosplenomegaly</li> <li>• Papular pruritic eruptions</li> <li>• Fungal nail infections</li> <li>• Lineal gingival erythema (LGE)</li> <li>• Extensive wart virus infection</li> <li>• Extensive molluscum infection (&gt; 5% of body area)</li> <li>• Recurrent oral ulcerations (two or more episodes in 6 months)</li> <li>• Parotid enlargement</li> <li>• Herpes zoster</li> <li>• Recurrent or chronic upper respiratory tract infections (otitis media, otorrhoea, sinusitis, two or more episodes in any 6-month period)</li> </ul>
Stage 3	<ul style="list-style-type: none"> <li>• Unexplained moderate malnutrition not responding to standard therapy</li> <li>• Unexplained persistent diarrhoea (for &gt; 14 days)</li> <li>• Unexplained persistent fever (intermittent or constant, for &gt; 1 month)</li> <li>• Oral candidiasis (outside the neonatal period)</li> <li>• Oral hairy leukoplakia</li> <li>• Pulmonary tuberculosis<sup>1</sup></li> <li>• Severe recurrent presumed bacterial pneumonia (two or more episodes in 6 months)</li> <li>• Acute necrotising ulcerative gingivitis or periodontitis</li> <li>• Lymphoid interstitial pneumonia (LIP)</li> <li>• Unexplained anaemia (&lt; 8 grams/dL), neutropenia (&lt; 500/mm<sup>3</sup>) or thrombocytopenia (&lt; 30 000/mm<sup>3</sup>) for &gt; 1 month</li> </ul>

(continued)

Stage 4	<ul style="list-style-type: none"> <li>● Unexplained severe wasting or severe malnutrition not responding to standard therapy</li> <li>● Pneumocystis pneumonia</li> <li>● Recurrent severe presumed bacterial infections (two or more episodes within 1 year, e.g. empyema, pyomyositis, bone or joint infection, or meningitis, but excluding pneumonia)</li> <li>● Chronic orolabial or cutaneous herpes simplex infection (for &gt; 1 month)</li> <li>● Disseminated or extrapulmonary tuberculosis</li> <li>● Kaposi's sarcoma</li> <li>● Oesophageal candidiasis</li> <li>● Symptomatic HIV seropositive infant &lt; 18 months of age with two or more of the following: oral thrush, with or without severe pneumonia, with or without failure to thrive, with or without severe sepsis<sup>2</sup></li> <li>● CMV retinitis</li> <li>● CNS toxoplasmosis</li> <li>● Any disseminated endemic mycosis, including cryptococcal meningitis (e.g. extrapulmonary cryptococcosis, histoplasmosis, coccidiomycosis, penicilliosis)</li> <li>● Cryptosporidiosis or isosporiasis (with diarrhoea for &gt; 1 month)</li> <li>● Cytomegalovirus infection (onset at age &gt; 1 month in an organ other than liver, spleen or lymph nodes)</li> <li>● Disseminated mycobacterial disease other than tuberculous</li> <li>● Candida of trachea, bronchi or lungs</li> <li>● Acquired HIV-related recto-vesical fistula</li> <li>● Cerebral or B-cell non-Hodgkin's lymphoma</li> <li>● Progressive multifocal leukoencephalopathy (PML)</li> <li>● HIV encephalopathy</li> <li>● HIV-related cardiomyopathy</li> <li>● HIV-related nephropathy</li> </ul>
---------	--

<sup>1</sup> TB may occur at any CD4 count, and CD4% should be considered where available.

<sup>2</sup> Presumptive diagnosis of stage 4 disease in seropositive children under 18 months of age requires confirmation with HIV virological tests, or with HIV antibody test if over 18 months of age.

### Antiretroviral therapy (ART)

Antiretroviral (ARV) drugs are becoming more widely available, and have revolutionised the care of children with HIV/AIDS. ARV drugs are not a cure for HIV, but they have dramatically reduced mortality and morbidity, and improved the quality and length of life. The WHO recommends that in resource-limited settings, HIV-infected adults and children should start ARV therapy based upon clinical or immunological criteria, and using simplified standardised treatment guidelines.

Resistance to single or dual agents is quick to emerge, so **single-drug regimens are contraindicated**. Indeed **at least three drugs are the recommended minimum standard for all settings**. Although new ARV drugs are coming on to the market, frequently these are not available for use in children, due to lack of suitable formulations or dosage data, or their high costs.

As children with HIV are often part of a household that includes an adult with HIV, ideally access to treatment and ARV drugs needs to be ensured for other family members, and where possible similar drug regimens should be used. Fixed-dose combinations are increasingly available, and are preferred as they promote and support treatment adherence, as well as reducing the cost of treatment. Existing tablets often cannot be divided into lower dosages for children (under 10 kg), so syrups or solutions and suspensions are needed.

The underlying principles of ART and the choice of first-line ART in children are largely the same as for adults. However, it is also important to consider the following:

- availability of a suitable formulation that can be taken in appropriate doses
- simplicity of the dosage schedule
- taste/palatability and thus compliance in young children
- the ART regimen that the parent(s) or carers are or will be taking.

Suitable formulations for children are not available for some ARVs (particularly the protease inhibitor class of drugs).

### Antiretroviral drugs

Antiretroviral drugs fall into three main classes, namely nucleoside analogue reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), and protease inhibitors (PIs) (see Table 6.2.D.4).

#### Triple therapy is the standard of care.

The WHO currently recommends that first-line regimens should be based upon two nucleoside analogue reverse transcriptase inhibitors (NRTIs) plus one non-nucleoside drug (NNRTI). The use of triple NRTI as first-line therapy is currently considered a secondary alternative because of recent research findings in adults. Protease inhibitors are usually recommended as part of second-line regimens in most resource-limited settings.

Efavirenz (EFV) is the NNRTI of choice in children who are on rifampicin, if treatment needs to start before anti-tuberculous therapy is completed.

For drug dosages and regimens, see Appendix 4.

### Calculation of drug dosages

Drug doses are given per kg for some drugs and per m<sup>2</sup> surface area of the child for others. A table giving the equivalent weights of various surface area values is provided in Section 9 of this textbook, to aid dosage calculation. In general, children metabolise PI and NNRTI drugs faster than adults, and require higher than adult equivalent doses to achieve appropriate drug levels. Drug doses have to be increased as the child grows, otherwise there is a risk of under-dosage and development of resistance.

### Formulations

Liquid formulations may not be readily available, are more expensive, and may have a reduced shelf-life. As the child gets older, the amount of syrup that needs to be taken becomes quite considerable. Therefore, in patients over 10 kg in weight, it is preferable to give parts of scored tablets or combination preparations (see Appendix 4).

**TABLE 6.2.D.4** Classes of antiretroviral drugs recommended for use in children in resource-limited settings

<i>Nucleoside analogue reverse transcriptase inhibitors (NRTIs)</i>		
Zidovudine	ZDV/AZT	180–240 mg/m <sup>2</sup> twice daily
Lamivudine	3TC	4 mg/kg twice daily up to a maximum of 150 mg twice daily
Stavudine	d4T	1 mg/kg twice daily up to 30 mg twice daily
Didanosine	ddl	90–120 mg/m <sup>2</sup> /dose twice daily
Abacavir	ABC	8 mg/kg/dose given twice daily up to 300 mg twice daily
<i>Non-nucleoside reverse transcriptase inhibitors (NNRTIs)</i>		
Nevirapine	NVP	160–200 mg/m <sup>2</sup> up to a maximum of 200 mg twice daily
Efavirenz	EFV	15 mg/kg/day up to 600 mg once daily
Etravirine	ETV	200 mg twice daily for adolescents
<i>Protease inhibitors (PIs)</i>		
Lopinavir/ritonavir	LPV/r	230–350 mg/m <sup>2</sup> twice daily
Darunavir	DRV	10–20 mg/kg twice daily
Atazanavir	ATV	7 mg/kg once daily
Ritonavir	RTV	Given as a ‘booster’ with another PI
<i>Integrase inhibitors</i>		
Raltegravir	RAL	400 mg twice daily for adolescents

**First-line ART for children under 3 years of age**

An LPV/r-based regimen should be used as first-line ART for all children infected with HIV who are under 3 years (36 months) of age, regardless of NNRTI exposure. If LPV/r is not feasible, treatment should be initiated with an NVP-based regimen.

Where viral load monitoring is available, consideration can be given to substituting LPV/r with an NNRTI after virological suppression is sustained.

For infants and children under 3 years of age who are infected with HIV, ABC + 3TC + AZT is recommended as an option for children who develop TB while on an ART regimen containing NVP or LPV/r. Once TB therapy has been completed, this regimen should be stopped and the initial regimen should be restarted.

For infants and children under 3 years of age who are infected with HIV, the NRTI backbone for an ART regimen should be ABC + 3TC or AZT + 3TC (this is a strong recommendation but with low-quality evidence).

**First-line ART for children aged 3 years or older (including adolescents)**

For children aged 3 years or older (including adolescents) who are infected with HIV, EFV is the preferred NNRTI for first-line treatment, and NVP is the alternative.

For children aged 3–9 years (and adolescents weighing less than 35 kg) who are infected with HIV, the NRTI backbone for an ART regimen should be one of the following, in order of preference:

- ABC + 3TC
- AZT or TDF + 3TC (or FTC).

For adolescents who are infected with HIV (10–19 years old, weighing 35 kg or more), the NRTI backbone for an ART regimen should align with that of adults and be one of the following, in order of preference:

- TDF + 3TC (or FTC)
- AZT + 3TC
- ABC + 3TC.

**When to start ART**

About 20% of HIV-infected infants in developing countries progress to AIDS or death by 12 months of age (with a substantial contribution from PCP infections in infants under 6 months of age who are not receiving co-trimoxazole treatment).

ART should be initiated in all children infected with HIV below 5 years of age, regardless of WHO clinical stage or CD4 count, that is:

- Infants diagnosed in the first year of life.
- Children infected with HIV when aged 1–4 years.

ART should be initiated in all children infected with HIV aged 5 years or older with a CD4 cell count of less than 500 cells/mm<sup>3</sup>, regardless of WHO clinical stage, that is:

- CD4 count less than 350 cells/mm<sup>3</sup>.
- CD4 count between 350 and 500 cells/mm<sup>3</sup>.

ART should be initiated in all children infected with HIV with severe or advanced symptomatic disease (WHO clinical stage 3 or 4) regardless of age and CD4 count.

ART should be initiated in any child younger than 18 months who has been given a presumptive clinical diagnosis of HIV infection.

**Infants and children with specific conditions**

- For children or adolescents with severe anaemia (< 7.5 g/dL) or severe neutropenia (< 0.5/mm<sup>3</sup>), avoid AZT.
- For adolescents over 12 years of age with hepatitis B, the preferred regimen is tenofovir (TDF) + emtricitabine (FTC) or 3TC + NNRTI.

**Side effects of antiretroviral therapy and monitoring**

The response to antiretroviral treatment and the side effects of treatment both need to be monitored. Where CD4 cell count or viral load monitoring is available, this should be done every 3 to 6 months and can provide information on the success or failure of the response to treatment, and therefore guide changes to treatment. Where this is not possible, clinical parameters, including clinical staging events, need to be used (see Table 6.1.D.3).

**Monitoring the response after ARV initiation**

- After ARV initiation or a change in ARVs see the child at 2 and 4 weeks after the start or change.
- All children should be seen if there are any problems that concern the caregiver, or inter-current illness.

**Long-term follow-up**

- A clinician should see the child at least every 3 months.
- A non-clinician (ideally the provider of ARV medication, such as a pharmacist, who would assess adherence and provide adherence counselling) should see the child monthly.
- The child should be seen more frequently, preferably by a clinician, if clinically unstable.

**Monitoring the response (see Appendix 1)**

At entry into care and at initiation of ART, and then at regular intervals and as required by symptoms, monitor the following:

- weight and height (monthly)
- neurodevelopment (monthly)
- adherence (monthly)
- CD4 (%) if available (then every 3 to 6 months)
- viral load if available (every 3 to 6 months)
- baseline haemoglobin or haematocrit (if on ZDV/AZT), full chemistry (renal function, liver enzymes, especially ALT for liver toxicity) and lipids (if available)
- symptom-related determination: haemoglobin or haematocrit or full blood count, ALT.

General long-term side effects of antiretroviral therapy include lipodystrophy. The specific side effects of individual antiretroviral drugs are summarised in Appendix 5.

**When to change treatment**

Drugs need to be substituted for others when there is:

- treatment-limiting toxicity, such as:
  - Stevens–Johnson syndrome (SJS)
  - severe liver toxicity
  - severe haematological findings
- drug interaction (e.g. tuberculosis treatment with rifampicin interfering with NVP or PI)
- potential lack of adherence by the patient if they cannot tolerate the regimen.

**TABLE 6.2.D.8 Clinical and CD4 definition of ARV treatment failure in children (after 6 months or more of ARV)**

Clinical criteria	CD4 criteria
Lack of or decline in growth among children with an initial growth response to ARV	Return of CD4% if aged < 6 years (% or count if aged ≥ 6 years) to pre-therapy baseline or below, without other cause
Loss of neurodevelopmental milestones or onset of encephalopathy	≥ 50% fall from peak CD4% if aged < 6 years (% or count if aged ≥ 6 years), without other aetiology
New or recurrent WHO clinical Stage 4 conditions	

**First-line regimen treatment failure; when to switch regimens**

- 1 A switch to a second-line regimen is recommended when:
  - clinical failure is recognised **and/or**
  - immunological failure is recognised **and/or**
  - virological failure is recognised.
- 2 Clinical failure is defined as the appearance or reappearance of WHO clinical stage 3 or stage 4 events after at

least 24 weeks on ART in a treatment-adherent child. It is important to exclude TB as a cause of clinical failure, especially when there is poor growth.

- 3 Immunological failure is defined as developing or returning to the following age-related immunological thresholds after at least 24 weeks on ART, in a treatment-adherent child:
  - CD4 count of < 200 cells/mm<sup>3</sup> or CD4+% < 10% for a child between 2 and 4 years of age
  - CD4 count of < 100 cells/mm<sup>3</sup> for a child aged 5 years or older.
- 4 Virological failure is defined as a persistent viral load above 5000 RNA copies/mL, after at least 24 weeks on ART, in a treatment-adherent child.

**Principles**

Virological failure is due to resistance mutations acquired either at the time of infection or as a result of poor adherence. Even a resistance test before starting treatment (not widely available) will not always show archived mutations (not in the majority of the virus tested). Acquired resistance is more likely if there is initial improvement (ideally documented virologically). A history of missed doses is usually not given readily, but it is essential that support to ensure 100% adherence is put in place before second-line treatment is started.

In the absence of routine CD4 or viral load assays, judgements should be made about treatment failure based on:

- clinical progression
- CD4 decline as defined in Table 6.2.D.8.

Generally, patients should have received 6 months or more of ARV therapy, and adherence problems must be ruled out where possible before considering treatment failure and switching ARV regimens.

If an apparent deterioration is due to the immune reconstitution inflammatory syndrome (IRIS), this is not a reason for switching therapy. IRIS usually starts within weeks or the first few months after starting ART in children who have very low CD4 counts (< 15%). The most common initiator is TB which has been latent, but the symptoms of other opportunistic infections can develop as the immune recovery enables a response. Treatment is of the infection, and ART should be continued.

**Immune reconstitution inflammatory syndrome (IRIS)**

It is important to differentiate IRIS clinically from treatment failure, because the symptoms may be similar. IRIS can be confused with several other clinical events that are also observed in children with advanced HIV disease, such as opportunistic infections, ARV-related toxicity, or HIV disease clinical progression.

**What is IRIS?**

IRIS is an exaggerated immune response to antigens or organisms. The related organisms could be mycobacteria (e.g. *Mycobacterium tuberculosis*, non-tuberculosis mycobacteria), viruses (e.g. herpes zoster, herpes simplex) or fungi (e.g. *Cryptococcus neoformans*).

**Who is at risk of developing IRIS?**

It usually occurs in a child with low baseline CD4 or WHO clinical stage 3 or 4 before initiation of ART. The incidence rate of IRIS could be as high as 15–25%.

**When does IRIS develop?**

It usually occurs during the first 6 months after initiation of ART, although it commonly manifests during the first month. During the initial period of ART, antiretroviral drugs cause a rapid decline in HIV viral load and a rapid rise in CD4, so a brisk immune response to antigen is developed.

**What are the common manifestations of IRIS?**

There are two types of IRIS:

- **'Worsening type':** clinical worsening of a previously treated opportunistic infection. For example:
  - worsening of respiratory symptoms and/or chest X-ray finding in a child with previously treated pulmonary tuberculosis
  - severe headache in a child with previously treated cryptococcal meningitis.
- **'Unmasking type':** unmasking of a previously subclinical infection with exaggerated inflammatory response. For example:
  - suppurative lymphadenitis from *Mycobacterium* infection
  - development of an abscess at the BCG vaccination site.

**How should IRIS be managed?**

- ARVs should be continued.
- For the 'unmasking type', the appropriate anti-infective agents are needed.
- In most cases, the symptoms of IRIS resolve after a few weeks. However, some reactions can be severe or life-threatening, requiring a short course of steroid treatment (e.g. IRIS from pulmonary tuberculosis with acute respiratory distress syndrome (ARDS), IRIS from *M. avium* complex infection with high-grade fever and severe abdominal pain, IRIS from cryptococcal meningitis with a severe increase in intracranial pressure).

**Second-line treatment regimens in the event of treatment failure**

After failure of a first-line NNRTI-based regimen, a boosted PI plus two NRTIs are recommended for second-line ART. LPV/r is the preferred boosted PI.

After failure of a first-line LPV/r-based regimen, children younger than 3 years should remain on their first-line regimen, and measures to improve adherence should be undertaken.

After failure of a first-line LPV/r-based regimen, children aged 3 years or older should be switched to a second-line regimen containing an NNRTI plus two NRTIs. EFV is the preferred NNRTI.

After failure of a first-line regimen of ABC or TDF + 3TC (or FTC), the preferred NRTI backbone option for second-line ART is AZT + 3TC.

After failure of a first-line regimen containing AZT or d4T + 3TC (or FTC), the preferred NRTI backbone option for second-line ART is ABC or TDF + 3TC (or FTC).

**Third-line ART**

Third-line regimens should include new drugs with minimal risk of cross-resistance to previously used regimens, such as integrase inhibitors and second-generation NNRTIs and PIs.

Patients on a failing second-line regimen with no new ARV options should continue with a tolerated regimen.

Strategies that balance the benefits and risks for children need to be explored when second-line treatment fails.

- For older children and adolescents who have more therapeutic options available to them, constructing third-line ARV regimens with novel drugs used to treat adults, such as ETV, DRV and RAL, may be possible.
- Children on a second-line regimen that is failing with no new ARV drug options should continue with a tolerated regimen. If ART is stopped, opportunistic infections still need to be prevented, symptoms relieved and pain managed.

**Nutritional care and failure to thrive (see Appendix 3)**

Nutrition is a long-term concern in all HIV-infected children. Stunting frequently develops within the first 12 months, although most children maintain normal weight-for-height ratios. Close monitoring of growth, and early protein/calorie, vitamin A and other micronutrient supplementation need to be evaluated.

- Regular vitamin A as per WHO guidelines.
- Supplementary feeding if possible (aim for 150 kcal/kg/day).
- Exclude or treat *Candida*.
- Exclude or treat enteric infection.
- Consider zinc deficiency (see Section 5.10.A).
- Consider fever.
- Consider depression.
- Consider pain.

**Clinical management**

- 1 HIV-infected children should be assessed routinely for nutritional status, including weight and height, at scheduled visits, particularly after the initiation of ART.
- 2 HIV-infected children on or off ART who are symptomatic, who have conditions requiring increased energy (e.g. TB, chronic lung disease, chronic oral infections, malignancies) or who have weight loss or evidence of poor growth, should be provided with 25–30% additional energy.
- 3 HIV-infected children who are severely malnourished should be managed as per the guidelines for uninfected children and provided with 50–100% additional energy.
- 4 HIV-infected children should receive one recommended daily allowance of micronutrients daily. If this cannot be ensured through the diet, or there is evidence of deficiency, supplementation should be given.
- 5 HIV-infected infants and children should receive high-dose vitamin A supplementation every 6 months between 6 and 59 months of age, as per the guidelines for uninfected children (see Section 5.10.A).
- 6 HIV-infected children who have diarrhoea should receive zinc supplementation as part of management, as per the guidelines for uninfected children.

- 7 For infants and young children who are known to be HIV infected, mothers are strongly encouraged to exclusively breastfeed for 6 months and to continue breastfeeding as per recommendations for the general population (i.e. up to 2 years of age and beyond).

### Respiratory disorders in children with HIV infection

Symptoms include cough, shortness of breath, fever, sweats and cyanosis.

The aetiology of acute respiratory infections is similar to that of community-acquired infections in immunocompetent children (*Mycobacterium tuberculosis*, *Pneumococcus*, *Haemophilus influenzae*, *Staphylococcus aureus*, *Mycoplasma pneumonia*) (see Section 5.3.A and Section 6.1.N). However, children with HIV may require more prolonged courses of treatment.

Studies on the aetiology of pneumonia among HIV-infected children in resource-limited countries have identified *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Haemophilus influenzae* and *Klebsiella* species as the major bacterial pathogens in HIV-infected children. HIV-negative children are affected by the same pathogens, although at lower rates. The post-mortem studies showed similar results, except that *H. influenzae* was slightly less prominent. *M. tuberculosis* was prevalent regardless of HIV status, reflecting its significance in resource-limited countries. From the limited data available, **RSV** and **parainfluenza** appear to be the most prevalent viral causes of pneumonia.

In cases of failed treatment, consider using a second-line antibiotic.

Treatment of recurrent infections is the same, regardless of the number of recurrences.

### Specific HIV-related causes of infection and illness

#### **Pneumocystis jirovecii (formerly carinii) pneumonia (PCP)**

- PCP should be suspected and anti-pneumocystis therapy considered in any HIV-positive infant with severe pneumonia.
- Severe generalised pneumonia usually includes ventilation/perfusion mismatch and severe hypoxaemia.
- High fever is uncommon compared with bacterial pneumonia.

PCP is most likely to develop in a child whose HIV infection occurred in the previous 12 months (the peak time is 4–6 months), or over 12 months if they have a low CD4 count and are not on co-trimoxazole prophylaxis. There is an absent or low-grade fever, non-productive cough and difficulty breathing. Signs include severe respiratory distress (tachypnoea, chest indrawing), which is disproportionate to findings on auscultation (usually normal breath sounds or only a few crackles). If an oxygen saturation monitor is available, check at rest and, if normal, again after exercise. The latter may show hypoxia or, if there is a severe infection, cyanosis.

There may be a history of a poor response to 48 hours of first-line antibiotics, and elevated levels of lactate dehydrogenase.

PCP is often the first clinical indicator of HIV infection, and is a WHO clinical stage 4 criterion.

Clinical and radiological signs are not diagnostic. However, a clear chest or diffuse chest signs on auscultation are typical with PCP infection, as is the presence of diffuse infiltrates and areas of hyperinflation rather than focal signs on a chest X ray.

Induced sputum and nasopharyngeal aspiration are useful for obtaining sputum for examination. Nasopharyngeal aspirate has a low sensitivity with conventional staining techniques, and requires **PCR**. Induced sputum techniques greatly increase the diagnostic yield. Beware the risk of infection being transmitted to operators, especially of multiple drug-resistant tuberculosis, for example. **Bronchoalveolar lavage** may provide a diagnosis if adequate resources are available.

#### **Treatment of PCP**

**Severe disease** (severe respiratory distress, severe hypoxia): treat with co-trimoxazole 60–90 mg/kg IV 12-hourly for a minimum of 7 days, followed by oral drugs in the same doses for another 2 weeks (IV if there is severe nausea). In addition, give high-dose dexamethasone for the first 5 days (150 micrograms/kg/dose 6-hourly for 4 days) or prednisolone 0.5 mg/kg 12-hourly for 5 days, then 0.25 mg/kg 12-hourly for 5 days, then 0.25 mg/kg daily for 5 days. The response usually occurs after more than 5–7 days of appropriate high-dose therapy.

**Less severe disease:** treat with oral co-trimoxazole 30 mg/kg 6-hourly for 21 days (trimethoprim (TMP) 5 mg/kg; sulfamethoxazole (SMX) 25 mg/kg).

If the child has a severe drug reaction, change to pentamidine (4 mg/kg once a day by IV infusion) for 3 weeks, or trimethoprim 5 mg/kg/dose orally 6-hourly and dapsone 100 mg/kg once a day for 21 days.

Continue co-trimoxazole prophylaxis (see below) on recovery, and ensure that ART is being given.

#### **Co-trimoxazole prophylaxis**

Co-trimoxazole prophylaxis has been shown to be very effective in HIV-infected infants and children in reducing mortality and the likelihood of PCP as a cause of severe pneumonia. PCP is now unusual in countries where prophylaxis is routine.

Co-trimoxazole also protects against common bacterial infections, toxoplasmosis and malaria.

#### **Who should be given co-trimoxazole?**

- All HIV-exposed children (children born to HIV-infected mothers) from 4–6 weeks of age, whether or not they are part of a prevention of mother-to-child transmission (PMTCT) programme.
- Any child under 5 years old identified as HIV-infected, regardless of CD4 count.
- Any child over 5 years old with a CD4 count of less than 25%.
- Any child with a history of PCP.

See Appendix 2 for management.

#### **For how long should co-trimoxazole be given?**

- HIV-exposed children: for the first year, or until HIV infection has been definitively ruled out and the mother is no longer breastfeeding.

- HIV-infected children:
  - Indefinitely where ARV treatment is not yet available.
  - Where ARV treatment is being given, co-trimoxazole may only be stopped once clinical or immunological indicators confirm restoration of the immune system for 6 months or more (also see below). On the basis of current evidence it is not yet clear whether co-trimoxazole continues to provide protection after immune restoration is achieved.
  - If there is a history of PCP pneumonia, continue indefinitely.

#### Under what circumstances should co-trimoxazole be discontinued?

- If severe cutaneous reactions such as Stevens–Johnson syndrome occur with co-trimoxazole or other sulpha drugs, or if there is renal and/or hepatic insufficiency or severe haematological toxicity (severe anaemia or pancytopenia). It is contraindicated in children with glucose-6-phosphate dehydrogenase (G6PD) deficiency.
- **In an HIV-exposed child**, only after HIV infection has confidently been excluded:
  - For a non-breastfeeding child under 18 months of age, this is by negative DNA or RNA virological HIV testing.
  - For a breastfed HIV-exposed child under 18 months of age, negative virological testing is only reliable if performed 6 weeks after cessation of breastfeeding.
  - For a breastfed HIV-exposed child over 18 months of age, negative HIV antibody testing 6 weeks after stopping breastfeeding.
- **In an HIV-infected child:**
  - If the child is on ARV therapy, co-trimoxazole can be stopped only when evidence of immune restoration has been obtained. Continuing co-trimoxazole may continue to provide benefit even after the child has clinically improved.
  - If ARV therapy is not available, co-trimoxazole should not be discontinued.

#### What doses of co-trimoxazole should be used?

- Recommended dosages of 6–8 mg/kg TMP once daily should be used.
  - For children under 6 months of age, give 2.5 mL of suspension (40/200 mg in 5 mL) or 1 paediatric tablet (or ¼ adult tablet, 20 mg TMP/100 mg SMX: tablets can be crushed).
  - For children aged 6 months to 5 years, give 5 mL of suspension or 2 paediatric tablets (or ½ adult tablet).
  - For children aged 6–14 years, give 10 mL of suspension or 1 adult tablet.
  - For children over 14 years, give 2 adult tablets.
- Use weight-band dosages rather than body-surface-area doses.
- If the child is allergic to co-trimoxazole, dapsone is the best alternative. Give dapsone after 4 weeks of age in an oral dose of 2 mg/kg/24 hours once daily.
- If the patient is G6PD-positive, consider giving pentamidine or atovaquone.

#### What follow-up is required?

Co-trimoxazole prophylaxis should be a routine part of the care of HIV-infected children, and must be assessed for tolerance and adherence at all regular clinic visits or follow-up visits by healthcare workers and/or other members of the multidisciplinary care team. It is suggested that initial clinic follow-up in children takes place monthly, and then every 3 months if co-trimoxazole is well tolerated.

#### Lymphocytic interstitial pneumonitis (LIP)

LIP is a non-infectious pulmonary disorder caused by white cell infiltration into alveolae. It is most common in children over 2 years old, and is a clinical stage criterion which is an indication for starting ART.

LIP is common in children (it occurs in at least 40% of children with perinatal HIV), but rare in adults (it occurs in about 3% of adults with HIV). Various studies in Africa have documented a 30–40% prevalence of LIP in HIV-infected children, and up to 60% prevalence in those with chronic lung disease. LIP is often mistaken for pulmonary TB (miliary) because of the chronic cough and the miliary-like pattern on chest X-ray.

**Pathogenesis:** Possible explanations for LIP include a co-infection of the lungs by HIV and Epstein–Barr virus (EBV), leading to immune stimulation with lymphoid infiltration and chronic inflammation.

The child is often asymptomatic in the early stages, but may later have a mild persistent cough, with or without difficulty in breathing, bilateral parotid swelling, persistent generalised lymphadenopathy, poor growth, hepatomegaly and other signs of heart failure (tender hepatomegaly, bilateral pitting pedal oedema, loud second heart sound and finger clubbing). Chest auscultation may be normal, or there may be widespread crackles. It may produce severe ventilatory perfusion mismatch with hypoxaemia, but may be asymptomatic.

There is an increased risk of lower respiratory tract infection, including bronchiectasis. It is also associated with parotid, adenoid and tonsillar enlargement (and may produce sleep-related upper airway obstruction; see Section 5.1.D).

LIP may be mistaken for miliary TB, but the child is systematically too well.

Suspect LIP if the chest X-ray shows a bilateral reticulo-nodular interstitial pattern that is prominent in the lower lobes, nodules less than 5 mm in diameter, a single patchy alveolar opacity, hyperinflation or isolated bullae. It must be distinguished from pulmonary tuberculosis and bilateral

**FIGURE 6.2.D.4** Chest X ray showing lymphocytic interstitial pneumonia (LIP): typical is hilar lymphadenopathy and lacelike infiltrates.

hilar adenopathy (see Figure 6.2.D.4). Chest X-ray diffuse infiltrations and hilar lymphadenopathy persisting for more than 2 months despite antibiotic treatment are also a clue.

X-ray appearances are often more severe than the clinical features.

**FIGURE 6.2.D.5** *Pneumocystis jirovecii* pneumonia (PCP): typical is a ground glass appearance.

### Treatment of LIP

- Give oxygen therapy during episodes of hypoxia.
- Give a trial of antibiotic treatment for bacterial pneumonia before starting treatment with prednisolone.
- Start treatment with steroids only if there are chest X-ray findings suggesting lymphocytic interstitial pneumonitis, plus any of the following signs:
  - fast or difficult breathing
  - cyanosis
  - pulse oximetry reading of oxygen saturation < 90% (normal value is > 93%).
- Bronchodilators (e.g. salbutamol) are of benefit where wheezing is a problem. For moderate symptoms give oral prednisone, 1–2 mg/kg daily for 3 days, and for more severe symptoms for up to 4 weeks. Then slowly decrease the dose over 2–4 weeks depending on the treatment response. If there is no response by 4 months, slowly taper the dose to stop over a further 2 months.
- Only start steroid treatment if it is possible to complete the full treatment course (which may take several months depending on the resolution of signs of hypoxia), as partial treatment is not effective and could be harmful. Beware of reactivation of TB.

### Tuberculosis (see also Section 6.1.N)

In a child with suspected or proven HIV infection, it is important always to consider the co-diagnosis of tuberculosis, a diagnosis which is often difficult. Early in HIV infection, when immunity is not impaired, the signs of tuberculosis are similar to those in a child without HIV infection. Pulmonary tuberculosis is still the commonest form of tuberculosis, even in HIV-infected children. As HIV infection progresses and immunity declines, dissemination of tuberculosis becomes more common. Tuberculous meningitis, miliary tuberculosis and widespread tuberculous lymphadenopathy occur.

All children with HIV should be screened for TB.

Avoid, if practicable, children with HIV being in contact with a TB-infected person.

### Isoniazid preventive therapy (IPT)

- 1 All HIV-infected infants and children who are exposed to TB through household contacts, but show no evidence of active disease, should begin isoniazid preventive therapy (IPT).
- 2 Children who have either poor weight gain, fever, cough or a contact with TB should be evaluated for active TB. If TB is excluded, give IPT.
- 3 Children living with HIV (over 12 months of age, and including those previously treated for TB), who are not likely to have active TB, and who are not known to be exposed to TB, should receive 6 months of IPT as part of a comprehensive package of HIV care.
- 4 Infants living with HIV, who have been exposed to TB but are evaluated as not having active TB, should receive IPT as part of a comprehensive package of HIV care.
- 5 The recommended dose of isoniazid (INH) for preventive therapy in HIV co-infection is 10 mg/kg daily for 6 months (maximum 300 mg/day).
- 6 See the child monthly and give a 1-month supply of isoniazid at each visit.

### Investigations

A tuberculin skin test (TST, Mantoux) is unreliable in HIV and should not be used. Since a definitive diagnosis of TB in children is difficult, there could be clinical features that are very suggestive of TB, leading to a high index of suspicion. In such cases a negative TST should not prevent you from starting anti-TB treatment. Furthermore, several people develop TB infection when they come into contact with the TB pathogens, but they do not go on to develop signs and symptoms of TB disease, because their immune systems control the infection. When the immune systems break down, such individuals develop signs and symptoms suggestive of TB disease. A TST can be positive in either state, and without signs and symptoms would be suggestive of TB infection and not TB disease.

**Chest X-ray:** this may be normal, or it may show non-specific infiltrates, hilar or paratracheal lymphadenopathy, persistent opacities after an antibiotic trial, or a miliary pattern.

**Microscopy** (alcohol and acid-fast bacilli, AAFB), Ziehl-Neelsen (ZN) stain **and culture:** this is the most important investigation. Sputum which may need to be induced by saline nebuliser (in an isolation room with staff wearing a fine-particle (FP3) mask), and gastric aspirate (if the child is coughing, take this in the early morning before they have had anything to eat or drink). Collect at least three specimens.

### Treatment of infants and children diagnosed with TB and HIV

Treat TB in HIV-infected children with the same anti-TB drug regimen as for non-HIV-infected children with TB.

**Thiacetazone is associated with a high risk of severe, and sometimes fatal, skin reactions in HIV-infected children, and must not be given.** These reactions can start with itching, but progress to severe reactions.

### Recommended ART regimens for children who need TB treatment

**Recommended regimens for children and adolescents initiating ART while on TB treatment**  
**Younger than 3 years**

Two NRTIs + NVP, ensuring that the dose is 200 mg/m<sup>2</sup>  
**or**  
 Triple NRTI (AZT + 3TC + ABC).

### 3 years or older

Two NRTIs + EFV  
**or**  
 Triple NRTI (AZT + 3TC + ABC).

### Recommended regimens for children and infants initiating TB treatment while receiving ART

#### Child on standard NNRTI-based regimen (two NRTIs + EFV or NVP)

#### Younger than 3 years

Continue NVP, ensuring that the dose is 200 mg/m<sup>2</sup>  
**or**  
 Triple NRTI (AZT + 3TC + ABC).

#### 3 years or older

If the child is receiving EFV, continue the same regimen.  
 If the child is receiving NVP, substitute with EFV

**or**

Triple NRTI (AZT + 3TC + ABC).

- TB should be treated with standard regimes, the emphasis being on achieving high adherence rates. The development of multi-drug-resistant TB is a very real threat if compliance is poor. Directly observed therapy (DOT) may be the best approach.
- Any child with active TB disease and HIV infection should begin TB treatment immediately, and start ART as soon as tolerated in the first 8 weeks of TB therapy, irrespective of CD4 count and clinical stage.
- For all HIV-infected children, anti-TB therapy should be started immediately upon the diagnosis of TB, and ART should continue.

### Bronchiectasis

Suspect bronchiectasis if there is a persistent cough productive of copious sputum (in vomit in young children) or haemoptysis associated with fever, anorexia and failure to thrive. There may be clubbing and localised coarse crackles on auscultation. Obtain a chest X-ray and sputum for Gram stain and culture as well as AAFB; differential diagnoses include TB and LIP. Treatment consists of physiotherapy with postural drainage, bronchodilators and antibiotics. Intravenous amoxicillin (50 mg/kg 6-hourly) and gentamicin (7.5 mg/kg daily) may be required for 2 weeks.

### Cytomegalovirus (CMV)

CMV can present with pneumonia with fever, dry cough, respiratory distress and hypoxia. CMV also causes oesophagitis and gastroenteritis presenting with nausea, difficulty swallowing, diarrhoea and vomiting. CMV retinitis is often asymptomatic or may cause blurred vision, strabismus and ultimately blindness. The fundi show white perivascular infiltrates and haemorrhages, reduced acuity and field defects.

A chest X-ray may show diffuse interstitial infiltrates. Oesophageal endoscopy may show linear, localised or punctate ulcers. Biopsies show typical inclusion cells.

Treatment is with ganciclovir 6 mg/kg 12-hourly for 14 days.

### Other lung infections

Other opportunistic lung infections that may occur include *Pseudomonas aeruginosa*, *Chlamydia*, *Mycoplasma*, *Cryptococcus neoformans*, *Aspergillus*, cytomegalovirus, *Histoplasma*, *Coccidioides*, *Legionella* and *Nocardia*.

### Gastrointestinal disorders

#### Oral and oesophageal problems

##### Oral candidiasis

This is the most common form of fungal infection and the most common orofacial manifestation encountered in HIV-infected children. It progresses to involve the oesophagus in 20% of cases, and denotes significantly impaired T-cell function.

It presents as white plaques on mucosa that are difficult to remove, loss of taste, pain on swallowing, reluctance to eat, increased salivation and crying during feeds.

##### Treatment for oral candida

- Nystatin 100 000 IU/mL oral suspension, 1–2 mL four to six times a day for 7 days **or**
- Local gentian violet 0.5% aqueous solution twice daily for 7 days (dissolve one teaspoonful (5 mL) of crystals in 1 litre of water, filter off the residue, and use within 7 days) **or**
- Clotrimazole 1%, miconazole 2% gel, or amphotericin B suspension/lozenges three times daily **or**
- Fluconazole 3–6 mg/kg on the first day, then 3 mg/kg (maximum 100 mg) daily for 1–2 weeks. If there is rare resistance to fluconazole, give ketoconazole oral tablets, 3.3–6.6 mg daily.

##### Oesophageal candidiasis

Oesophageal candidiasis is a stage 4 clinical feature indicating profound immune impairment (advanced HIV disease). The only clinical symptom may be reluctance to feed. It presents as difficulty or pain while vomiting or swallowing, reluctance to take food, excessive salivation, or crying during feeding. The condition may occur with or without evidence of oral candida. If oral candida is not found, give a trial of treatment with fluconazole (3–6 mg/kg once a day). Exclude other causes of painful swallowing (e.g. cytomegalovirus, herpes simplex, lymphoma and, rarely, Kaposi's sarcoma), if necessary by referral to a larger hospital where appropriate testing is possible.

##### Treatment for oesophageal candidiasis

- Give oral fluconazole, 3–6 mg/kg once a day for 7 days, except if the child has active liver disease.
- Give amphotericin B, 0.5–1 mg/kg/dose once a day by IV infusion for 10–14 days to children with liver disease and in cases where there is a lack of response to oral therapy, inability to tolerate oral medications, or the risk of disseminated candidiasis (e.g. in a child with leukopenia).

##### Viral oesophagitis

##### Herpes simplex virus (HSV)

Herpes simplex virus (HSV) infection may either be primary (herpetic gingivostomatitis) or secondary (herpes labialis). The prevalence of oral HSV infection ranges from 10% to 35% in adults and children with HIV infection. The presence

of HSV infection for more than 1 month constitutes an AIDS-defining condition.

### Clinical appearance

HSV infection appears as a crop of vesicles, usually localised on the keratinised mucosa (hard palate, gingiva) and/or the vermillion borders of the lips and perioral skin. The vesicles rupture and form irregular painful ulcers. They may interfere with mastication and swallowing, resulting in decreased oral intake and dehydration.

Systemic therapy with antiviral agents is recommended. The treatment is more effective if it is instituted in the prodromal stage of infection. Treat with aciclovir 20–40 mg/kg orally or IV four times daily for 7 days (maximum single dose is 800 mg).

**Cytomegalovirus (CMV) infection:** treat with ganciclovir IV 5 mg/kg every 12 hours for 14–21 days.

Reflux oesophagitis may also be present. Treat with antacids and/or an H<sub>2</sub>-antagonist, such as ranitidine 2 mg/kg twice daily (see Section 5.12.E).

**Idiopathic aphthous ulcers:** if possible these need to be differentiated from HSV by viral culture. Pay attention to oral hygiene. Thalidomide is useful if they are severe.

### Severe periodontal and gingival disease (cancrum oris)

Periodontal (gum) disease is common among HIV-infected patients. It is characterised by bleeding gums, bad breath, pain or discomfort, mobile teeth, and sometimes sores. Its reported prevalence ranges widely, from 0% to 50%. If left untreated, HIV-associated periodontal disease may progress to life-threatening infections, such as Ludwig's angina and noma (cancrum oris).

**Noma** is a gangrenous condition that primarily affects children. It is a multifactorial disease. The most important risk factors are poverty, chronic malnutrition, poor oral hygiene and severe immunosuppression. Although it is considered to be a preventable disease, noma has a case-fatality rate of 70–90% if left untreated.

- Treat with benzylpenicillin 50 mg/kg 4-hourly or amoxicillin 40–60 mg/kg IV 8-hourly. Change to oral antibiotics once the child is able to swallow (usually after 24–48 hours).
- Provide materials for and education on dental hygiene.

Rarely, **malignancy** (Kaposi's sarcoma or non-Hodgkin's lymphoma) or oral hairy leukoplakia (white lacy markings on the sides of the tongue associated with Epstein-Barr virus infection; no treatment required) occur. Visceral Kaposi's sarcoma may present with persistent diarrhoea, intestinal obstruction and abdominal pain.

### Persistent diarrhoea (see Section 5.12.B)

Case management should start with management of dehydration with oral rehydration solution. Dysentery (loose stools with blood) should be managed in the same way as for non-HIV-infected children (e.g. for *Shigella* infection). Concur with the local prevalence of treatable infections. Giardiasis, cryptosporidiosis, microsporidiosis, *Shigella*, *Salmonella*, *Campylobacter*, enteropathogenic *E. coli* and *Yersinia* may each contribute to gastrointestinal dysfunction. HIV itself may cause an enteropathy, and in highly immunosuppressed children, atypical mycobacterial infection and protozoa such as *Blastocystis hominis* may cause diarrhoea. Even with sophisticated microbiology, no pathogen

may be found, and malabsorption due to lactase deficiency and other brush-border defects should be considered. All antiretroviral drugs (except AZT) can cause diarrhoea, particularly ritonavir.

### Chronic or recurrent diarrhoea

Normal endemic pathogens may be responsible, such as rotavirus, *Giardia lamblia*, *Campylobacter jejuni* (see Section 5.12.A and Section 5.12.B), salmonellae (typhoid and non-typhoid), *E. coli*, *Shigella*, *Entamoeba histolytica* and *Strongyloides stercoralis*.

### Investigations

- Fresh stool microscopy and culture: *Giardia*, *Entamoeba*.
- Ova and cysts: helminths.
- ZN stain: cryptosporidia, cyclospora.
- pH and reducing substances: lactose intolerance.
- CD4 count < 50: CMV, mycobacterium avium intracellulare
- CD4 count < 100: cryptosporidium, microsporidiosis.

Look for signs of vitamin deficiencies:

- Vitamin A: night blindness, dry eyes, Bitot's spots (on conjunctivae).
- Vitamin D: rickets (wide wrist, double malleoli, bow legs, rachitic rosary, Harrison's sulcus).
- Vitamin E: dry rough skin.
- Vitamin K: ecchymosis, purpura.

Opportunistic infections such as those listed below may be responsible:

- Bacterial: atypical mycobacterial infections, such as *Mycobacterium avium* complex (MAC) (see below).
- Protozoa and parasites: cryptosporidia, microsporidia, *Isospora belli*. Treat with azithromycin 10 mg/kg once daily.
- Viral: cytomegalovirus, herpes simplex virus.
- Fungal: histoplasmosis, coccidiomycosis, *Candida*. If severe, treat with fluconazole 3 mg/kg once daily.

Diarrhoea may be secondary to antibiotics, either by direct effects or through *Clostridium difficile*. Stop antibiotics as soon as possible. Give live yoghurt with or without oral vancomycin.

If lactose intolerance is present, give lactose-free feeds.

Treat dysentery with ciprofloxacin 15 mg/kg 12-hourly for 3 days, or ceftriaxone 50 mg/kg once a day for 2–5 days, plus metronidazole 7.5 mg/kg 8-hourly for 7 days.

Nutritional management includes calorie replacement, which may need to be nasogastric, but always encourage eating. Ensure that additional food is not just recommended but actually given. Vitamin A, multivitamins and zinc (10–20 mg once a day for 10–14 days) supplementation may be of benefit (see Section 5.10.A).

**Prevention:** Use hygienic practices during food preparation, always use clean water, avoid bird and animal faeces, avoid swimming in fresh water, and avoid reptiles (salmonellae).

### Abdominal pain

This is most frequently related to infections, but occasionally is caused by tumours (non-Hodgkin's lymphoma and Kaposi's sarcoma).

### Malabsorption

HIV can be directly associated with an enteropathy. Lactase deficiency and other brush-border defects can also be responsible. Consider trial of a lactose-free diet.

### Central nervous system disorders

A myriad of HIV-related CNS diseases have been described. Primary CNS infection by HIV is quite common, as it is a neurotropic virus. Various abnormalities of the central nervous system (CNS) and peripheral nervous system (PNS) are associated with HIV and AIDS. These abnormalities may be attributable to the following causes: HIV infection, complications related to immunosuppression, neurotoxic effects of antiretroviral treatments, and other systemic complications of HIV that affect brain function.

Neurological disorders in people with HIV infection include peripheral neuropathies (nerve disorders that affect the limbs or feet and hands), myelopathy (disorders of the spinal cord), focal cerebral mass lesions (brain tumours such as CNS lymphoma), CNS complications of opportunistic infections, vascular (blood vessel) abnormalities,

seizures and encephalopathies. Developmental delays and regression are also important CNS-related problems in HIV-infected children.

The neurological manifestations of HIV infection include the following:

- progressive or static encephalopathy
- seizures
- strokes
- HIV myopathy
- HIV myelopathy
- peripheral neuropathy
- psychiatric manifestations
- sleep problems.

The effect of HIV on the brain ranges from severe effects, found in more than 50% of patients dying of AIDS at post-mortem, to the much more common and milder effects on the developing brain in children, which result in mild learning difficulties. It is particularly important to recognise this so that appropriate support can be given (e.g. reminding the patient to take ART).

**TABLE 6.2.D.10 Comparison of features of major CNS mass lesions in HIV**

Clinical			Neuroimaging (if available)		
Disease	Timing	Fever	Number of lesions	Type of lesions	Location of lesions
Cerebral toxoplasmosis	Acute onset of symptom	Common	Multiple	Enhancing spherical rings; mass effect	Basal ganglia
Primary CNS lymphoma	Insidious onset of symptom	Usually absent	One or few	Irregular shape, weakly enhancing, mass effect	Periventricular, peri-ependymal, corpus callosum
Tuberculoma	Insidious onset of symptom	Common	One or few	Discrete lesions, significant surrounding oedema, mass effect	Supratentorial in adults, infratentorial in children (at the base of the brain near the cerebellum)
Cryptococcoma cryptococcal meningitis	Acute onset of symptom	Common	Variable	Mass lesions, dilated perivascular spaces, oedema	Basal ganglia

Care of HIV-infected children with CNS involvement requires a thorough evaluation and stepwise therapy according to the underlying aetiology. A multidisciplinary approach is usually needed for appropriate care.

### Specific neurological problems

#### HIV encephalopathy

- Rapid onset or chronic and relapsing forms.
- Hypertonic (spastic) diplegia and expressive language delay.
- Acquired microcephaly with developmental regression (loss of skills).
- White-matter disease predominates. It does not cause seizures, and therefore seizures need to be fully investigated for another pathology.

#### Encephalitis

##### *Toxoplasma gondii*

- Prevention: avoid cats and cat faeces:
  - avoid raw uncooked or partially cooked food
  - can be acquired congenitally.
- Diagnosis: CT/MRI of the brain, and serology (if available).
- Treat with co-trimoxazole 60 mg/kg orally (IV if there is severe nausea) 12-hourly for 2 weeks.
- Then give lifelong prophylaxis: sulfadiazine 85–120 mg/

kg/day in two doses, pyrimethamine 1 mg/kg/day (maximum 25 mg) and folinic acid 5 mg every 3 days.

#### JC virus (papovavirus)

The JC virus is associated with progressive multifocal leukoencephalopathy, a disease characterised by altered mental status, limb weakness, or both. Patients may also exhibit personality changes with frequent emotional outbursts. There is no treatment for this illness, but strong antiretroviral medications (if available) can sometimes improve the symptoms.

#### Fungal lesion

This is rare.

#### Diffuse CMV encephalitis

Treat with ganciclovir 5 mg/kg orally or IV 12-hourly for 14–21 days.

#### Malaria

See Section 6.3.A.d.

#### Meningitis

##### Bacterial meningitis

This has the usual spectrum of pathogens, such as

TABLE 6.2.D.11 Neurological manifestations of paediatric HIV infection

Abnormality	Clinical findings	Diagnostic studies (if available)
Focal cerebral mass lesions	Headache, nausea/vomiting, motor deficits (usually asymmetrical), discoordination, visual changes, altered mental status	CT/MRI: enhancing lesions Lumbar puncture: CSF may reveal abnormal cytology or Epstein–Barr virus via PCR Brain biopsy: sometimes needed to confirm diagnoses
Myelopathy	Gait disturbances, lower-extremity weakness/spasticity incontinence, sensory abnormalities, abnormal lower-extremity reflexes	CT/MRI on mass lesions seen; nerve-root thickening may be present CSF: polymorphonuclear pleocytosis
Myopathy	Muscle weakness, muscle soreness, weight loss	EMG: irritative myopathy Muscle biopsy: inflammation, degeneration
Opportunistic infections	Headache, nausea/vomiting, fever, seizures, altered mental status, malaise	CT/MRI: multiple enhancing lesions (toxoplasmosis), periventricular and meningeal abnormalities (CMV)
Peripheral neuropathy	<i>Distal symmetrical neuropathy</i> <ul style="list-style-type: none"> <li>● Distal numbness/pain</li> <li>● Paraesthesias</li> <li>● Stocking/glove sensory loss</li> <li>● Decreased ankle reflexes</li> </ul>	<i>Distal symmetrical neuropathy</i> EMG: distal axonopathy
	<i>Inflammatory demyelinating polyneuropathy</i> <ul style="list-style-type: none"> <li>● Progressive weakness</li> <li>● Paraesthesias</li> <li>● Areflexia</li> <li>● Mild sensory loss</li> </ul>	<i>Inflammatory demyelinating polyneuropathy</i> EMG: demyelination
	<i>Progressive polyradiculopathy</i> <ul style="list-style-type: none"> <li>● Lower-extremity weakness</li> <li>● Paraesthesias</li> <li>● Urinary incontinence and retention</li> <li>● Diminished reflexes</li> </ul>	<i>Progressive polyradiculopathy</i> EMG: polyradiculopathy Serum: increased creatine kinase
Progressive encephalopathy	Fine and gross motor deficits (usually symmetrical), abnormal tone, neurodevelopmental delay, microcephaly, altered mental status	CT/MRI: brain atrophy, white-matter abnormalities
Seizures	Focal or generalised seizures, post-ictal stare (fatigue and confusion following seizure)	EEG: abnormal patterns CT/MRI and CSF studies: mass lesions may be seen via imaging, and CSF may be positive for pathogens and abnormal cells if aetiology is infectious or neoplastic Lumbar puncture: may reveal infection
Strokes (cerebrovascular accidents)	Rapid onset of focal neurological signs, seizures, altered mental status	CT/MRI: extent of bleeding seen (in ischaemic strokes, CT may not show changes during the first 2–1 hours); contributing factors such as CNS neoplasms may be identified Lumbar puncture: with subarachnoid haemorrhages, blood will be present in the CSF

*Pneumococcus*, *Haemophilus influenzae*, *Meningococcus* and *Mycobacterium TB*. (see Section 5.16.B).

#### Viral meningitis

See Section 5.16.C.

#### Cryptococcosis and other fungi

- Prevention: avoid bird faeces.
- Clinical features: chronic onset, headache (common), fever, meningism (usually but not always present), and there may be a change in mental state.
- Diagnosis: based on staining of CSF sample with Indian ink.
- Treatment:
  - Fluconazole 6–12 mg/kg orally or, if there is severe nausea, IV once daily for 14 days. There is a high

relapse rate, therefore give prophylactic fluconazole 3–6 mg/kg/day or amphotericin IV 0.5–1.5 mg/kg/day for 14 days followed by oral fluconazole for 8 weeks.

#### Syphilis

Treat with benzylpenicillin IV 50 mg/kg every 6 hours for 48 hours, then oral penicillin 25 mg/kg 6-hourly for 3 weeks (20% of cases may have a systemic febrile response to penicillin).

#### Tuberculosis

See Section 6.1.N.

#### Cerebral abscess

Acute bacterial or tuberculosis.

**TABLE 6.2.D.12 Care guidelines for children with neurological manifestations of paediatric HIV infection**

Abnormality	Care guidelines
Focal cerebral mass lesions	<ul style="list-style-type: none"> <li>● Assess for signs of increased intracranial pressure, fever, focal neurological signs and behavioural changes</li> <li>● Administer chemotherapy or antibiotics as needed</li> <li>● Provide support to family and education regarding specific medications needed by patients</li> </ul>
Myelopathy	<ul style="list-style-type: none"> <li>● Assess for pain, muscle weakness, lower-extremity weakness, incontinence and spasticity</li> <li>● Administer HAART to reverse immune suppression</li> <li>● Administer muscle relaxants as needed</li> <li>● Provide physical therapy for weakened muscles and to maintain range of motion</li> <li>● Teach exercises to the family so that they can help the patient at home</li> </ul>
Myopathy	<ul style="list-style-type: none"> <li>● Assess for pain, muscle weakness and range of motion</li> <li>● Consider discontinuing medications that may be contributing to the condition</li> <li>● Administer corticosteroids and pain medications as needed</li> <li>● Provide physical therapy for weakened muscles and to maintain range of motion</li> <li>● Teach exercises to the family so that they can help the patient at home</li> </ul>
Opportunistic infections	<ul style="list-style-type: none"> <li>● Assess for signs of increased intracranial pressure, fever, focal neurological signs and behavioural changes</li> <li>● Administer appropriate medication based on the suspected or confirmed pathogen: <ul style="list-style-type: none"> <li>– toxoplasmosis: pyrimethamine, sulfadiazine, clindamycin</li> <li>– cryptococcosis: fluconazole, flucytosine, amphotericin B</li> <li>– herpes simplex: aciclovir</li> <li>– cytomegalovirus: ganciclovir, foscarnet</li> </ul> </li> </ul>
Peripheral neuropathy	<ul style="list-style-type: none"> <li>● Assess for numbness, paraesthesias, pain and weakness</li> <li>● Administer analgesics, tricyclic antidepressants, anticonvulsants and steroids as needed</li> <li>● Provide support to the family and education regarding progression of symptoms</li> </ul>
Progressive encephalopathy	<ul style="list-style-type: none"> <li>● Assess for progressive motor dysfunction, and failure to reach or loss of age-appropriate milestones</li> <li>● Administer antiretroviral medications and muscle relaxants as needed</li> <li>● Assist with ambulation and activities of daily living</li> <li>● Provide information to the family regarding progression of symptoms</li> </ul>
Seizures	<ul style="list-style-type: none"> <li>● Assess for seizure activity</li> <li>● Protect the patient from injury during seizure activity</li> <li>● Monitor respiratory status: suction airway and administer oxygen as needed</li> <li>● Administer anticonvulsant medications as needed</li> <li>● Provide support to the family during seizures</li> <li>● Educate the patient and the family about long-term use of anticonvulsant medications and seizure precautions (e.g. patients with seizures should never swim alone or climb to high places from which they could fall during a seizure)</li> </ul>
Strokes	<ul style="list-style-type: none"> <li>● Intensive care, including neurosurgical intervention, is often needed immediately after a stroke occurs</li> <li>● Look for contributing factors, such as low platelet levels, which may be correctable</li> <li>● Assess for seizures</li> <li>● Assist with ambulation and activities of daily living</li> <li>● Provide physical therapy as needed</li> <li>● Provide support and education to the family regarding the long-term prognosis</li> </ul>

### Skin disorders

Cutaneous lesions are often the first manifestation of HIV noted by patients and healthcare professionals. These can be due to infectious or non-infectious causes. Viral, bacterial and fungal infections have been very frequently reported in HIV-infected children. These usually tend to be more severe and resistant to therapy. Common skin diseases may present with unusual skin lesions such as Norwegian scabies and disseminated, confluent and large lesions of molluscum contagiosum (see Table 6.2.D.13).

### Seroconversion rash

Maculopapular erythematous rash (very rarely observed in infants).

### Viral infections

#### Varicella

- Chickenpox: can be very severe (affecting the lungs and brain) or even fatal.

- Herpes zoster: can involve single or multiple dermatomes and may affect the eyes.

#### Treat with:

- 1 IV aciclovir (poorly absorbed by the oral route):
  - Age < 3 months: 10 mg/kg 8-hourly.
  - Age > 3 months: 20 mg/kg 8-hourly.
- 2 Valacyclovir is the prodrug of aciclovir, and achieves better blood levels orally and is an alternative to IV aciclovir (if available).
- 3 VZIG within 96 hours of contact (if available).

### HSV 1 and 2

Infection appears as a crop of localised vesicles. It may affect the lips, mouth and anogenital areas (rare in children unless sexually abused). The vesicles rupture and form irregular painful ulcers. They may interfere with mastication and swallowing, resulting in decreased oral intake and dehydration.

**TABLE 6.2.D.13 Common infectious and non-infectious skin lesions in paediatric HIV**

Infectious disorders and lesions	Non-infectious disorders and lesions
Viral infections <ul style="list-style-type: none"> <li>• Herpes simplex, herpes zoster</li> <li>• Molluscum contagiosum</li> <li>• CMV</li> <li>• Warts</li> </ul>	Seborrhoeic dermatitis, atopic dermatitis, general dermatitis Nutritional deficiency Eczema Psoriasis
Fungal infections <ul style="list-style-type: none"> <li>• Candida</li> <li>• Tinea onychomycosis</li> </ul>	Drug eruptions Vasculitis Alopecia
Bacterial infections <ul style="list-style-type: none"> <li>• Impetigo</li> <li>• Scabies</li> </ul>	

- May be recurrent and severe.
- Treat with oral aciclovir, 20mg/kg four times daily for 5–7 days (maximum single dose 800mg).

### ***Molluscum contagiosum***

Umbilicated papular lesions. Treat with ARVs (no other measures are effective). If neglected, giant lesions can result which require surgical excision.

### ***Measles***

- Prevent by immunisation (see below and Section 6.2.E).
- May not have a rash.
- Giant-cell pneumonitis may occur.
- Treat with Vitamin A and human immunoglobulin (if available).

### ***Viral warts***

These can be persistent and severe. Topical treatment is ineffective (see molluscum contagiosum above), and ARVs are the only effective treatment.

### ***Bacterial infections***

Impetigo and furunculitis due to *Staphylococcus aureus* are common. Treat with (flu)cloxacillin, 12.5–25 mg/kg four times daily orally, or a first-generation cephalosporin such as cephadrine.

### ***Fungal infection***

Fungal infection is common and involves the feet, hands and groin. Treat with topical imidazole (e.g. miconazole 2% twice daily until healed) or terbinafine cream. If severe, widespread or for nail infections, use itraconazole or terbinafine. Treatment will be needed for 4–6 weeks.

Antifungal drugs commonly used in paediatric patients include the following:

- **Itraconazole:** children aged 1–12 years: course ('pulse') of 5 mg/kg (maximum 200 mg) daily for 7 days, with subsequent courses repeated after 21-day intervals; fingernails need two courses, and toenails need three courses. For children aged 12–18 years: either 200 mg once daily for 3 months or course ('pulse') of 200 mg twice daily for 7 days, with subsequent courses repeated after 21-day intervals; fingernails need two courses, and toenails need three courses.
- **Terbinafine:** children aged over 1 year: body weight

10–20 kg, 62.5 mg once daily; body weight 20–40 kg, 125 mg once daily; body weight over 40 kg, 250 mg once daily, for 6 weeks to 3 months.

- **Fluconazole:** 6 mg/kg weekly.
- **Griseofulvin:** 20–25 mg/kg/day (microsize formulation) or 10–15 mg/kg/day (ultramicrosize formulation) for 6–12 weeks.

### **Seborrhoeic dermatitis and pityriasis versicolor**

Seborrhoeic dermatitis occurs in up to 85% of adults and children with HIV infection. It may be an early sign of HIV. It is caused by the yeast *Malassezia furfur*.

It is characterised by thick yellow hypopigmented scaly macules occurring on the scalp but also on the face or in the diaper (nappy) area. Older children may also have involvement of the nasolabial folds, the skin behind the ears, and the eyebrows.

Treatment consists of selenium-based or ketoconazole shampoo, topical coal tar or antifungal creams, aqueous cream, UVB light therapy or salicylic acid. To decrease inflammation, 1% hydrocortisone cream can be applied to the affected area (except for the face) three times per day. Parents should be instructed to use 1% hydrocortisone cream sparingly in the diaper area.

If the condition is severe, give oral fluconazole 3 mg/kg once daily.

### **Non-specific pruritic papular rash**

This is a common and severe problem in children with HIV infection. In a previously untested child it should be an indication for HIV testing. In a child who is known to have HIV, the CD4 count should be checked and ARV started if appropriate.

### **Treatment**

- Bathe in a skin antiseptic wash (e.g. dilute chlorhexidine solution).
- Antihistamines: give chlorpheniramine:
  - Age < 1 year: 1 mg twice daily.
  - Age 1–5 years: 1–2 mg three times daily.
  - Age 6–12 years: 2–4 mg three times daily.
  - Age > 12 years: 4 mg three times daily.
- Aqueous cream and calamine lotion may be of benefit.

### **Drug side effects**

Drug eruptions can occur in patients who are receiving treatment for HIV infection. These can be severe (e.g. erythema multiforme, Stevens–Johnson syndrome, toxic epidermal necrolysis).

Drug side effects are most common with co-trimoxazole, sulfadiazine, anti-tuberculous drugs (e.g. thiacetazone, which is contraindicated in HIV infection), penicillin, cephalosporins and dapsone.

Drug eruptions usually appear as pink to erythematous papules that run together and create a blotchy appearance, but may include elevated patches (hives), mucous membrane ulceration, scaling and light sensitivity.

NRTIs (nevirapine and efavirenz) have been associated with pruritic maculopapular eruptions. Most eruptions are mild, and the medication can be continued with eventual spontaneous resolution of the eruption.

To promote comfort, the patient can be given oral antihistamine such as diphenhydramine hydrochloride 1 mg/kg

every 6 hours. In more severe cases, the eruptions resolve when the medication is discontinued.

Most drug eruptions are mild and resolve after the causative medication is discontinued.

### Infestations

*Sarcoptes scabiei* (see Section 5.18) may present as in children without HIV infection. It is characterised by pruritic papular lesions that most commonly occur in the webs of the fingers and toes, the folds of the wrist, the antecubital area and the axilla. Infants may also have lesions on the palms and soles of the feet. Scrapings observed under a microscope may reveal the mite, eggs or faeces.

Treatment consists of an application of topical benzyl benzoate lotion, 25%, which is left on the skin to dry and repeated the next day. HIV-infected patients with advanced disease can experience a variant of scabies called Norwegian scabies. This type of scabies is characterised by generalised scaling and enlarged crusted plaques. After a patient is treated for scabies, the family should be advised to wash all clothing and bedclothes in hot water and iron them to kill any mites that may be living in the cloth.

### Malignancy

Consider Kaposi's sarcoma in children presenting with nodular skin lesions, diffuse lymphadenopathy and lesions on the palate and conjunctiva with peri-orbital bruising. The diagnosis is usually clinical, but can be confirmed by a needle biopsy of skin lesions or a lymph node biopsy. Suspect Kaposi's sarcoma also in children with persistent diarrhoea, weight loss, intestinal obstruction, abdominal pain or a large pleural effusion. Consider referral to a larger hospital for management.

### Eye involvement (see Section 5.15)

- Malignancy (e.g. non-Hodgkin's lymphoma, Kaposi's sarcoma).
- HIV retinopathy: this is a microangiopathy with soft exudates. It is asymptomatic and does not require treatment. It needs to be differentiated from tuberculosis.
- Cytomegalovirus retinitis: this is the most common cause of visual loss in HIV. Treat with ganciclovir 5 mg/kg IV or orally 12-hourly for 14–21 days.
- Herpes zoster: this may produce corneal ulceration and retinal necrosis.
- Toxoplasmosis: this usually causes CNS disease and reactivation disease, and may cause visual problems or blindness. Treatment includes pyrimethamine, 1–2 mg/kg/day orally for 2 days, then 1 mg/kg/day orally for 2 months, then 1 mg/kg/day orally for 3 days a week (maximum 50 mg). Secondary prophylaxis may also be given to prevent reactivation.

Prophylaxis for any opportunistic infections consists of the following:

- **Primary prophylaxis:** giving medication to prevent infection that has not yet occurred.
- **Secondary prophylaxis:** giving medication to prevent recurrence of an infection after an episode.

Prophylaxis can often be stopped after sustained immune reconstitution secondary to ART, but not in all cases.

### *Mycobacterium avium* complex (MAC)

- This produces a systemic infection with fever, chronic diarrhoea, abdominal pain, chronic malabsorption, generalised lymphadenopathy and obstructive jaundice (from lymph node enlargement around the porta hepatis).
- Treat with clarithromycin 7.5 mg/kg twice daily IV or orally or azithromycin 10 mg/kg once daily and ciprofloxacin and rifabutin.
- Consider prophylaxis with the above drugs if **CD4 cell counts are persistently < 50/mm<sup>3</sup> despite antiretroviral therapy, as the risk of MAC is high.** The opportunistic infection guidelines recommend that all HIV-infected individuals with CD4 counts of < 50 cells/mm<sup>3</sup> should have primary prophylaxis against disseminated MAC initiated. Prior to initiating prophylaxis, patients should be evaluated for active MAC infection by clinical assessment.

### Fever of unknown origin

- HIV infection itself can cause fever.
- In an endemic area, always treat for malaria (ideally after a blood film). Malaria has not usually been reported to be more severe in HIV-infected children in terms of parasite density or response to treatment. The main interaction between the two diseases has been the acquisition of HIV by children through blood transfusion for malaria-associated anaemia.
- Have a low threshold for diagnosing septicaemia and meningitis and giving powerful empirical antibiotics if severe sepsis is suspected.
- Consider tuberculosis and non-Hodgkin's lymphoma.

### Immunisation

Early immunisations can help HIV-infected children who are more likely to acquire diseases that are preventable by immunisation because of their compromised immune system. Appropriate immunisations vary according to geographical location.

Routine immunisations appear to be generally safe for children with HIV infection without fever. Although immune responses may be suboptimal in some HIV-infected children, because of the severe nature of infections and associated mortality, routine immunisation of all children with HIV exposure or confirmed HIV infection is recommended with few exceptions.

Immunisations should generally follow the Expanded Programme on Immunisation (EPI) scheme. The current EPI schedule includes DTP, OPV, hepatitis B, *Haemophilus influenzae* type B vaccine (Hib) and measles vaccine. The difference in HIV-infected children is an extra dose of measles vaccine to be given at the age of 6 months. **BCG and yellow fever vaccines should not be given to HIV-symptomatic children.**

In HIV-endemic areas, BCG is routinely administered postnatally. This should be given even to infants of mothers known to be HIV-infected, as the damage to the immune system generally occurs after the onset of viraemia (i.e. after the first 6 weeks of life). There is no evidence of frequent dissemination occurring after neonatal administration of BCG, although BCG-osis is not an easy diagnosis to establish, and there may be unrecognised cases.

Because most HIV-positive children have an effective immune response in the first year of life, EPI should be

started as early as possible after the recommended age of vaccination.

There are theoretical risks associated with giving live oral polio vaccine, particularly to other immunocompromised members of the household. However, cases of vaccine-associated paralytic illness are rare, and oral poliomyelitis vaccine (OPV) continues to be recommended.

Live attenuated measles vaccine is recommended by the WHO for children in resource-limited countries, where the risks from wild-type measles virus are high. Responses to the vaccine tend to be lower in HIV-infected children with more advanced disease. The WHO recommends giving an extra dose of measles vaccine at 6 months, as well as the standard dose at 9 months, to HIV-infected children. It is important to be aware of measles in the differential diagnosis of any child with fever or pneumonia and HIV, as a typical morbilliform rash and standard symptoms may not be present.

Other non-EPI vaccines are encouraged and recommended, especially in children whose immune systems have recovered. These more expensive but strongly recommended vaccines include MMR, pneumococcal conjugate vaccine, hepatitis A, typhoid and varicella vaccines. Diseases caused by these organisms have a greater propensity to cause severe life-threatening infections in HIV-infected children.

### **Terminal care of children dying from HIV infection**

See *also* Section 1.16.

Despite the increased availability and effectiveness of ARVs, death is still a possible outcome of HIV/AIDS. Each year, millions of children lose one or both parents to AIDS. Although relatives often go to heroic lengths to provide orphans with food, shelter and housing, often the children's psychosocial needs are overlooked, and these young people are not given full recognition or support after their loss. This is usually due to the belief that children are too young to understand what is happening or are better off not dwelling on their loss. Consequently, they are not properly supported in their time of mourning.

Local groups for the support of families with HIV infection are essential, and ideally should be funded by local government.

Give end-of-life (terminal) care if:

- the child has had a progressively worsening illness
- everything possible has been done to treat the present illness.

Keep up to date on how to contact local community-based home care programmes and HIV/AIDS counselling groups. Find out whether the carers are receiving support from these groups. If not, discuss the family's attitude towards these groups and the possibility of linking the family with them.

### **Pain control for children with HIV**

See Section 1.15.

### **Need for referral**

Often the facilities or expertise that are needed will not be available at the health centre or hospital to which a child

with suspected or confirmed HIV has come for treatment. If the child is not suffering from a life-threatening condition that requires urgent treatment, and referral can be arranged, it is advisable to refer the child to a paediatric infectious disease specialist or HIV treatment centre for the following:

- HIV testing with pre- and post-test counselling
- further investigations to confirm the diagnosis
- evaluation of immunological status and the need to initiate ART
- management of complicated HIV-related conditions and infections
- evaluation of possible treatment failure
- second-line treatment if there has been little or no response to treatment
- HIV medication-related toxicities
- HIV-related expert counselling.

### **Summary**

- The major practical focus should be on prevention of childhood HIV infection. This means implementing effective strategies for reduction of mother-to-infant transmission, such as prenatal screening of mothers and administration of ARV drugs for mother and baby.
- Unfortunately, establishing the infrastructure that is required to implement effective interventions is lagging far behind the scientific advances in this field. Surmounting the sense of hopelessness among health-care professionals who are dealing with overwhelming numbers of patients without resources is a critical issue. This may come in part from research that identifies practical interventions which improve the quality of life for HIV-infected children and their families.
- Limiting the use of blood transfusions and ensuring that the blood supply is safe, and preventing sexual transmission among adolescents, are vital public health issues.
- Positive education is required to encourage testing in the knowledge that there is now accessible safe treatment to keep children alive so that they can have a full healthy life.
- The key to successful treatment is 100% adherence. Do not start outpatient treatment until the child's carer and ideally all the family have expressed a commitment to treatment. Choose ART regimes which are simple, and ensure that there is no problem with swallowing.
- Predict growth for dosing so that the child is never under-dosed.
- Frequent review is necessary to re-emphasise the importance of adherence and education of young people.
- It is essential that resource-limited countries are permitted by multinational drug companies to develop low-cost and effective forms of HAART, without being limited by international patent regulations.
- Without question, health system strengthening is essential if the advent of ARVs for all is to be adequately managed.

This is a very optimistic time in the field of paediatric HIV, with the potential to aim for eradication of mother-to-child transmission, and to provide successful treatment.

## Appendix 1

**TABLE 6.2.D.14 Monitoring children on ART**

Item	Before or at ART initiation	Month (M) 1	M 2	M 3	M4	M5	M 6	Every 2–3 months	Symptom-directed
Clinical evaluation: history and physical examination (including neurodevelopment)	X	X	X	X	X	X	X	X	X

CD4% or count <sup>6</sup>	X							X*	X
HIV viral load measurement <sup>7</sup>									X

\* If signs of clinical progression of disease are seen, the CD4 count should be done earlier.

- The child should be seen again within 1 week of starting ART to resolve any problems.
- If the child has missed a visit, attempts should be made to call or visit the child's home.
- In addition to these suggested appointments, caregivers should be encouraged to bring the child in if he or she is sick, especially during the first few months of ART when the child may experience ART side effects and intolerance.

<sup>1</sup> Children may show rapid weight and height gain after ART, in addition to expected normal growth. Therefore the ART dose should be recalculated at every visit. Under-dosing of ART can lead to the development of resistance.

<sup>2</sup> Concomitant drugs should be asked for at every visit to ensure that the child is on appropriate CTX dosing (if indicated) and is not taking drugs that have potential interactions with ART.

<sup>3</sup> ART adherence can be assessed by asking questions about missed doses and the times when the child takes ART. Performing a pill count is time consuming, but may give a more accurate indication of adherence, if done correctly.

<sup>4</sup> Haemoglobin (Hb) and white blood cell count (WBC) monitoring may be considered in children on ZDV at 1, 2 and 3 months.

<sup>5</sup> Full chemistry includes but is not restricted to liver enzymes, renal function, glucose, lipids, amylase, lipase and serum electrolytes. Monitoring depends on symptoms and regimens. Regular liver enzyme monitoring during the first 3 months of treatment may be considered for certain children using nevirapine-based regimens, in particular for adolescent girls with a CD4 count of > 250 cells/mm<sup>3</sup>, and for infants and children who are co-infected with hepatitis B or hepatitis C virus, or other hepatic disease.

<sup>6</sup> TLC is not suitable for monitoring of therapy; therefore it cannot be a substitute for CD4. If CD4 is not available, clinical monitoring alone is used.

<sup>7</sup> At present, viral load measurement is not recommended for decision making about the initiation or regular monitoring of ART in resource-limited settings. Tests for assessment of HIV RNA viral load can also be used to diagnose HIV infection, and to assess discordant clinical and CD4 findings in children in whom ART is suspected of failing.

## Appendix 2

### Treatment of PCP infection

TABLE 6.2.D.15 Starting co-trimoxazole (CTX) prophylaxis for *Pneumocystis jiroveci* pneumonia (PCP)

HIV-exposed infants and children	Confirmed HIV-infected infants and children		
	Under 1 year	1–5 years	6 years or older
CTX prophylaxis is universally indicated, starting at 4–6 weeks after birth, and maintained until cessation of risk of HIV transmission and exclusion of HIV infection	CTX prophylaxis is indicated regardless of CD4 percentage or clinical status	WHO stages 2, 3 and 4 regardless of CD4 percentage <b>or</b> Any WHO stage and CD4 < 25%	Any WHO clinical stage and CD4 < 350 cells/mm <sup>3</sup> <b>or</b> WHO stage 3 or 4 and any CD4 level

*Patient information:* It needs to be explained to patients that although CTX does not cure HIV, regular dosing is essential for protection of children from infections that are

more common or more likely to occur in HIV infection. CTX does not replace the need for antiretroviral therapy.

TABLE 6.2.D.16 Dosing for PCP: once-daily CTX dosing

Weight	Suspension: 40 mg TMP + 200 mg SMX/5 mL	Tablets (SS): 80 mg TMP/400 mg SMX	Tablets (DS): 160 mg TMP/800 mg SMX
1–4 kg	2.5 mL	–	–
5–8 kg	5 mL	½ tablet	–
9–16 kg	10 mL	1 tablet	½ tab
17–50 kg	20 mL	2 tablets	1 tablet
> 50 kg	20 mL	2 tablets	1 tablet

## Appendix 3

### Summary of nutritional recommendations and support for HIV-infected children

- Regular growth monitoring.
- Safe infant feeding advice (the emphasis is on an **exclusive** infant feeding option). Substitute feeds if they are acceptable, affordable, feasible, sustainable and safe, otherwise exclusive breastfeeding, and early weaning. Avoid all mixed feeding.
- Dietary counselling for asymptomatic children to increase energy intake by 10% compared with HIV-uninfected children.
- Dietary counselling for symptomatic children to increase energy intake by 20–30% compared with HIV-uninfected children.
- Counselling on the importance of a balanced diet, including affordable choices from all food groups (micro-nutrient requirement of 1 RDA for age).
- Counselling on high-energy affordable food options for children with growth failure.
- Counselling on the use of clean water and hygienic food preparation.
- Vitamin A supplementation to prevent vitamin A deficiency in children aged 6 to 59 months with dosing schedule as follows:
  - Children aged 6–11 months: 100 000 IU (30 mg) once every 6 months.
  - Children aged 12–59 months: 200 000 IU (60 mg) once every 6 months.
- Zinc supplementation during diarrhoeal episodes: 10 mg once daily for 10 days in children older than 6 months if weight is ≤ 10 kg, and 20 mg if weight is > 10 kg.
- Assessment and management for underlying HIV-associated illnesses.
- Assessment for need to initiate ART.
- Referral to outreach service providers for food assistance, if needed.

## Appendix 4

TABLE 6.2.D.17 Formulations and dosages of ART drugs for children

Name of drug	Formulation	Age	Age (weight), dose and dose frequency	Other comments
<i>Nucleoside analogue reverse transcriptase inhibitors (NRTIs)</i>				
Zidovudine (ZDV) AZT	Syrup: 10 mg/mL Capsules: 100 mg, 250 mg Tablet: 300 mg	All ages	< 4 weeks: 4 mg/kg/dose twice daily 4 weeks to 13 years: 180–240 mg/m <sup>2</sup> /dose twice daily Maximum dose: ≥ 13 years: 300 mg/dose twice daily	Large volume of syrup is not well tolerated in older children, Syrup needs to be stored in glass jars and is light sensitive Can give with food Doses of 600 mg/m <sup>2</sup> /dose per day required for HIV encephalopathy Capsule can be opened and its contents dispersed, or tablet crushed and its contents mixed with a small amount of water or food and immediately taken (solution is stable at room temperature) Do not use with d4T (antagonistic antiretroviral effect)
Lamivudine (3TC)	Oral solution: 10 mg/mL Tablet: 150 mg	All ages	< 30 days: 2 mg/kg/dose twice daily ≥ 30 days or < 60 kg: 4 mg/kg/dose twice daily Maximum dose: > 60 kg: 150 mg/dose twice daily	Well tolerated Can give with food Store solution at room temperature (use within 1 month of opening) Tablet can be crushed and its contents mixed with a small amount of water or food and immediately taken
Fixed-dose combination of ZDV plus 3TC	No liquid formulation available Tablet: 300 mg ZDV plus 150 mg 3TC	Adolescents and adults	Maximum dose: > 13 years old or weight > 60 kg: 1 tablet per dose twice daily (should not be given if weight is < 30 kg)	Ideally, tablet should not be split Tablet can be crushed and its contents mixed with a small amount of water or food and immediately taken At weights of < 30 kg, ZDV and 3TC cannot be dosed accurately in tablet form
Stavudine (d4T)	Oral solution: 1 mg/mL Capsules: 15 mg, 20 mg, 30 mg, 40 mg	All ages	< 30 kg: 1 mg/kg/dose twice daily 30–60 kg: 30 mg/dose twice daily Maximum dose: > 60 kg: 40 mg/dose twice daily	Large volume of solution Keep solution refrigerated; it is stable for 30 days, but must be shaken well. It needs to be stored in glass bottles Capsules can be opened and their contents mixed with a small amount of food or water (stable in solution for 24 hours if kept refrigerated) Do not use with ZDV (antagonistic antiretroviral effect)
Didanosine (ddl, dideoxyinosine)	Oral suspension paediatric powder/water: 10 mg/mL (In many countries needs to be made up with additional antacid) Chewable tablets: 25 mg, 50 mg, 100 mg, 150 mg, 200 mg Enteric-coated beadlets in capsules: 125 mg, 200 mg, 250 mg, 400 mg	All ages	< 3 months: 50 mg/m <sup>2</sup> /dose twice daily 3 months to < 13 years: 90–120 mg/m <sup>2</sup> /dose twice daily or 240 mg/m <sup>2</sup> /dose once daily Maximum dose: ≥ 13 years or > 60 kg: 200 mg/dose twice daily or 400 mg once daily	Keep suspension refrigerated; it is stable for 30 days, but must be shaken well Administer on an empty stomach, at least 30 minutes before or 2 hours after eating If tablets are dispersed in water, at least 2 appropriate-strength tablets should be dissolved for adequate buffering Enteric-coated beadlets in capsules can be opened and sprinkled on a small amount of food

(continued)

Name of drug	Formulation	Age	Age (weight), dose and dose frequency	Other comments
<b>Abacavir (ABC)</b>	Oral solution: 20 mg/mL Tablet: 300 mg	Over 3 months	< 16 years or < 37.5 kg: 8 mg/kg/dose twice daily Maximum dose: > 16 years or ≥ 37.5 kg: 300 mg/dose twice daily	Can give with food Tablet can be crushed and its contents mixed with a small amount of water or food and immediately ingested <b>Warn parents about hypersensitivity reaction</b> ABC should be stopped permanently if a hypersensitivity reaction occurs
<i>Non-nucleoside reverse transcriptase inhibitors (NNRTIs)</i>				
Nevirapine (NVP)	Oral suspension: 10 mg/mL Tablet: 200 mg	All ages	15–30 days: 5 mg/kg/dose once daily for 2 weeks, then 120 mg/m <sup>2</sup> /dose twice daily for 2 weeks, then 200 mg/m <sup>2</sup> /dose twice daily > 30 days to 13 years: 120 mg/m <sup>2</sup> /dose once daily for 2 weeks, then 120–200 mg/m <sup>2</sup> /dose twice daily Maximum dose: > 13 yrs: 200 mg/dose once daily for first 2 weeks, then 200 mg/dose twice daily	If rifampicin co-administration, avoid use Store suspension at room temperature, but it must be shaken well Can give with food Tablets are scored and can be divided into two equal halves to give a 100 mg dose; can be crushed and combined with a small amount of water or food and immediately administered Warn parents about rash Do not dose escalate if rash occurs (if mild or moderate rash, hold drug; when rash has cleared, restart dosing from beginning of dose escalation; if severe rash, discontinue drug)
Efavirenz (EFV)	Syrup: 30 mg/mL (note that syrup requires higher doses than capsules; see dosing chart) Capsules: 50 mg, 100 mg, 200 mg	Only for children over 3 years of age or who weigh > 10 kg	Capsule (liquid) dose: 10–15 kg: 200 mg (270 mg = 9 mL) once daily 15–19 kg: 250 mg (300 mg = 10 mL) once daily 20–24 kg: 300 mg (360 mg = 12 mL) once daily 25–32 kg: 350 mg (450 mg = 15 mL) once daily 33–39 kg: 400 mg (510 mg = 17 mL) once daily Maximum dose: ≥ 40 kg: 600 mg once daily	Capsules may be opened and added to food, but have a very peppery taste; however, can mix with sweet foods or jam to disguise taste Can give with food (but avoid giving after high-fat meals which increase absorption by 50%) Best given at bedtime, especially in the first 2 weeks, to reduce CNS side effects
Etravirine	100 mg, 200 mg dispersible tablets	Child over 6 years	16–20 kg, 100 mg twice a day 21–25 kg, 125 mg twice a day 26–30 kg, 150 mg twice a day > 30 kg, 200 mg twice a day	AUC decreased by 50% if taken on an empty stomach
<i>Protease inhibitors (PIs)</i>				
Nelfinavir (NFV)	Powder for oral suspension (mix with liquid): 200 mg per level teaspoon (50 mg per 1.25 mL scoop): 5 mL Tablet: 250 mg (tablets can be halved; can be crushed and added to food or dissolved in water)	All ages However, extensive pharmacokinetic variability in infants, with requirement for very high doses in infants under 1 year	< 1 year: 50 mg/kg/dose three times daily or 75 mg/kg/dose twice daily ≥ 1 year to < 13 years: 55–65 mg/kg/dose twice daily Maximum dose: ≥ 13 years: 1250 mg/dose twice daily	Powder is sweet, faintly bitter, but gritty and hard to dissolve; must be reconstituted immediately prior to administration in water, milk, formula, pudding, etc.; do not use acidic food or juice (which increase the bitter taste); solution is stable for 6 hours Because of difficulties with use of powder, the use of crushed tablets is preferred (even for infants) if the appropriate dose can be given

(continued)

Name of drug	Formulation	Age	Age (weight), dose and dose frequency	Other comments
Nelfinavir (NFV) (cont.)				Powder and tablets can be stored at room temperature Take with food Drug interactions (less than with ritonavir-containing protease inhibitors)
Lopinavir/ ritonavir (LPV/r)	Oral solution: 80 mg/ mL lopinavir plus 20 mg/mL ritonavir Note that oral solution contains 42% alcohol Capsules: 133.3 mg lopinavir plus 33.3 mg ritonavir	6 months or older	> 6 months to 13 years: 225 mg/m <sup>2</sup> LPV and 57.5 mg/ m <sup>2</sup> ritonavir twice daily, or weight-based dosing as follows: 7–15 kg: 12 mg/kg LPV and 3 mg/kg ritonavir twice daily 16–40 kg: 10 mg/kg lopinavir and 5 mg/kg ritonavir twice daily Maximum dose: > 40 kg: 400 mg LPV and 100 mg ritonavir (3 capsules or 5 mL) twice daily	Preferably oral solution and capsules should be refrigerated; however, they can be stored at room temperature up to 25°C (77°F) for 2 months; at temperatures > 25°C (77°F) the drug degrades more rapidly Liquid formulation has low volume but bitter taste Capsules are large Capsules should <b>not</b> be crushed or opened, but must be swallowed whole Should be taken with food
Saquinavir/r	Soft gel capsule: 200 mg Hard gel capsule: 200 mg, 500 mg	> 25 kg	Approved dosing in adults: SQV 1000 mg and RTV 100 mg twice daily There are no data for children For children who weigh > 25 kg, the approved adult dosing can be used If possible, monitoring of SQV level is recommended	Capsules are large Capsules should <b>not</b> be crushed or opened, but must be swallowed whole Should be taken with food
Darunavir plus Ritonavir (DRV)	75 mg (white), 150 mg (white), 400 mg (light orange), 600 mg (orange)		<b>PI experienced, 3–6 years:</b> 10–11 kg: 200 mg twice a day + RTV 32 mg twice a day 11–12 kg: 220 mg twice daily + RTV 32 mg twice a day 12–13 kg: 240 mg twice a day + RTV 40 mg twice a day 13–14 kg: 260 mg twice a day + RTV 40 mg twice a day 14–15 kg: 280 mg twice a day + RTV 48 mg twice a day <b>6 years:</b> 15–30 kg: 375 mg twice a day + RTV 50 mg twice a day 31–40 kg: 450 mg twice a day + RTV 60 mg twice a day. > 40 kg: 600 mg twice a day + RTV 100 mg twice a day	DRV and RTV levels reduce in combination
<i>Integrase inhibitor</i>				
Raltegravir	400 mg tablets (pink)	> 6 years	> 25 kg: 400 mg twice a day	With or without food Avoid indigestion remedies

## Appendix 5

**TABLE 6.2.D.18 Side effects of ARVs**

Drug		Side effects	Comments
<i>Nucleoside analogue reverse transcriptase inhibitors (NRTIs)</i>			
Lamivudine	3TC	Headache, nausea, abdominal pain, diarrhoea, fatigue, pancreatitis	Well tolerated, can be crushed
Stavudine	d4T	Headache, abdominal pain, neuropathy, pancreatitis, lactic acidosis, hepatitis, lipodystrophy	Large volume of suspension, capsules can be opened
Zidovudine	AZT	Headache, anaemia, neutropenia, nausea, hepatitis, neuropathy, nail pigmentation	Do not use with d4T (antagonistic ARV effect)
Abacavir	ABC	Hypersensitivity reaction, with fever, mucositis and rash; this is rare, but if it occurs stop the drug	Tablets can be crushed
Didanosine	ddl	Peripheral neuropathy, diarrhoea, nausea, abdominal pain, lipodystrophy. Lactic acidosis and pancreatitis (especially with d4T)	On empty stomach, give with antacid
<i>Non-nucleoside reverse transcriptase inhibitors (NNRTIs)</i>			
Efavirenz	EFV	Vivid dreams, sleepiness, rash, mood changes, hypercholesterolaemia	Take at night, avoid taking with fatty food
Nevirapine	NVP	Rash (Stevens–Johnson syndrome), liver toxicity (check liver function tests at 2, 4 and 8 weeks)	When given with rifampicin, increase NVP dose by 30% or avoid use
<i>Protease inhibitors (PIs)</i>			
Lopinavir/ritonavir*	LPV/r	Diarrhoea, nausea, vomiting, headache	Liquid: bitter taste. Take with food Take within 2 hours of food
	NFV	Diarrhoea, vomiting, rash	
	SQV	Diarrhoea, abdominal discomfort	
Darunavir	DRV	Rash, nausea, diarrhoea, headache	
Atazanavir	ATV	Rash, nausea, jaundice, headache	Avoid antacids
Ritonavir*	RTV	Rash, nausea, diarrhoea, peri-oral paraesthesia, flushing, hepatitis	Liquid: bitter taste
<i>Integrase inhibitor</i>			
Raltegravir		Nausea, dizziness, insomnia, rash, pancreatitis, elevated ALT, AST, GGT	Avoid indigestion remedies

\*Requires cold storage and cold chain for transport.

World Health Organization (2010) *Antiretroviral Therapy for HIV Infection in Infants and Children: towards universal access*. [http://whqlibdoc.who.int/publications/2010/9789241599801\\_eng.pdf](http://whqlibdoc.who.int/publications/2010/9789241599801_eng.pdf)

## 6.2.E Measles

### BOX 6.2.E.1 Minimum standards

- Immunisation.
- Vitamin A.
- Oral rehydration solution and nutritional provision.
- Antibiotics for secondary infection.
- Oxygen.
- Nebulised adrenaline and corticosteroids for croup.
- Eye pads.
- Public health measures.

### Introduction

Measles is an acute viral disease characterised by fever, cough, coryza, conjunctivitis, an erythematous maculopapular rash, and typical oral lesions (Koplik's spots). It is caused by an RNA virus, a member of the genus *Morbillivirus* in the Paramyxoviridae family. Humans are the only natural hosts. It is transmitted by direct contact with infectious droplets or, less commonly, by airborne spread. It has a high incidence in winter. Measles is one of the most highly communicable of all infectious diseases.

Measles occurs worldwide, and is a significant cause of morbidity and mortality worldwide. It is the fifth most common cause of death in children under 5 years of age. There has been a 78% reduction in measles mortality worldwide in recent years, largely as a result of immunisation, from 733 000 deaths in 2000 to 164 000 in 2008, and a reduction in the total number of cases from 39.9 to 20 million.

### Epidemiology

- Measles is transmitted by droplet spread of virus in nasopharyngeal secretions. It is most infectious before the appearance of rash, and for at least 7 days after the onset of the first symptoms. The incubation period is 10–12 days. Quarantine can be lifted 2 days after the fever subsides.
- Epidemic cycles of infection in urban areas may occur every 2 years. In isolated communities, all age groups are affected. In resource-limited countries, the population peak incidence is at 1–2 years, with a mortality of 1–5%, although during epidemics it may rise to 30%. Mortality is low in the well nourished. Children who acquire infection in overcrowded conditions tend to have more severe disease, probably due to a larger infecting dose of the virus.
- Pneumonia and upper airway obstruction account for about 75% of measles deaths. Measles is more severe in HIV-infected children.
- In resource-limited countries, measles commonly occurs in previously vaccinated children. This is partly explained by a persistent maternal antibody at 9 months of age when vaccine is usually given, and also a relatively poor efficacy of the vaccine and waning immunity.
- It rarely occurs in infants under 3 months of age because of maternal immunity transferred *in utero*.

### Clinical features

Prodromal period (3–5 days): acute coryza-like illness with high-grade fever, cough and conjunctivitis. Febrile seizures may occur. Koplik's spots (tiny bluish-white specks on a

red base on the buccal mucosa of the cheeks, resembling grains of salt) appear by days 2–4.

A maculopapular rash commences on day 4 on the face and neck, behind the ears and along the hairline, and spreads to become generalised and reaches the feet after 3 more days). Fades after 5–6 days in order of appearance, developing a brownish colour and often becoming scaly. If severe, there may be petechiae and ecchymoses. The rash is due to infiltration of lymphocytes into areas of virus replication in skin.

Persistence of fever beyond day 3 of the rash is usually due to complications (see below).

### Diagnosis

This is mostly clinical (diagnosis is based on the specific pattern of rash, history of contact with a measles patient, and Koplik's spots). Serology, viral culture or PCR may be used to confirm it.

### Laboratory findings

Leukopenia and thrombocytopenia may be observed during measles infection. Chest radiography may demonstrate interstitial pneumonitis.

### Complications

Recovery following acute measles may be delayed for weeks or months due to failure to thrive, recurrent infections, persistent pneumonia and diarrhoea.

#### *Pneumonia* (see Section 5.3.A)

- Bacterial pneumonia usually occurs during convalescence and after several days of an afebrile period. It is the most frequent cause of death with an incidence of 10–25% of hospitalised cases in developing countries.
- Viral pneumonia occurs during the acute phase of measles, and may progress to giant-cell pneumonia in the immunosuppressed (e.g. leukaemia, HIV).
- Mediastinal emphysema occurs in 1 in 300 measles cases, and may lead to subcutaneous emphysema.

#### *Diarrhoea*

Incidence 20–40%. May become persistent and frequently precipitates malnutrition (see Section 5.12.A).

#### *Tracheobronchitis*

This presents as croup. Laryngeal tissue sometimes becomes necrotic, which may lead to laryngeal obstruction (see Section 5.1.A).

#### *Otitis media*

This is common, especially in infants. Mastoiditis may develop. It is an important cause of chronic otitis media and hearing impairment (see Section 5.1.C).

#### *Stomatitis*

There is mucosal inflammation and ulceration with bleeding gums and secondary *Candida albicans* and herpes simplex infections. Stomatitis causes difficulty in eating and worsens malnutrition. Cancrum oris (noma) may develop.

**Xerophthalmia**

Vitamin A deficiency may combine with measles to precipitate xerophthalmia and blindness (see Section 5.10.A).

**Malnutrition**

Malnutrition secondary to measles results from anorexia and poor nutrition following infection. Mortality is high (> 15%) (see Section 5.10.B).

**Tuberculosis**

Tuberculosis, including tuberculous meningitis, may first be noticed in the post-measles period (see Section 6.1.N).

**Encephalitis**

- **Acute allergic encephalitis:** this is a demyelinating disorder and the most common CNS complication of measles. Onset is often in the second week as exanthema is clearing. It occurs in one or two per 1000 cases of measles, and can be fatal. Virus is not found in the brain.
- **Acute measles inclusion-body encephalitis:** this results from direct invasion of brain cells by virus (which may be isolated from CSF). There is a more rapid onset if there is immunosuppression or malignancy.
- **Subacute sclerosing panencephalitis (SSPE):** there is a long latent period (several years) between infection and the onset of symptoms. Commonly, measles occurred at an early age. SSPE is characterised by lethargy, psychological changes, myoclonic jerks and mental deterioration, eventually leading to death. Virus has been isolated from brain biopsy specimens.
- Atypical measles may have prolonged fever and present with pneumonia or rarely encephalitis. Rash may or may not appear. Prolonged fever for 2–3 weeks with diarrhoea may simulate enteric fever.

**Differential diagnosis**

- Other exanthema and drug reactions.
- Koplik's spots are the most helpful diagnostic feature in the prodromal period.

**Case assessment and classification**

Cases may be classified into:

- uncomplicated measles
- severe measles requiring treatment or urgent referral.

**TABLE 6.2.E.1 Clinical features of severe disease**

Symptom	Complication
Cough, tachypnoea or indrawing	Pneumonia
Stridor when quiet	Croup, necrotising tracheitis
Severe diarrhoea	Dehydration
Recent severe weight loss	Malnutrition
Corneal damage or Bitot spots	Blindness
Ear discharge	Otitis media, deafness
Lethargy, convulsions	Encephalitis
Inability to drink or eat	Dehydration, malnutrition
Blood in the stools	Dysentery, haemorrhagic measles
Severe stomatitis	Cancrum oris

**Danger signs**

These include the following:

- breathing difficulty
- cyanosis
- bleeding
- corneal/mouth ulcers
- coma/lethargy
- seizures
- inability to eat or drink.

**Management****Mild measles**

- Give small frequent feeds. Infants should continue breastfeeding. Extra energy should be provided by adding vegetable oil or sugar to cereals (1 teaspoon of each). Follow-up nutritional support is needed.
- Give paracetamol for temperature > 39°C. Saline drops for blocked nose.
- Maintain oral hygiene by rinsing the mouth several times daily. Apply 1% gentian violet to mouth sores. Treat oral thrush with nystatin drops.
- If mouth ulcers are secondarily infected, give an antibiotic (penicillin or metronidazole orally for 5 days).
- If the mouth is too sore to feed or drink, a nasogastric tube may be required.
- Maintain ocular hygiene for purulent conjunctivitis, with daily washings with sterile 0.9% saline or boiled water (using cotton-wool swabs) and the application of tetracycline eye ointment three times daily. **Never use topical steroids.** Consider using protective eye pads.
- **Vitamin A treatment** of children with measles in developing countries has been associated with decreased morbidity and mortality rates. The dose is 100 000 IU as a capsule (in children under 1 year old) or 200 000 IU (in those over 1 year old). **Give a second capsule the next day.**
- Give oral rehydration solution (ORS) for diarrhoea.
- Give an oral antibiotic (co-trimoxazole, amoxicillin, ampicillin) if there is a clear indication of lower respiratory tract infection (see Section 5.3.A).
- Admit the child to hospital if they show signs or symptoms of severe measles.

**Severe measles**

Admit the child to hospital and isolate them. Airborne transmission precautions are indicated for 4 days after the onset of rash in otherwise healthy children, and for the duration of illness in immunocompromised patients.

- In addition to the care for mild measles described above:
- Give parenteral antibiotics for pneumonia or septicaemia (e.g. benzylpenicillin or ceftriaxone/cefotaxime if available). Give (flu)cloxacillin plus gentamicin or cefuroxime (if available) if *Staphylococcus aureus* is suspected. If stridor associated with fever is present use ceftriaxone/cefotaxime (if available) or chloramphenicol. Rapidly spreading pulmonary tuberculosis may be difficult to distinguish from a progressive pyogenic pneumonia.
  - Give oxygen as required to keep SpO<sub>2</sub> ≥ 94%.
  - Croup: nebulised adrenaline, 1 mL adrenaline (1 in 1000) mixed with 1 mL of saline every 2 hours, **careful observation** (see Section 5.1.A, which also describes the use of oral steroids or nebulised budesonide, either of which can be life-saving in this situation).
  - Diarrhoea: give oral rehydration and appropriate

antibiotic if the child passes bloody stools. Persistent diarrhoea requires nutritional support.

- Otitis media: give antibiotics and maintain regular aural hygiene. Screen for hearing impairment during follow-up.
- Xerophthalmia: use protective eye pads, and give vitamin A capsules (see above).
- Malnutrition: treat according to management guidelines (see Section 5.10.B).
- Encephalopathy: follow the management guidelines for coma and convulsions (see Section 5.16.A and Section 5.16.E).

#### Prevention and follow-up

- Give 'normal immunoglobulin' (if available) for susceptible immunocompromised contacts of measles cases or those under 1 year old. It is given intramuscularly to

prevent or modify measles in a susceptible child within 6 days of exposure. The usual recommended dose is 0.25 mL/kg given intramuscularly; immunocompromised children (e.g. those with HIV) should receive 0.5 mL/kg intramuscularly (the maximum dose is 15 mL).

- Improve vaccination coverage (see Section 1.17).
- Give a follow-up vitamin A dose (after 2 weeks) if the child is malnourished or has an eye disorder.
- Measles control by immunisation is one of the most important public health interventions in reducing child mortality. If a child with measles is admitted, immunise all other unimmunised children under 6 months of age in the hospital, with a follow-up second dose in all aged 6–9 months as soon after 9 months as possible. A second dose is given at 12–15 months of age.

## 6.2.F Mumps

### BOX 6.2.F.1 Minimum standards

Measles, mumps, rubella (MMR) vaccination two-dose schedule.

### Introduction

Mumps is a systemic disease characterised by swelling of one or more of the salivary glands, usually the parotid glands. It is caused by a virus of the paramyxovirus family (which also includes measles and parainfluenza). The virus is spread by airborne droplets through the respiratory tract, mouth and possibly the conjunctivae and urine, and is present in saliva, CSF, blood and urine. Other viruses and bacteria (cytomegalovirus, parainfluenza virus types 1 and 3, influenza A virus, coxsackieviruses and other enteroviruses, human immunodeficiency virus (HIV), *Staphylococcus aureus* and non-tuberculous *Mycobacterium*) may also cause parotitis.

### Clinical presentation

- The incubation period is 14–24 days. Onset is with painful swelling of parotid glands, fever, general malaise, and occasionally headache. Parotid swelling may be unilateral at first, followed a couple of days later by swelling of the opposite parotid gland, with pain on opening the dry mouth.
- Mild meningoencephalitis is common and usually neither serious nor recognised clinically. There may be nausea and vomiting, and abdominal pain.
- Orchitis presents with fever and tender oedematous swelling of the testis. In 10–20% of cases the second testicle may be affected. However, infertility is rare.
- Differential diagnosis of parotitis includes cervical

adenitis, pyogenic parotitis, recurrent parotitis, tumours of the parotid and tooth infections.

- Mumps orchitis can mimic hernias, tumours, haematomas, epididymo-orchitis and testicular torsion.

### Complications

Complications include oophoritis, mastitis, pancreatitis, nephritis, myocarditis, thyroiditis, labyrinthine disturbance, painful swelling of the lacrimal glands, optic neuritis, uveokeratitis, rapid loss of vision, arthritis, jaundice, pneumonia and thrombocytopenia. Transient or permanent unilateral nerve deafness has been reported. Infection during pregnancy very rarely causes disease of the fetus (e.g. aqueductal stenosis, hydrocephalus).

### Management

Symptomatic treatment includes analgesics, fluids, and scrotal support for orchitis. Antibiotics are usually not warranted for the uncomplicated disease, but each complication should be treated on its own merits with antibiotics (in the case of pneumonia or wherever a secondary bacterial infection is suspected), or with appropriate local treatment and monitoring. The value of corticosteroids for orchitis is not established.

### Prevention

Measles, mumps, rubella (MMR) immunisation is routine in well-resourced countries, and has reduced mumps by over 90%. The recommended two-dose vaccine schedule has an effectiveness of approximately 90% (range 88–95%).

## 6.2.G Poliomyelitis

### BOX 6.2.G.1 Minimum standards

- Immunisation.
- ABC, including airway protection if there is bulbar palsy.
- Public health measures.
- Bed rest and physiotherapy.
- Nutritional support and hydration.
- Nasogastric feeding and airway protection if there is bulbar palsy.

### Introduction

Poliomyelitis is caused by polioviruses type 1, 2 and 3, which are ingested and then multiply in the tonsils and Peyer's patches of the gut. In most cases, infection is contained at this point and the child is asymptomatic.

Due to both vertical and mass vaccination campaigns, the number of reported cases has fallen by 90% since 1988. Wild poliovirus is now mainly found in Afghanistan and a few countries in sub-Saharan Africa.

### Severity

#### Minor illness

This is associated with viraemia and non-specific symptoms, such as nausea, vomiting, abdominal pain and sore throat.

#### Major illness

##### Non-paralytic poliomyelitis

This occurs in a minority of symptomatic children. Incubation period is 10–14 days and symptoms include: fever, headache and two to five days later, signs of meningeal irritation with severe pain and stiffness of neck, back and limbs.

##### Paralytic poliomyelitis

- Paralysis occurs within the first 2 days of major illness.
- It can affect any muscles, but particularly large ones and those of the lower limbs.
- Asymmetrical paralysis, flaccid muscles and absent tendon reflexes are characteristic. There is intact sensation. Paralysis is maximal within 3–5 days of onset, and rarely extends once the temperature has settled.
- In **bulbar form**, the involvement of cranial nerve nuclei and vital centres in the brainstem results in paralysis of the facial, pharyngeal, laryngeal and tongue muscles, causing swallowing difficulties, aspiration and respiratory failure.
- Hypertension may occur, as well as transient bladder paralysis.

### Diagnosis

CSF initially shows neutrophil predominance, but after 5–7 days is mainly lymphocytic. CSF protein levels are normal or slightly elevated. CSF glucose levels are normal. Virus can be isolated from throat and stool for up to 3 months after onset. The differential diagnosis includes other causes of acute flaccid paralysis (see Section 5.16.F).

### Prognosis

- This depends on the extent of paralysis and the quality of care during the acute phase.
- Early identification of and intervention for respiratory and bulbar paralysis will reduce mortality to 5–10%.
- With appropriate physiotherapy, improvement in the function of paralysed muscles can occur for up to 18 months.
- Factors that adversely affect outcome include intramuscular injections, muscle fatigue, corticosteroid therapy and immunocompromised states. Removal of tonsils or teeth during the incubation period increases the risk of bulbar paralysis.

### Management

#### Acute phase

- Absolute bed rest is mandatory. Avoid intramuscular injections and exercise.
- Analgesics should be given for severe pain. Keep paralysed muscles in a neutral position to prevent contractures.
- Gentle passive exercises and warm compresses should be used to help to relieve pain. Active exercises are introduced a few days after the temperature has settled.
- Respiratory paralysis requires ventilatory support (if available) (see Sections 1.25 and 8.3).
- Bulbar paralysis requires nasogastric tube feeding and, to protect the airway, may require tracheostomy.

#### Convalescent phase

- Aim to improve motor function, prevent deformities and generally reintegrate the child into society.
- Encourage active participation by the parents in the rehabilitation process. The educational and emotional needs of the child must not be neglected. The services of an orthopaedic surgeon and an orthoptist may be required.
- See Sections 4.2.C, 4.2.D and 4.2.E for further information on the long-term care of children with a disability.

### Prevention

See Section 1.17 on immunisation.

## 6.2.H Rabies management and prevention after animal bites

### BOX 6.2.H.1 Minimum standards

- Palliative care, including morphine.
- Wound care.
- Rabies vaccine.
- Rabies immunoglobulin.

### Rabies encephalitis

Furious and paralytic (dumb) forms of human rabies can occur. Furious rabies is characterised by agitation, hyper-excitability and hydrophobia, which is due to spasms of the inspiratory muscles, accompanied by an inexplicable feeling of terror. Spasms occur on attempting to drink water or from a draught of air. Flaccid paralysis without hydrophobia occurs in some patients, but this paralytic rabies is rarely recognised. It is likely to be misdiagnosed as another encephalitis or cerebral malaria. Once symptoms of encephalitis have begun there is no treatment. The disease is always fatal in Asia, Africa and Europe. A very few patients have survived infection after contact with bats in the Americas. North and South American bat rabies viruses appear to be less pathogenic.

### Management

The treatment of established rabies is palliative. Sedatives (e.g. diazepam, midazolam) and strong analgesics (e.g. morphine) may be given parenterally to control symptoms and relieve anxiety. An IV infusion assuages the feeling of thirst. Relatives and staff should wear gloves when handling the child, their vomitus or their saliva. Close attendants are at risk of exposure to the virus, but there is no documented case of transmission of rabies to a carer. However, if anti-rabies vaccine is available it should be offered to them, but rabies immunoglobulin (RIG) is not needed.

### Rabies prophylaxis

**Dog** bites are the usual cause of rabies in humans, but cats, foxes, bats, jackals, wolves, mongooses and domestic mammals may also transmit the infection.

### Estimating the risk of exposure to rabies

- 1 Is there a bite wound with broken skin? Have mucous membranes or an existing skin lesion been contaminated by virus in the animal's saliva? Intact skin is a barrier against the virus.
- 2 How did the animal behave? An unprovoked attack by a frantic dog is a high risk, but so is contact with a paralysed animal, or an unusually tame wild mammal.
- 3 Is rabies known to occur in the biting animal species?
- 4 Regularly vaccinated animals are unlikely to be rabid, but vaccinated dogs or cats can transmit the infection.
- 5 Try to have the animal's brain examined for rabies. If this is not possible, the animal may be kept under safe observation, but post-exposure treatment must not be delayed. If the animal is still healthy after 10 days, vaccine treatment of the patient can be stopped.

### Post-exposure treatment

Table 6.2.H.1 lists the criteria for initiating treatment. All

three parts of post-exposure therapy are always **urgent**. The aim is to chemically kill or neutralise the rabies virus at the wound site before it can enter a nerve ending and travel to the brain. Neutralising antibody is provided by local injection of rabies immunoglobulin, or it may be present already in previously vaccinated individuals.

- 1 Wound care: this is important for all bites, irrespective of the rabies risk.
- 2 Rabies vaccine (active immunisation).
- 3 Rabies immunoglobulin (RIG) is passive immunisation which provides antibody locally for the first week, until the vaccine-induced antibody appears.

### Wound care

- Scrub and flush the lesion repeatedly and energetically with **soap or detergent and water**. Remove any foreign material. Local analgesia may be necessary.
- Apply povidone iodine (or 70% ethyl alcohol, but this is painful).
- Do not suture the wound, or at least delay suturing.
- Give tetanus immunisation if appropriate.
- Treat bacterial infection of wounds with an oral antibiotic, such as amoxicillin/clavulanic acid or tetracycline.

### Rabies vaccine

Active immunisation with vaccine should be given whenever there is a risk from contact with a suspect rabid animal. Rabies vaccines are suitable for people of all ages, including pregnant women.

Vaccines accredited by the WHO include the following:

- Purified chick embryo cell vaccine (PCEC) (Rabipur<sup>®</sup>, RabAvert<sup>®</sup>) (1.0 mL/ampoule).
- Purified vero cell vaccine (PVRV) (Verorab<sup>®</sup>) (0.5 mL/ampoule).
- Purified duck embryo vaccine (PDEV) (Vaxirab<sup>®</sup>) (1.0 mL/ampoule).
- Human diploid cell vaccine (HDCV) by Sanofi (1.0 mL/ampoule).

These vaccines are interchangeable, so a change may be made to a different vaccine during a course of treatment.

The side effects of these vaccines are mild local or non-specific generalised symptoms. Transient maculopapular or urticarial rashes are occasionally seen.

### Other vaccines

- 1 Tissue culture rabies vaccines not listed above should be used according to the manufacturer's instructions.
- 2 Vaccines of nervous tissue origin (e.g. Semple vaccine and suckling mouse brain vaccine) should only be used if no other vaccine is available.

### Three post-exposure regimens (see Table 6.2.H.2)

#### Standard five-dose intramuscular (IM) 'Essen' regimen

- Days 0, 3, 7, 14 and 28: Inject one IM dose (1 mL or 0.5 mL) into the deltoid or antero-lateral thigh in small children. Do not inject into the gluteal region.

**Economical four-site intradermal (ID) regimen**

The intradermal dose is **0.1 mL per site for vaccines containing 0.5 mL/ampoule** (e.g. Verorab®), and **0.2 mL per site for vaccines containing 1 mL/ampoule** (e.g. Rabipur®).

- Day 0: draw up a whole ampoule of vaccine into a 1-mL (Mantoux-type) syringe. Give intradermal injections at four sites (deltoid, and either thigh or suprascapular areas) using all of the vaccine.
- Day 7: give an intradermal dose (**0.1 mL or 0.2 mL**) at two sites (deltoid areas).
- Day 28: give one intradermal dose.

**Practical points**

- Intradermal injections should raise a **papule** as with BCG vaccine.
- Inject using strict aseptic precautions. If ampoules are shared, use a new **sterile needle and syringe** for each patient. If there is difficulty in injecting 0.2 mL intradermally, withdraw the needle and inject the remainder at an adjacent site.
- **Do not waste vaccine.** Ampoules shared between patients must be stored at 5°C and used on the same day.
- If few patients are treated, on day 0 ask the patient to bring their relatives and friends for pre-exposure vaccine on day 7.
- If vaccine is very scarce or unaffordable, and 1-mL vaccines (e.g. Rabipur®) are used, half the dose (i.e. 0.1 mL per intradermal site) may be used.
- The timing of the final dose can be varied for economy. A clinic could assign 1 or 2 days a week for intradermal rabies vaccination for the day 28 doses and pre-exposure immunisation (see below).
- This is the **most economical** rabies post-exposure regimen both for the healthcare provider and for the patient.
- This regimen is as immunogenic as IM vaccination, and may become the treatment of choice in Asia and Africa.

**Economical two-site ID regimen**

The **intradermal dose is 0.1 mL per site for vaccines containing 0.5 mL/ampoule** (e.g. Verorab®). The equivalent dose is **0.2 mL for vaccines containing 1 mL** (e.g. Rabipur®), but half the dose (i.e. 0.1 mL per site) is used.

- Days 0, 3, 7 and 28: give an intradermal dose at two sites (deltoids).

The same precautions for intradermal use as described above apply. This regimen is less economical if few patients are being treated. It has mainly been used in large clinics.

**Rabies immunoglobulin (RIG)**

- Passive immunisation with RIG is recommended to accompany vaccine following contact with suspected rabid animals where the skin has been broken or mucous membranes have been contaminated (see Table 6.2.H.2).
- It is vital for bites with a high risk of infection (on the head, neck or hands) or for multiple bites.
- If supplies are limited, ensure that the high-risk, severely exposed patients have access to RIG.
- If RIG is not available immediately, it should be given up to 7 days after the first dose of vaccine. After that it is no longer needed.

- RIG is not required if a course of vaccine has been completed previously.

**Dosage:** equine RIG (40 IU/kg) or human RIG (20 IU/kg) is infiltrated into and around the wound on day 0. If this is not anatomically possible (e.g. on a finger), inject any remainder IM, at a site remote from the vaccine site, but not into the gluteal region.

- Skin tests are **not** useful for predicting anaphylactoid reactions to equine RIG, and should not be used.
- In very rare cases there may be **anaphylaxis**.

**Anaphylaxis treatment (see also Section 5.1.B)**

**Adrenaline (epinephrine) intramuscular treatment is essential.**

Dosage:

- Age < 6 years: 150 micrograms or 0.15 mL of 1:1000 (1 mg/mL).
- Age 6–12 years: 300 micrograms or 0.3 mL of 1:1000.
- Age > 12 years: 500 micrograms or 0.5 mL of 1:1000.

The dose can be repeated at 5-minute intervals if necessary. In addition, if available give the following:

**Chlorpheniramine maleate IM or by slow IV injection**

- Dosage:
- Age 6 months to 6 years: 2.5 mg.
  - Age 6–12 years: 5 mg.
  - Age > 12 years: 10 mg.

**Hydrocortisone sodium succinate by slow IV injection or IM**

- Dosage:
- Age 1–5 years: 50 mg.
  - Age 6–12 years: 100 mg.
  - Age > 12 years: 200 mg.

**Post-exposure treatment for previously vaccinated adults**

Thorough wound care and vaccine treatment are always **urgent** following possible exposure to a rabid animal. Patients who have previously had a complete pre-exposure (three doses) or post-exposure course of vaccine only require a short booster course, and RIG is not necessary.

**Two post-exposure booster regimens (see Table 6.2.H.2)****Standard two-dose IM regimen**

- Days 0 and 3: inject one IM vaccine dose.

**Economical single-day four-site ID regimen**

- Day 0: Give 0.1 mL intradermal injections at four sites (deltoids, and either thigh or suprascapular areas).
- The intradermal dose is 0.1 mL, which is sufficient for vaccines of any volume. For Verorab® (0.5 mL/ampoule) a whole ampoule is used.
- For 1 mL vaccines, the total dose is half an ampoule. **Do not waste vaccine.** Ampoules may be shared between patients or used as pre-exposure prophylaxis for relatives, hospital staff, etc. on the same day. **See above for precautions when sharing ampoules.** If the ampoule cannot be shared, give the whole 1 mL to the patient at four sites, as for the primary four-site intradermal regimen described above.

### Pre-exposure treatment

Pre-exposure vaccination is the best means of rabies prophylaxis. No one who has had pre-exposure treatment and a post-exposure booster injection is known to have died of rabies.

#### Indications for pre-exposure rabies prophylaxis

People working with dogs, bats or other wild mammals should be immunised. Anyone in an area where dog rabies is enzootic is at risk of infection, especially children. Ideally, rabies should be included as part of the routine Expanded Programme on Immunisation (EPI). Pre-exposure vaccine should be given whenever it is affordable to residents of dog rabies areas, and should be strongly encouraged if RIG may not be available locally.

#### Pre-exposure three-dose regimen (see Table 6.2.H.2)

Days 0, 7 and 28: Inject one dose of a vaccine IM (1 ampoule) or intradermally (0.1 mL). Variation in timing does not matter. The final dose may be given from day 21 to months later, but aim for a total of three doses. Having had one or two doses is still an advantage if the individual is exposed to rabies in the future, especially if RIG may not be available.

- Patients on chloroquine, steroids or other immunosuppressive drugs should have IM not intradermal injections for pre-exposure treatment.
- Patients who have been vaccinated should keep a record of their immunisations.
- Routine booster doses are only recommended for people at high occupational risk of exposure.
- If contact with a rabid animal occurs, **post-exposure booster vaccine treatment is still required.**

### Summary

- The only treatment for rabies encephalitis is palliative care.
- Rabies can be prevented by education about the

**TABLE 6.2.H.1 Recommended criteria for post-exposure treatment**

Type of exposure	Criteria	Action
No exposure*	Touching animals, or being licked on intact skin	No treatment
Minor exposure, WHO Category II	Nibbling (tooth contact) with uncovered skin, or minor scratches or abrasions without bleeding	Start vaccine immediately
Major exposure, WHO Category III	Single or multiple bites or scratches that break the skin, or licking on broken skin, or licking or saliva on mucosae, or physical contact with bats	Immediate rabies immunoglobulin and vaccine
Severe exposure, WHO Category III	Bites on the head, neck or hands, or multiple bites	Immediate rabies immunoglobulin is mandatory with vaccine

For all cases:

- Stop treatment if the dog or cat remains healthy for 10 days.
- Stop treatment if the animal's brain is shown to be negative for rabies by appropriate investigation.

\*The confusing term 'WHO Category I' should be avoided, as misunderstanding leads to unnecessary treatment.

dangers of animal contact, the need for vaccination of pets, first-aid cleaning of wounds with soap, and the need to attend a clinic for vaccine.

- Pre-exposure vaccination should be encouraged, especially for children and if RIG is not available locally.
- Post-exposure prophylaxis is urgent.
- If rabies vaccine is unaffordable or in short supply use robust economical ID regimens that are suitable for use globally.

This scheme is a modification of WHO recommendations.

**TABLE 6.2.H.2 Selected standard intramuscular and economical intradermal rabies vaccine regimens**

Vaccine regimen and route	Days of injection (number of sites injected denoted by superscript number)				Visits to clinic	Total vaccine used (ampoules)
Pre-exposure:						
IM	0	7		28	3	3
ID 0.1 mL <sup>‡</sup>	0	7		28	3	< 1–3
Post-exposure (+ RIG day 0):						
IM five-dose	0	3	7	14	28	5
ID four-site <sup>†</sup>	0 <sup>4</sup>		7 <sup>2</sup>		28	3
Post-exposure booster if previous vaccine course:						
IM	0	3			2	2
ID*	0 <sup>4</sup>				1	1 (or < 1)*

IM, intramuscular; ID, intradermal.

\* 0.1 mL/site, whole ampoule used for 0.5 mL vaccines. For 1 mL ampoules share between two, or alternatively use the whole dose to avoid wastage.

<sup>†</sup> Intradermal doses are 0.1 mL/site for PVRV vaccine (0.5 mL/ampoule) or the equivalent dose, 0.2 mL/site of injection, for PCECV vaccine (1.0 mL/ampoule).

<sup>‡</sup> Intradermal doses are all 0.1 mL/site of injection.

## 6.2.1 Viral haemorrhagic fevers

### BOX 6.2.1.1 Minimum standards

- ABCD.
- Management of shock.
- Blood transfusion and clotting factors.
- Isolation and infection control.
- Public health measures.

### Introduction

Viral haemorrhagic fevers (VHFs) are a group of severe infections caused by viruses that normally affect animals. Human infection is characterised by high fever and, in a proportion of cases, haemorrhage. Animal hosts such as rodents are usually asymptomatic and are often infected with virus from birth, excreting it in urine or body fluids throughout life.

In primary cases, transmission to humans occurs by a variety of routes, such as food contaminated with urine (e.g. Lassa, Junin, Machupo and Hantaan fevers) via arthropod vectors such as ticks (e.g. Crimean-Congo and Omsk fevers) or mosquitoes (e.g. Rift Valley fever). The hosts for Ebola and Marburg haemorrhagic fevers are not yet known.

Humans with disease are usually highly infectious. Most VHFs cause severe disease with a high mortality, especially following human-to-human spread (secondary cases). Some (e.g. Lassa fever) may also cause asymptomatic or mild illness.

Symptomatic disease is commonly mistaken for other febrile illnesses, typically malaria, typhoid fever or *Shigella* dysentery, which fail to respond to treatment. Individual VHFs are geographically restricted in distribution. As with all geographical illnesses, clinicians only need to know of those present in the local area. VHFs are fortunately rare.

### Lassa fever

- Distribution: West Africa (Nigeria, Sierra Leone, Liberia and Guinea).
- Host: Mastomys rat (habitat is rural).
- Transmission:
  - **Primary:** mainly from contact with host (rat) urine. Food may be contaminated.
  - **Secondary:** transmission from patient to carer, or to hospital and laboratory staff is common, particularly from haemorrhagic cases. Maternal illness is particularly severe, with a high risk of vertical transmission to the baby (which is invariably fatal).

### Prevalence

This disease is relatively common. Most primary human infections are not severe, and many are subclinical. Childhood seroprevalence in Sierra Leone can be as high as 20% in some rural villages. Outbreaks may occur in displaced communities or when humans enter host habitat.

### Clinical features

- High fever (>39°C) with cough and vomiting in 65% of hospital cases.
- Abdominal pain and diarrhoea are common (around 35% of cases).

- In children, wheeze and pleural effusions are more frequent than in adults.
- Sore throat and pharyngeal ulcers occur less frequently in children than in adults, but are highly suggestive of Lassa fever.
- In children, oedema (especially of the face) and overt bleeding are seen in 10% of cases, and in a febrile child from an appropriate area should suggest Lassa fever.
- At the epicentre of the transmission area, Lassa fever is a common cause of a febrile child with convulsions.

### Diagnosis of Lassa fever

#### Clinical case diagnosis

- An unexplained febrile illness compatible with Lassa fever, in a child from an area of known transmission, with no response of either fever or illness to an anti-malarial drug plus a broad-spectrum antibiotic (e.g. chloramphenicol).
  - Note that malaria parasitaemia in an area of endemic malaria transmission is not sufficient to exclude other causes of fever (e.g. VHF) as the cause of a febrile illness, as many adults and older children may have coincidental asymptomatic malaria parasitaemia as the cause of a febrile illness.

#### Supportive indirect laboratory tests

- Raised liver transaminases (AST/SGOT) (in adults this reflects a poorer prognosis).
- Low initial white blood cell counts, but often a normal platelet count.

#### Confirmation of diagnosis

- **Positive specific IgM serology** (on admission only 50% of cases are positive).
- **Rising IgG titres** to Lassa on acute and convalescent serum.
- Isolation of virus: this is rarely appropriate and, **due to the high risks of laboratory infection, samples should not be taken without senior expert advice.**
  - Samples must be marked as high infection risk, ideally with standard yellow hazard tape, and sent in two sealed plastic bags. Samples should only be taken if laboratory staff are aware of the potential risks, and are able to take the necessary precautions to handle such specimens safely. The laboratory should be informed that the specimen has been sent.

### Management

- Appropriate symptomatic management of fever, distress and pain.
- Fluid and nutritional requirements.
- Supportive care includes oxygen (if hypoxic) and initial IV volume replacement if the patient is hypovolaemic (see Section 5.5).
- Blood transfusion may be required for a falling PCV or haemorrhage. Fresh-frozen plasma (FFP) may not be of benefit, as inhibitors of clotting factors may cause bleeding.
- **Early ribavirin can improve the prognosis in severe disease, but is very expensive.**

**Infection control**

See below and Section 1.2.

**Ebola**

- Distribution: Central Africa (Sudan, Democratic Republic of the Congo, Gabon, Cote d'Ivoire, Uganda) and West Africa (Guinea, Liberia and Sierra Leone).
- Host: the main animal reservoir is unknown.
- Transmission:
  - **Primary:** infection occurs mainly in adults trekking in tropical Central African forests. Transmission from primates to humans has been recorded.
  - **Secondary:** patients with advanced disease are viraemic and highly infectious. Once in a human host, transmission to carers, hospital and laboratory staff is frequent (30% of doctors developed Ebola during an outbreak in Kikwit, Democratic Republic of the Congo). However, once effective infection control measures have been implemented, secondary cases are rare.

The disease is invariably severe, with a high death rate, but only 20% of cases in the Democratic Republic of the Congo outbreak were under 15 years of age. Children are at low risk in the community, and boys have half the incidence of girls, possibly because they are less involved in the care of sick adults.

Invariably, in children, there is a history of contact with a primary case, and an outbreak of an illness that could be Ebola is present in the hospital and/or community. Post-mortem transmission does occur, possibly through skin contact.

**Prevalence**

**Prevalence is low:** the disease occurs sporadically in well-localised outbreaks.

**Clinical disease (data for adults)**

- Fever is invariably present, and diarrhoea occurs in 85% of cases. This is bloody in 20% of cases, and can be confused with *Shigella* dysentery.
- Vomiting and abdominal pain are common (75% of cases).
- Headaches, myalgia or arthralgias are reported in 50% of cases.
- Sore throat occurs in 50% of cases, and is a distinguishing feature, as is conjunctival injection (45%).
- A maculopapular rash, although poorly visible on black African skin, is common.
- Cough occurs in 10% of cases.
- Bleeding is seen in 40% of cases, and is usually either gastrointestinal, oral, at injection sites or as skin petechiae. This is a major diagnostic sign.
- Hospital mortality is around 80%. Recovery starts 2 weeks into the illness.

**Diagnosis of Ebola****Clinical diagnosis**

- **Suspected clinical case (during epidemic):** any febrile illness associated with haemorrhage. No contact history is required.
- **Probable case (during epidemic):** a febrile illness occurring within 3 weeks of contact with a case of Ebola

or

a febrile illness in which three or more of the above clinical features are present.

- **Possible clinical case (non-epidemic):** an unexplained severe febrile illness, particularly with haemorrhage, in an area of Ebola transmission, with no response to an antimalarial drug plus a broad-spectrum antibiotic (e.g. chloramphenicol).

**Indirect laboratory tests supportive of diagnosis**

- Raised liver transaminases (AST/SGOT).
- Low or normal initial white blood cell count.

**Confirmation of diagnosis**

Early serological tests were difficult to interpret, but newer specific IgM ELISAs may allow diagnosis of acute cases on a single positive test. However, IgM is not always positive at presentation.

- **Specific IgG (by ELISA) rises too slowly to be used as a test of acute infection, but may be useful in epidemiological surveys.**
- **Isolation of the virus is not appropriate outside a specialised laboratory.**
- **A post-mortem skin biopsy (in formalin at room temperature) is not infectious, and can allow a diagnosis to be made using immunohistochemistry.**

Samples need to be marked as **high infection risk**, ideally with standard yellow hazard tape, and sent in two sealed plastic bags. Samples should only be taken where laboratory staff are aware of the potential risks and can take the necessary precautions to handle such specimens safely. The laboratory should be informed that the specimen has been sent.

**Infection control**

See below and Section 1.2.

**Notification**

Consider formal identification of a possible outbreak of Ebola if there is a new illness of high mortality in adults in a recognised area of transmission, particularly if hospital-acquired secondary cases have occurred.

**Management**

- Apart from supportive care, particularly with regard to adequate fluid and nutritional intake, there are no specific treatments that modify the course of the illness.
- Antimalarial and antibiotic therapy should be given routinely, directed at treating possible alternative diagnoses (e.g. shigellosis, typhoid).

**Infection control of VHF**

At increased risk are laboratory staff, midwives, and those staff and family members who are handling body fluids and excreta. High-risk patient groups are those with active haemorrhage, those who are confused and agitated, and pregnant mothers.

**Barrier nursing**

- Secondary spread is usually by contact with blood, urine-infected secretions, used needles or stool, but

some viruses (e.g. Ebola) have also been found on patients' skin.

- There is little clinical evidence of respiratory aerosol spread for the VHFs, although virus may be present in the nose and oropharynx.
- Surgical and obstetric procedures carry a particularly high risk of infection for staff.
- **Transmission is substantially reduced by strict adherence to barrier nursing, disinfection of excreta, and clear labelling of 'at risk' specimens.**
  - **Only essential samples should be taken.**
  - The laboratory should be aware of and prepared to receive specimens.
  - Family contact should be restricted to the minimum required for care.
  - Soap and water should be available for hand washing before and after patient contact.
  - **For all carers, including family members, careful barrier nursing with gloves and plastic aprons is mandatory, and stocks of these must be readily to hand.**
  - Hospital staff and carers are advised to wear double gloves, plastic aprons, gowns (with boots), a head covering, HEPA-type face masks and goggles or eye shields. However, in a tropical setting these can only be tolerated for a few hours at a time, so arrange work to account for this.
  - If outer gloves are not changed between patients, gloved hands should be washed in 1:100 bleach.
  - Appropriate disposal of excreta and clinical waste is essential, so incinerate burnable clinical waste daily, and flush excreta down a dedicated toilet, having added 1:10 household bleach (0.5% chlorine) first.

- (a) Disinfect bedpans and urine bottles with 1:10 bleach.
- (b) Disinfect beds and equipment with 1:100 bleach.
- (c) Disinfect the dead with 1:10 bleach before burying in a sealed plastic bag.

Consider using seropositive staff to nurse these patients. The identification and involvement of these staff has been successful in some outbreaks. They must follow the ward infection control measures. Remember that convalescent patients may continue to excrete virus for many months (in both Lassa and Ebola).

Fear among staff and the community needs to be addressed openly, and staff and carers must be educated about the role of barrier nursing measures, and the risks involved if these are not implemented.

Careful attention should be paid where local culture and customs (e.g. burial rites, 'widow cleansing', care of the sick, etc.) cause 'high-risk' activity. Education and participation of community leaders is important to ensure safe practice.

### Which patients should be isolated?

#### Isolation of all patients who are likely to have a VHF on admission

- The different categories of **clinical diagnostic probability** are based on fever, contact history, haemorrhagic and non-haemorrhagic clinical signs, initial laboratory tests and geography. These categories are as follows:

- suspected clinical VHF
- probable VHF
- illness probably not a VHF.

- Distinguishing signs (e.g. conjunctivitis in Ebola) are particularly helpful for categorising cases.

#### Isolation of suspected and probable cases on presentation to hospital

- Isolation should ideally be in single rooms, but an identified separate communal ward for probable and confirmed cases is often all that is available.
  - This should have an adjoining toilet, for safe waste disposal.
  - There should be a separate adjoining area for changing into and storing isolation clothing.
  - Supplies of gloves, gowns, etc. need to be readily available.
  - Hand-washing facilities are mandatory.
- The area should be marked as 'access restricted' to only those trained in VHF isolation precautions, and attention should be paid to screening windows.

#### Written infection control measures should be clearly displayed on the ward.

#### Differential diagnosis of VHFs

- The important differential diagnoses are, depending on geography, falciparum malaria, typhoid, meningococcaemia, *Shigella* or non-specific bloody dysentery, severe sepsis, leptospirosis, plague, yellow fever and dengue.
- It is crucial to exclude other treatable disease in patients presenting with symptoms suggestive of a VHF, and to initiate therapy directed at these.
- All patients should therefore receive a broad-spectrum antibiotic (e.g. chloramphenicol), and in some areas an antimalarial drug.
- In an endemic area, or during a known outbreak, the clinical diagnosis of a VHF is relatively straightforward. Difficulty arises when sporadic or new cases occur.
- A history of contact with a case in the previous 3 weeks and a history of recent travel to a transmission area should be sought. As no VHF has an incubation period longer than 3 weeks, travellers or contacts of known or suspected cases who are well after this period are unlikely to be infected.

#### Further reading

## 6.2.J Yellow fever

### BOX 6.2.J.1 Minimum standards

- Immunisation.
- Intensive supportive care.
- Blood transfusion.
- Vector control.
- Internationally notifiable.

### Introduction

Yellow fever is a flavivirus infection spread by the bite of *Aedes* and other mosquitoes.

### Epidemiology

- Yellow fever is currently confined to tropical Africa and parts of South America, especially around the Amazon basin. It does not occur in Asia.
- A reservoir of infection exists in jungle primates, and mosquitoes which bite the animals in the tree canopy.
- Three transmission cycles are recognised:
  - sylvatic (jungle), in which a reservoir is maintained among jungle primates by mosquitoes, with humans being infected incidentally
  - intermediate (savannah), the commonest cycle occurring in Africa, in which semi-domestic mosquitoes may cause small epidemics in rural villages
  - urban, in which infected humans introduce infection to urban areas, where the day-biting *Aedes aegypti* flourishes and may cause major epidemics in unvaccinated populations.

### Pathophysiology

Symptoms are due to toxic effects on the liver, kidneys and sometimes other organs, such as the heart and brain. Asymptomatic infections may also occur.

### Clinical features

- The incubation period is 3–6 days.
- Many patients have an initial febrile illness, with chills and muscle pains, from which they recover.
- Others, after an illness of about 5 days, have a brief period of apparent improvement followed by deterioration and the following complications:
  - vomiting: first bilious and then black ('coffee grounds')
  - jaundice, liver failure and hypoglycaemia
  - bleeding of the gums, nose and stomach
  - proteinuria, oliguria and renal failure
  - delirium and coma.

- Mortality among complicated cases is 20–50%.

### Laboratory diagnosis

- Leukopenia, thrombocytopenia, initial haemoconcentration and then haemodilution.
- Raised transaminases and bilirubin levels.
- Abnormal clotting.
- Proteinuria and impaired renal function.
- Rapid detection methods for yellow fever virus include PCR and antigen detection.
- The serum IgM-ELISA assay is 95% sensitive if performed within 7–10 days of clinical onset.
- **A probable case is defined as positive IgM-ELISA taken within days 3–10** of symptoms.
- A confirmed case is defined as a clinically compatible case plus a fourfold rise in antibody titre in a patient with no history of recent yellow fever vaccination and having excluded cross-reactivity with other flaviviruses.
- Post-mortem liver biopsy specimens show mid-zone necrosis of hepatic lobules, often with eosinophilic Councilman bodies. Antigen may also be detected in tissue.

### Management

- **Universal cross-infection precautions**, careful nursing and symptom control.
- Nurse suspected patients under permethrin-treated bed nets, as blood may remain infective for mosquitoes up to 5 days after onset.
- Supportive management, fluids, blood transfusion, fresh-frozen plasma, inotropes, dialysis, and ventilation if required.
- No specific antiviral treatment is available. Caution in prescribing and beware risk of bleeding, hepatic and renal impairment. H<sub>2</sub>-receptor antagonists may reduce risk of gastric bleeding.
- **Suspected cases of yellow fever must be notified within 24 hours** to national public health authorities, which in turn notify the WHO.

### Prevention

- Elimination of the breeding sites of *Aedes aegypti* mosquitoes around human dwellings.
- Immunisation of the local population with live attenuated 17D yellow fever vaccine. Immunisation becomes effective after 10 days. Vaccine may be given to children aged 6 months or older unless there are specific contraindications (e.g. if they are immunocompromised).

## 6.3 Other parasitic infections

### 6.3.A Systemic protozoal infections

#### 6.3.A.a African trypanosomiasis

##### BOX 6.3.A.A.1 Minimum standards

- Hydration, nutritional support, and treatment of intercurrent infections.
- Confirm the diagnosis, including lumbar puncture for clinical staging.
- Pentamidine, suramin, melarsoprol, eflornithine and nifurtimox.
- Prednisolone.
- Public health measures and vector control.

#### Introduction

Gambian trypanosomiasis, caused by *Trypanosoma brucei gambiense*, is a slowly progressive disease of West and Central Africa. Rhodesian trypanosomiasis, caused by *T. b. rhodesiense*, is a subacute infection found in East and Southern Africa. Trypanosomiasis of wild and domestic animals is often caused by other 'subspecies' of *T. brucei* which are indistinguishable morphologically from those that cause human infection.

#### Transmission

- By the bite of infected tsetse flies (*Glossina*).
- Riverine tsetse (*Glossina palpalis* group) are responsible for transmission of *T. b. gambiense*, chiefly from a human reservoir. Infection may be endemic or epidemic.
- Savannah tsetse flies (*Glossina morsitans* group) are mainly responsible for sporadic transmission of *T. b. rhodesiense* from animals to humans.
- Congenital transmission is also well recognised.

#### Clinical features

A painful bite lesion (the trypanosomal chancre) may form at the site of the infected bite and last for up to 3 weeks. Among indigenous people in endemic areas, this is more commonly seen in *T. b. rhodesiense* (19%) than in *T. b. gambiense* infections. However, a chancre may be seen in 25–40% of early presentations of *T. b. gambiense* among expatriates. Clinical staging is essential for planning treatment, and depends on evidence of CNS involvement based on lumbar puncture findings.

#### Haemolymphatic stage 1

- Symptoms of fever and malaise that last for about a week are associated with waves of parasitaemia.

Lymph nodes (especially those at the back of the neck in Gambian disease) become enlarged.

- There may be short-lived oedematous swellings of the face or limbs, and sometimes a patchy circular erythematous rash or skin itching.
- Early symptoms are often milder in Gambian disease, and this stage may last for months to years.
- In Rhodesian disease, patients are usually more ill with tachycardia, high fever, hepatosplenomegaly, myocarditis, anaemia and sometimes jaundice.

#### Meningo-encephalitic stage 2

- Severe headache and altered behaviour are often seen.
- Patients may become apathetic, depressed or frankly psychotic.
- Sleep is disturbed, so that patients are often awake during the night and sleep by day; eventually deep coma results.
- Ataxia and cerebellar signs are frequent.
- Delayed response to pain after deep pressure, the appearance of primitive reflexes and altered tendon reflexes may be seen.
- Death often results from intercurrent infection.

#### Diagnosis

- In *T. b. rhodesiense* infections, trypanosomes can usually be observed in thick blood films. These are also useful for *T. b. gambiense* infections, but may be negative during periods of low parasitaemia.
- More sensitive methods of examining the blood include microhaematocrit centrifugation, use of the quantitative buffy coat (QBC) technique, and the mini-anion exchange column method.
- When there are enlarged lymph nodes, particularly posterior cervical nodes in *T. b. gambiense* infections (Winterbottom's sign), microscopy of a node aspirate may demonstrate trypanosomes.
- **Serological methods: The card agglutination test for trypanosomiasis (CATT) is useful only for population screening for *T. b. gambiense* infections. Positive results need to be confirmed by the finding of parasites. Other serological tests exist that may be useful for screening suspected cases of *T. b. gambiense*, but are rarely available in resource-limited settings. Seropositives require parasitological confirmation. Negative serology does not exclude the diagnosis. Always search for**

parasites. No serological screening tests are currently available for *T. b. rhodesiense*.

- Treatment depends on evaluation of the stage of infection, so lumbar puncture is essential. Criteria for stage 2 disease in a previously untreated patient include either the presence of trypanosomes in the CSF, or a raised CSF lymphocyte count ( $> 5$  cells/mm<sup>3</sup>) in the absence of another cause. CSF protein levels are usually raised. CSF IgM (if available) may be useful as an early marker of CNS invasion.

### Treatment

Drug resistance is becoming more widespread. Check local resistance patterns and treatment recommendations.

The drugs used for treatment are toxic. They should only be started after a parasitological diagnosis has been confirmed and, particularly in stage 2 *T. b. gambiense* disease, after the patient's general condition has been improved by attention to hydration, nutrition and intercurrent infections.

#### *T. b. gambiense* stage 1

- Give pentamidine isethionate 4 mg/kg IM daily for 7–10 days.
- Children should be given a meal or a sweet drink 1 hour prior to treatment (to reduce the risk of hypoglycaemia), and must lie down for an hour after an injection and have careful checks of pulse and blood pressure (there is a risk of severe hypotension).
- **Side effects:** hypoglycaemia (may occur up to 7 days after treatment), arrhythmias, bone-marrow suppression, electrolyte disturbances (low K<sup>+</sup>, Ca<sup>2+</sup>, Mg<sup>2+</sup>). Monitoring is recommended if possible.

#### *T. b. gambiense* stage 2

- **Recommended treatment is nifurtimox–eflornithine combination treatment (NECT).**
- Give nifurtimox 5 mg/kg orally three times daily for 10 days plus eflornithine 200 mg/kg every 12 hours by IV infusion (over 2 hours) for 7 days.
- Second choice, if nifurtimox is not available and the patient is under 12 years of age, is to give eflornithine 150 mg/kg every 6 hours by IV infusion (over 2 hours) for 14 days. If the patient is over 12 years of age, give eflornithine 100 mg/kg every 6 hours by IV infusion (over 2 hours) for 14 days.
- There is a risk of infection and phlebitis at the IV site. Care is needed with regard to sterile procedures and securing the IV line. Change the IV site every 2 days.
- Side effects include **CNS abnormalities (due to nifurtimox), convulsions**, and bone-marrow suppression (due to eflornithine).
- **Relapse after NECT or eflornithine:** Give melarsoprol, 2.2 mg/kg/day slowly IV for 10 days. **Encephalopathy occurs in up to 15% of patients treated with melarsoprol, and is associated with a 50% case-fatality**

rate. Co-administration of prednisolone reduces the risk of encephalopathy to less than 5%. Prior to the first dose of melarsoprol, start prednisolone orally 1 mg/kg (maximum 40 mg/day) daily for 10 days, then taper and stop over 3 days.

- **Side effects include encephalopathy, peripheral neuropathy, skin reactions including Stevens–Johnson syndrome, and phlebitis.** Note that melarsoprol IV is very painful, particularly if extravasation occurs, and may cause tissue necrosis.

#### *T. b. rhodesiense* stage 1

- **Suramin:** initial test dose of 4–5 mg/kg slowly IV over 5 minutes on day 1, then 20 mg/kg slowly IV on days 3, 10, 17, 24 and 31. Maximum single dose 1 g/injection.
- The initial test dose is to reduce the risk of idiosyncratic anaphylactic reactions to suramin. Have IM adrenaline available (see Section 5.1.B).
- Test the urine for albumin before each dose, and modify the regime if more than a trace of protein is seen.
- This regime may also be used for **stage 1 *T. b. gambiense* if pentamidine is unavailable.**
- **Side effects include hypersensitivity, nephrotoxicity** (monitor urine albumin levels before each dose, and modify the regime if more than a trace of protein is seen) and peripheral neuropathy.

#### *T. b. rhodesiense* stage 2

- **Melarsoprol:** 3.6 mg/kg slowly IV for 3 or 4 days repeated three or four cycles with an interval of 7–10 days between treatment series.
- **Prednisolone:** 1 mg/kg (maximum 40 mg/day) orally daily throughout the course of melarsoprol, then gradually taper and stop. Note that the recommendation for use in *T. b. rhodesiense* stage 2 is largely based on evidence for use in *T. b. gambiense* stage 2.
- Side effects: see previous notes.

### Follow-up

- **Notify all cases** so that effective surveillance and public health action is taken.
- All patients should have follow-up lumbar puncture for 2 years (*T. b. gambiense*, lumbar puncture 6-monthly; *T. b. rhodesiense*, 3-monthly for 1 year and then 6-monthly).  
If initially stage 1 but at follow-up:  
(i) CSF 6–19 white blood cells/mm<sup>3</sup>: repeat lumbar puncture in 1–2 months.  
(ii) CSF  $\geq 20$  white blood cells/mm<sup>3</sup>: treat as stage 2.  
If initially stage 2, CSF white cell count trend at follow-up is more important than the actual value.
- Drug resistance is increasing – if suspected seek expert advice.

### 6.3.A.b American trypanosomiasis (Chagas disease)

#### BOX 6.3.A.B.1 Minimum standards

- Bed nets.
- Vector control.
- Benznidazole.
- Nifurtimox.

#### Introduction

American trypanosomiasis is potentially life-threatening and is caused by the protozoan parasite, *Trypanosoma cruzi*.

An estimated 10 million people are infected worldwide, mostly in Latin America, where it is endemic. In 2008 it killed more than 10 000 people. It is increasingly being detected in the USA, Canada, many European and some Western Pacific countries.

In Latin America, *T. cruzi* is mainly transmitted by the infected faeces of blood-sucking triatomine bugs. These bugs typically live in the cracks of poorly constructed homes in rural or suburban areas. They become active at night when they feed on human blood by biting an exposed area of skin such as the face, where the bug defecates close to the bite. The parasites enter the body when the person instinctively smears the bug faeces into the bite, the eyes, the mouth, or any break in the skin.

*T. cruzi* can also be transmitted in the following ways:

- via food contaminated with the parasite through, for example, contact with triatomine bug faeces
- by blood transfusions from infected donors
- by transmission from an infected mother to her newborn during pregnancy or childbirth.

#### Clinical management

##### Signs and symptoms

The disease presents in two phases. The initial acute phase lasts for about 2 months after infection. During the acute phase, a high number of parasites circulate in the blood. In most cases, symptoms are absent or mild, but can include fever, headache, enlarged lymph glands, pallor, muscle pain, difficulty in breathing, swelling and abdominal or chest pain. In less than 50% of people bitten by a triatomine bug, the characteristic first visible signs can be a skin lesion or a purplish swelling of the lids of one eye.

During the chronic phase, the parasites congregate in the heart and digestive tract. Up to 30% of patients suffer from cardiac disorders, and up to 10% suffer from digestive (typically enlargement of the oesophagus or colon), neurological or mixed pathology. The infection can lead to sudden death or heart failure caused by progressive destruction of the heart muscle.

##### Treatment

Benznidazole and nifurtimox are both almost 100% effective in curing the disease if given soon after infection. However, the efficacy of both diminishes the longer a person has been

infected. Treatment is also indicated for those in whom the infection has been reactivated (e.g. due to immunosuppression), for infants with congenital infection, and for patients during the early chronic phase. The potential benefits of medication in preventing or delaying the disease should be weighed against the long duration of treatment (up to 2 months) and possible adverse reactions (occurring in up to 40% of treated patients).

Benznidazole and nifurtimox should not be taken by pregnant women or by people with kidney or liver failure. Nifurtimox is also contraindicated in people with a history of neurological or psychiatric disorders. In addition, specific treatment for cardiac or digestive manifestations may be required.

##### Benznidazole 100 mg tablets

Acute or early chronic phase:

- Full term newborn infant give 5 mg/kg daily in 3 divided doses increasing after 3 days to 10 mg/kg daily if no leukopenia or thrombocytopenia occurs. Treat for 60 days.
- Infant or child, 40 kg body weight give 7.5 mg/kg daily in 2–3 divided doses for 60 days.
- Child > 40 kg give 5 mg/kg daily in 2–3 divided doses for 60 days.

Chronic phase:

Infant or child 5 mg/kg daily in 2–3 divided doses for 60 days.

##### Nifurtimox Tablets 30, 120 and 250 mg

Acute or early chronic phase: given after meals

- Neonate, infant or child < 40 kg give 15–20 mg/kg daily in 3 divided doses for 60 days
- Child > 40 kg 12.5–15 mg/kg daily in 3 divided doses for 60 days

Chronic phase:

Infant or child 8–10 mg/kg daily in 3 divided doses for 60 days.

##### Vector control and prevention

There is no vaccine for Chagas disease. Vector control is the most effective method of preventing this disease in Latin America. Blood screening is necessary to prevent infection through transfusion.

The WHO recommends:

- insecticide spraying of houses and surrounding areas
- house improvements to prevent vector infestation
- personal preventive measures such as bed nets
- good hygiene practices in food preparation, transportation, storage and consumption
- screening of blood donors
- screening of newborns from infected mothers, and of siblings of infected children to provide early diagnosis and treatment.

### 6.3.A.c Leishmaniasis

#### BOX 6.3.A.C Minimum standards

- Public health measures and vector control.

#### Leishmaniasis: visceral

- Bone-marrow, splenic and lymph-node aspirate.
- Pentavalent antimonials.
- Amphotericin B.
- Paromomycin.

#### Leishmaniasis: cutaneous and mucocutaneous

- Pentavalent antimonials.
- Topical 15% aminosidine plus 12% methyl benzethonium.
- Ketoconazole.

### Introduction

Leishmaniasis is caused by *Leishmania*, a protozoon whose reservoir is in animals, including rodents and dogs, and in some areas (e.g. India) in humans. The vector is the female sandfly.

There are three main clinical types of disease:

- cutaneous (CL)
- mucocutaneous (MCL)
- visceral leishmaniasis (VL) or kala-azar.

### Parasite and life cycle

- About 21 of the 30 or more species of *Leishmania* infect humans. They are morphologically similar and can only be differentiated by isoenzyme analysis which identifies the zymodeme in the cultured parasite.
- In animals and humans, *Leishmania* lives in macrophages in the reticulo-endothelial system in the form of amastigotes (Leishman–Donovan bodies). When taken up by the biting sandfly it transforms into a promastigote, which has a flagellum.
- There are two main genera of sandfly responsible for transmission, *Phlebotomus* in the Old World and *Lutzomyia* in the New World (Central and South America). Sandflies breed in organic material in dark moist sites, such as cracks in masonry, termite hills, or leaves on the forest floor. The female obtains her blood meal at night by feeding on animals, and also on humans if they are living or working in the vicinity.

### Epidemiology

The Old World comprises Africa, Asia and Europe (collectively known as Afro-Eurasia), plus the surrounding islands. It is used in the context of, and contrast with, the 'New World' (i.e. the Americas and sometimes Oceania). Old world CL and VL are found in the Mediterranean basin, the Middle East, the Sudan, Ethiopia, Kenya, Afghanistan, the Indian subcontinent, and southern regions of the former Soviet Union, and China. Where HIV infection and VL coexist, there are major problems in the treatment of VL. Drug resistance in VL is a serious concern in India and the Sudan. Bihar State has 90% of VL in India and 45% of world cases.

In the New World, CL and MCL are the main forms of infection. VL occurs mainly in North-East Brazil.

Currently, leishmaniasis occurs in four continents and is considered to be endemic in 88 countries, 72 of which are resource-limited:

- 90% of all visceral leishmaniasis cases occur in Bangladesh, Brazil, India, Nepal and Sudan
- 90% of mucocutaneous leishmaniasis cases occur in Bolivia, Brazil and Peru
- 90% of cutaneous leishmaniasis cases occur in Afghanistan, Brazil, Iran, Peru, Saudi Arabia and Syria.

Leishmaniasis is a disease of poverty associated with malnutrition, displacement, poor housing and migration of non-immune people to endemic areas. It is linked with deforestation and urbanisation.

### Immunology

- A strong cell-mediated immune (CMI) response is required for control of and recovery from disease. Polyclonal stimulation of B cells results in high levels of IgG.
- Subclinical infection is common. CL usually heals spontaneously, but untreated MCL will progress, and VL will result in death. Development of VL indicates that the host's CMI is unable to control the infection, and if untreated, progressive immunosuppression will develop.
- Death is usually due to a secondary infection (e.g. respiratory tract or gut infection).

### Cutaneous and mucocutaneous leishmaniasis

#### Cutaneous leishmaniasis

The species responsible are *L. tropica*, *L. major*, *L. aethiops* in the Old World, and *L. mexicana* and *L. amazonensis* in the New World. Single or multiple nodules develop on exposed areas, especially the face or extremities, and usually ulcerate. Most heal spontaneously within months to a year or so, leaving scars.

#### Mucocutaneous leishmaniasis

The species responsible is *L. braziliensis*. A nodule develops initially, as in CL, but at about the time of healing, metastatic lesions occur on mucosal surfaces, such as the nasal mucosa and oropharynx. If these are left untreated, progressive destruction of local tissue occurs.

### Diagnosis

- Slit skin smear or aspiration should be undertaken from the raised margin of the lesion (not the base of the ulcer). Material is spread on a slide, dried, fixed in methanol and stained with Giemsa or Leishman.
- If a biopsy is undertaken (e.g. in MCL), impression smears should be done before fixing.
- If available, the specimen should be cultured.

### Management

Most CL lesions are self-limiting. Treatment is indicated for

multiple, large and disfiguring lesions and all MCL. Clean the lesion, and give antibiotics if necessary.

Standard treatment for CL and MCL is with pentavalent antimonials (Sb): **sodium stibogluconate** (Pentostam, 100 mg Sb/mL) or **meglumine antimoniate** (Glucantime, 85 mg Sb/mL). **It is essential to remember that the doses of these two drugs are different, because they contain different concentrations of antimony (Sb).** Give 20 mg Sb/kg/day IV or IM in a single dose for 20–28 days depending on the species of *Leishmania* (e.g. MCL requires 28 days or more). The IV infusion is stopped if coughing or substernal pain occurs. Urinary excretion of Sb is rapid (its half-life is 2 hours), although slow accumulation occurs.

For *L. major*, weekly or twice weekly intra-lesional injections of Sb (which are painful) may be administered (1 mL/lesion at four sites per ulcer) to adolescents or adults, using a 1-mL syringe and a fine (24-gauge) needle, for 4–8 weeks. A topical ointment containing 15% aminosidine and 12% methylbenzethonium chloride applied twice daily for 10–20 days may be tried. Efficacy is variable, but it may be combined with intra-lesional Sb injections.

Oral fluconazole, 3 mg/kg once daily (maximum 100 mg) for up to 6 weeks, may be effective, but there is a **danger of liver dysfunction**.

In areas where there is antimonial resistance, pentamidine (IM 2 mg/kg every second day for seven injections), amphotericin B and oral miltefosine may be required (see management of VL below).

All three of these drugs have potentially serious side effects.

## Visceral leishmaniasis (kala azar)

Epidemics occur in situations of famine, complex emergencies and mass movements of populations. It has a high fatality rate if untreated. It is estimated that there are 360 000 new cases every year globally, of which more than 60% occur in Northern India (Bihar).

The species responsible are *L. donovani* and *L. infantum* in the Old World, and *L. chagasi* in the New World.

- The major presenting features include the triad of prolonged fever, anaemia and moderate to marked splenomegaly. In the early stages the child is often only mildly unwell and may have a reasonable appetite. In a minority of cases, the onset may be acute, with a high temperature, toxæmia and mild splenomegaly.
- Pancytopenia is the main laboratory finding.

### Diagnosis

- In children, the diagnosis is usually confirmed by demonstrating amastigotes on bone-marrow aspirate.
- Splenic aspirates have a higher sensitivity, and this procedure is safe in skilled hands so long as the platelet count is above  $40 \times 10^9$ /litre and coagulation is normal.
- Repeat bone-marrow or splenic aspiration to monitor progress if required.
- If there is lymphadenopathy, diagnosis may be attempted by fine-needle aspiration.
- **Serological antibody tests such as ELISA have a high sensitivity, and are particularly helpful if a parasitological diagnosis cannot be obtained.**
- If a microscopic diagnosis cannot be made, **the polymerase chain reaction (PCR) should be undertaken. The value of the PCR is being evaluated.**

### Differential diagnosis

- Differential diagnosis of marked hepatosplenomegaly, anaemia and pancytopenia includes hyper-reactive splenomegaly (tropical splenomegaly) syndrome and schistosomiasis, as well as myeloid leukaemia and myelofibrosis.
- In acute-onset disease, malaria, disseminated tuberculosis, typhoid, brucellosis, African trypanosomiasis, relapsing fever and leukaemia should be considered.
- **HIV infection greatly increases the risk of visceral leishmaniasis, and thus co-infection is common.**

**TABLE 6.3.A.C.1 Clinical features of visceral leishmaniasis**

Incubation period: 2–4 months (weeks to two years)
Fever: intermittent at first
Anaemia: bone-marrow depression, hypersplenism
Splenomegaly: progressive enlargement
Hepatomegaly
Weight loss
Epistaxis: haemorrhage from other sites may occur in advanced disease
Diarrhoea: invasion of gut by amastigotes, secondary infection
Cough
Oedema: hypoalbuminaemia
Hair and skin signs of malnutrition in chronic forms
Lymphadenopathy: in some African countries

**TABLE 6.3.A.C.2 Clinical pathology of visceral leishmaniasis**

Haemoglobin: low; normochromic, normocytic film
White blood cells: low, $2-3 \times 10^9$ /litre Eosinophils low
Platelets: low, $< 100 \times 10^9$ /litre
Reticulocytes: low
Serum albumin: low
Serum globulin: elevated
Liver transaminases and serum bilirubin: normal

## Management of visceral leishmaniasis

Consider HIV co-infection and secondary disorders such as malaria, respiratory and gut infections, and tuberculosis. Blood transfusion for anaemia is seldom required, as the child has usually adapted to the low haemoglobin level. Give haematinics and vitamin supplements during nutritional rehabilitation and convalescence.

**Liposomal amphotericin B used to be expensive, but following a campaign the WHO has brought about a 90% reduction in price, and consequently this is now the treatment of choice.**

The alternative treatment is with antimoniate (Sb), for which again the WHO has obtained a substantial reduction in cost. Meglumine antimoniate and sodium stibogluconate are available. The duration of Sb treatment is usually 4 weeks, but prolonged treatment (up to 6 weeks) may be necessary in resistant cases (see Table 6.3.A.c.3).

For relapse, a second course can be given after a few weeks. Serious toxicity is rare in children, but if a prolonged course of high dosage is required, or toxicity is suspected, liver function tests and an ECG looking for conduction

disorders should be undertaken. Serious toxicity may require dimercaprol to chelate and remove the antimony.

In areas where there is resistance to Sb, such as Bihar state in India, and the Sudan, alternative drugs are required as follows: amphotericin B by slow infusion; paromomycin (aminoglycoside, identical to aminosidine); or

oral miltefosine. Combinations of drugs (e.g. paromomycin and Sb) may be more effective. In patients with HIV/VL co-infection, management is difficult because of frequent relapse when treatment is stopped. HAART combined with maintenance anti-leishmanial therapy is important.

**TABLE 6.3.A.C.3 Drugs used in the treatment of visceral leishmaniasis**

Drug	Doses	Contraindications and cautions	Side effects
Liposomal amphotericin B	4 mg/kg IV over 30–60 minutes once daily by IV infusion on days 1, 2, 3, 5 and 10	An initial test dose of 100 micrograms/kg (maximum 1 mg) is infused over 15 minutes. Observe for 1 hour to ensure that anaphylaxis does not occur, then proceed	May produce hypotension, fever, vomiting, headache, and muscle and joint pain. Less commonly, chest pain, hypoxia, severe abdominal pain, flushing, urticaria, and flank or leg pain
Sodium stibogluconate (100 mg Sb/mL) or meglumine antimoniate (81 mg Sb/mL)	20 mg/kg (minimum 200 mg) IV infusion or deep IM injection over over 5–10 minutes once daily for 28 days Prolonged treatment for 6 weeks in resistant cases	Pre-existing severe cardiac, liver, renal, pancreatic or haematological abnormalities Not to be given during pregnancy Filter solution through 5-micron filter immediately before infusion	Vomiting, abdominal pain, myalgia and arthralgia, headache, metallic taste. Rarely sudden death with prolonged QT interval; therefore monitor ECG and stop infusion if QT exceeds 0.5 seconds
Conventional amphotericin B	Slow IV infusion, 1 mg/kg every second day for 15 days, or daily for 20 days. (daily dose must never exceed 1.5 mg/kg)	An initial test dose of 100 micrograms/kg (maximum 1 mg) is infused over 15 minutes. Observe for 1 hour to ensure that anaphylaxis does not occur, then proceed	May produce hypotension, fever, vomiting, headache, and muscle and joint pain
Paromomycin	Daily IV or IM injections 16–20 mg/kg/day for 21 days	Do not give at the same time as gentamicin or other aminoglycosides. Avoid if there is renal impairment	Vomiting, diarrhoea, abdominal pain, fever and ototoxicity
Miltefosine	2.5 mg/kg/day orally for 28 days	Not in pregnancy	Nausea and vomiting

A limited stock of the above drugs is kept by the WHO in Geneva for rapid response to an epidemic.

A study looking at the effectiveness of a single-dose treatment (by IV infusion) using liposomal amphotericin B is currently in progress in India.

#### Follow-up and prognosis

Symptomatic improvement usually occurs within a few days, and a haematological response occurs within 2 weeks. Splenomegaly slowly regresses, but may take a year or more to resolve. Prolonged follow-up (at least 1 year) is necessary to detect relapse. Relapse is treated with a repeat prolonged course of antimonials (up to 8 weeks). Unresponsiveness will require alternative drugs such as liposomal amphotericin B (if available), aminosidine, standard amphotericin B or pentamidine. Trials of miltefosine are in progress.

#### Prevention and control

Prevention is similar to that of malaria, and includes insect repellents and the use of fine-mesh bed nets impregnated with permethrin. Control includes spraying of sandfly resting sites and human dwellings, destruction of animal reservoirs and treatment of cases.

## 6.3.A.d Malaria

### BOX 6.3.A.D.1 Minimum standards for an effective malaria control programme

- 1 Prevention:
  - Impregnated bed nets (ITNs), preferably long-lasting insecticidal nets (LLINs).
  - Where appropriate, intermittent preventive treatment in infants (IPTi) and seasonal malaria chemoprevention (SMC) for older children.
  - Other methods of vector control, such as indoor residual spraying (IRS), personal protection (e.g. mosquito coils, impregnated clothing, repellents, etc.).
- 2 A well-informed population to improve early care seeking and adherence to treatment and preventive regimes.
- 3 Good case management:
  - Early accurate diagnosis: all patients should have a biological test before treatment:
    - Quality-assured thick blood film and/or rapid diagnostic test (RDT).
    - Haemoglobin measurement to detect and treat malaria anaemia (e.g. using a haemocue machine).
    - In severe disease, facilities to measure blood glucose levels and provide safe blood transfusion.
  - Effective treatment:
    - Treatment for simple malaria.
      - » Artemisinin combination therapy (ACT) (following the national protocol for recommended ACT).
    - Treatment for severe disease.
      - » IV or IM artesunate (IM artemether, rectal artesunate, or IV or IM quinine if artesunate is not available).
    - Pre-referral treatment.
      - » Rectal artesunate (if artesunate is not available, rectal quinine) or if injections are safe IV or IM artesunate or IM artemether, or IM quinine.
- 4 Accessible, acceptable and affordable care:
  - Consider training community health workers in remote areas to diagnose and treat malaria.
  - Make treatment free for pregnant girls and children under five.
  - Set up a good referral system from community and first-level health facilities to facilities with means to treat severe cases, including transport and facilities to access resources to pay for treatment if needed.

### BOX 6.3.A.D.2 Minimum standards for hospital treatment of severe malaria

- A triage system.
- RDTs and microscopy for initial diagnosis, plus laboratory facilities to determine levels of parasitaemia.
- Antimalarial drugs for IV, IM and oral treatment.
- Oxygen.
- Antibiotics and anticonvulsants.
- Safe blood transfusion services.
- Nasogastric feeding.
- Good nursing care (monitoring of vital signs and fluid balance, nasogastric feeding).

Malaria is estimated to cause at least 650 000 deaths each year, mostly among African children.

- Unlike anywhere else in the world, children aged 6–24 months in Africa are most at risk of the worst forms of malaria. Every 30 seconds an African child dies of malaria.

There are five *Plasmodium* species known to be infective to humans, namely *Plasmodium falciparum*, *P. vivax*, *P. ovale*, *P. malariae* and *P. knowlesi*.

*P. falciparum* causes severe disease and is the most prevalent form in sub-Saharan Africa (most sub-Saharan Africans are protected against *P. vivax* due to lacking a protein in their red blood cells (the Duffy antigen)). *P. falciparum* differs from the other species in that infected erythrocytes adhere to capillary epithelium, thus disappearing from the circulation and evading destruction by the spleen.

*P. vivax* and *P. ovale* can cause recurrent malaria attacks due to the formation of a dormant form existing as hypnozoites in the liver, which are periodically released into the blood. Drugs to eliminate the hypnozoites from the liver are limited (primaquine).

*P. malariae* can cause long-term problems, including kidney failure, and *P. knowlesi* is a newly emerging form which has caused severe disease in Asia (Papua New Guinea and Thailand).

### Life cycle

The infected *Anopheles* female mosquito injects sporozoites into the bloodstream of an individual. Sporozoites circulate for less than 30 minutes before being phagocytosed or entering liver parenchymal cells. The blood and liver phase prior to re-entry into the circulation is called the pre-erythrocytic phase, and it varies in length according to the species. At the end of this phase, merozoites invade the red blood cells and begin the erythrocytic phase. Parasites rapidly multiply within the red blood cells, which finally burst, releasing more merozoites into the bloodstream to invade further red blood cells.

Periodic bouts of fever are associated with the release of the merozoites. After some time, sexual forms of the parasites (gametocytes) are formed which are then ingested by a female mosquito to complete the cycle in humans. In the mosquito stomach, the gametocytes merge and eventually form sporozoites which migrate to the salivary

### Introduction

Malaria is an extremely important public health burden in Africa, disproportionately affecting the youngest and most vulnerable. Children under 5 years and pregnant women, especially in the first pregnancy, suffer from severe forms of the disease. In Asia, the disease is more common in men and older children.

- Nearly 80% of the world's malaria burden is in Africa.

glands, where they are injected into the bloodstream by the mosquito as it takes a blood meal to support its own reproductive effort.

In two species (*P. vivax* and *P. ovale*) some hepatic-stage parasites remain within the liver cells with the formation of the dormant phase, called hypnozoites. For various reasons (perhaps including waning immunity), at a later date the dormant phases activate and reseed blood. This leads to manifestations of malaria not from a new infection but from the latent exo-erythrocytic phase.

*P. falciparum* differs from the other species in that infected erythrocytes adhere to capillary epithelium, thus disappearing from the circulation and evading destruction by the spleen.

*P. falciparum* is the most likely species to cause life-threatening disease, and is a major cause of mortality in children.

## **Plasmodium falciparum**

### **Clinical features**

- Typical symptoms include high-grade fever alternating with cold spells, rigors, chills and sweating. There are usually associated myalgias and arthralgias.
- However, features in children under 5 years of age may be non-specific, with fever, vomiting, diarrhoea and abdominal pain being the main symptoms.
- In older immune individuals the only symptoms may be fever with headache and joint pains.
- All fevers in children from a malaria-endemic area are therefore due to malaria until proven otherwise.

### **Diagnosis**

#### **Microscopy**

- Blood smear for malaria remains the gold standard: a thick film for diagnosis, and a thin film to confirm the type of malarial parasite. Typically species-specific ring forms inside red blood cells are seen, but there may also be gametocytes.
- The level of parasitaemia is usually scored as 1–5+. If the malarial smear is 3+ or more, there is a high level parasitaemia. In areas where parasitic density is measured the smear is reported as parasites/mm<sup>3</sup>.
- Malaria microscopy in district hospitals can be of very poor quality. A quality assurance programme should be in place that includes the following:
  - a properly trained and regularly updated microscopist
  - adequate time to look at slides, particularly for low-level parasitaemia
  - the correct stains and good-quality slides
  - a binocular microscope that is properly serviced and maintained
  - a system of internal and preferably external cross-checking of a sample of slides, especially the low parasitaemias and negative slides.
  - If possible examination requires a reliable electricity supply or good lighting near a window in the day time. Many modern microscopes have an inbuilt LED light.

#### **Rapid diagnostic tests**

Antigen-capture test kits use a rapid simple dipstick test from a finger-prick blood sample to give a result in 10–20 minutes. RDTs should be used in circumstances where microscope facilities and/or diagnostic expertise are limited.

There are two main forms of rapid test.

#### **Histidine-rich protein 2 (HRP2) tests**

**These only detect *P. falciparum*.** HRP2 tests have a sensitivity of 97–100% (i.e. there are very few false-negative results). These tests can lack specificity (which may be as low as 59% in some studies), so there can be a high frequency of false-positive results, especially in a high transmission zone where malaria infection is frequent (children can have as many as six attacks a year). HRP2 remains in the bloodstream for at least 2 weeks after all viable parasites have been killed, and often for considerably longer (6–8 weeks), so patients returning with fever within 4 weeks after treatment cannot be diagnosed using an HRP2-based RDT. However, a presumptive diagnosis that fever equals malaria has an even lower specificity.

HRP2 tests are very heat stable, but are sensitive to humidity. They have a shelf-life of 2 years, and their use can be taught to healthcare workers, even at village level, in a few hours. They are especially suitable for use in sub-Saharan Africa, where other species of malaria are rare.

#### **Parasite lactate dehydrogenase (pLDH) tests**

The parasite lactate dehydrogenase (pLDH) antigen is produced by all four *Plasmodium* species. The pLDH-based tests detect the antigen using a panel of monoclonal antibodies. They can have high sensitivity for *P. falciparum*, and are more specific than HRP2. They return to negative in 3–14 days (the majority do so within 7 days).

Some pLDH tests are able to differentiate between *P. falciparum* and other *Plasmodium* species, and between viable and non-viable parasites, thereby enabling their use for monitoring therapy and for detecting new infections within 2 weeks of successful treatment.

The tests currently on the market are available in two forms. The first has a pan-pLDH antibody that can detect any species of malaria. When positive, it produces a single test line. The second produces two test lines, a pan-specific line and a line that detects *P. falciparum*. In theory, there are monoclonal antibodies that can individually detect all of the different species, but these have not yet been validated.

pLDH tests are not as heat stable as HRP2 tests. Although pLDH has a high sensitivity for *P. falciparum*, its sensitivity for *P. vivax* appears to be less satisfactory if the patient has a low parasitaemia. pLDH tests are more expensive than HRP2 tests, and are not therefore recommended in sub-Saharan Africa, where 97% of infections are due to *P. falciparum*.

#### **Advantages of RDTs over microscopy**

- The result is available within 15–20 minutes and one person can set up a new test every 1 or 2 minutes. In contrast, there are more steps involved in microscopy (i.e. slide preparation, drying, staining, and drying stained slides), and a negative slide requires 6 minutes of reading time (a microscopy report can be delayed up to an hour from collecting the blood).
- Training takes 2 hours with minimally educated workers.
- Many more tests can be done in one clinic or outreach session.

A quality control/quality assurance system for RDTs should be in place at the level of importation where the Compliance

with last Malarial Treatment (CMT) is based, and at project level after transportation, to ensure that tests remain in good condition (lot testing). Monitoring of the conditions to which the tests are subjected during transportation may account for problems with their function at project level.

**Field teams need to monitor the performance of healthcare staff regularly to ensure that tests are performed properly.**

### Other diagnostic tests that should be available in malaria programmes

- Haemacue to determine haemoglobin levels.
- Tests to deliver safe transfusion: two instant HIV tests, syphilis, hepatitis B and hepatitis C screen.
- Tests for G6PD deficiency if primaquine is to be used for radical treatment to eliminate hypnozoites and/or gametocytes of *P. falciparum*.
- Polymerase chain reaction (PCR) tests. These can be used to detect very low levels of parasitaemia. Work is progressing to develop a bedside PCR detection machine. PCRs are very important in elimination scenarios to detect very low parasitaemias, and in drug efficacy studies.

### Case definitions of malaria

**Suspected malaria:** a patient with a fever or history of fever in the last 48 hours who lives in or has come from a malaria-endemic area.

**Uncomplicated (simple malaria):** a patient with a fever or history of fever in the last 48 hours who has a positive biological test and no symptoms of severe disease.

**Complicated malaria:** a patient with the signs and symptoms of simple malaria who is unable to take oral drugs.

**Non-severe malaria may be associated with a variety of other symptoms, including cough, vomiting, diarrhoea, abdominal pain, myalgia, headache, sweating and rigors.**

### Severe malaria

A patient with one or more of the following signs or symptoms, with biologically confirmed *P. falciparum* infection (and occasionally *P. vivax*) and parasitaemia:

- prostration (inability to sit, or to drink or breastfeed)
- impaired consciousness (cerebral malaria)
- respiratory distress
- multiple convulsions
- circulatory collapse
- severe anaemia (haemoglobin concentration < 5 grams/dL or haematocrit of < 15%) may be the presenting symptom, especially in children and pregnant women, and can rapidly lead to death.

### Other conditions that may be associated with severe malaria

**Hyperparasitaemia** may be associated with severe malaria, but is not pathognomonic of severe disease in itself. It has been associated with a higher risk of mortality and needs to be rigorously treated, preferably in the first instance with parenteral medications. If there are no other signs of severity, the patient may not need hospital admission.

**Hypoglycaemia** often causes unconsciousness or death if not detected and treated rigorously. It is especially

dangerous in children, malnourished patients and pregnant women, and is exacerbated by quinine treatment.

**Pulmonary oedema is a grave and often fatal complication of malaria.** It can occur spontaneously (particularly during pregnancy), but it is often a result of fluid overload during treatment.

**Metabolic (lactic) acidosis:** see section on severe malaria below.

**Abnormal bleeding** is associated with thrombocytopenia, and leads to bleeding of gums and epistaxis, and sometimes more severe internal bleeding.

**Jaundice** is more common in adults than in children. Mild jaundice only reflects haemolysis, whereas very high bilirubin levels suggest hepatic dysfunction.

**Haemoglobinuria** is common, but its more extreme form, blackwater fever, is rare. It is associated with quinine therapy.

**Oliguria/anuria** can be a sign of renal dysfunction, but make sure that the patient is adequately rehydrated before commencing therapy for renal failure. **Fluid balance charts should be instituted and monitored closely for all patients with severe malaria.**

### Uncomplicated/simple malaria

There is a fever and a positive blood smear. There is no evidence of altered consciousness, hypoglycaemia, severe anaemia, jaundice or respiratory difficulties.

### Management

#### Management of children who have always lived in an endemic area

- There is no need to admit the child to hospital (unless they are under 4 months of age or less than 5 kg in weight, or pregnant).
- A diagnostic test should be done before treatment (microscopy if available and quality assured, or an RDT). This will confirm malaria and also ensure that patients who do not have malaria receive appropriate treatment. **Note that malaria is frequently accompanied by other serious infections, such as pneumonia.** Signs of bacterial or viral infections should be looked for and treated appropriately even if the malaria diagnostic test is positive.
- Give first-line antimalarial treatment (ACTs) as recommended in local national guidelines.
- Ensure that tablets or syrup are swallowed and not vomited.
- Give the first dose under direct observation and advise the carer on how to administer the drug to young children by dissolving tablets in breast milk or syrup and giving this slowly with a syringe.
- If the child vomits within the first 30 minutes, repeat the full dose. If they vomit after 1 hour give a half dose. Advise the carer to return if further doses are vomited. Remember to advise the carer to give the dose with food if artemether/lumefantrine is used, to improve absorption of the lipophilic lumefantrine.
- Encourage oral fluid intake and continued feeding with light nutritious foods plus catch-up meals when the child recovers. Measures to lower the body temperature may be necessary (tepid sponging and paracetamol).
- Test for iron deficiency, and if the patient is pale and anaemic (based on palmar and conjunctival examination and/or haemoglobin test), give haematinics (iron

and folic acid, **but** if sulfadoxine-pyrimethamine has been used for malaria treatment, do not give folic acid for 2 weeks).

#### Management of children visiting or returning from an endemic area for the first time

Hospital admission for management of *P. falciparum* is always advisable.

#### Treat with an ACT

The WHO recommends the use of **fixed-dose combinations (FDCs)** if available, or pre-packaged drugs if FDCs are not available. **The WHO discourages the use of monotherapies, to reduce the risk of resistance developing.** In particular, the use of artesunate monotherapy, which is commonly available on the private market, is strongly discouraged.

#### ACTs recommended by the WHO

- Artesunate/amodiaquine (AS/AQ FDC).
- Artesunate + mefloquine (AS+MQ or AS/MQ FDC).
- Artesunate + sulphadoxine/pyrimethamine (AS + SP).
- Artemether + lumefantrine (AM/LM FDC).
- DHA/piperazine (Duo-Cotecxin, Eurartesim) FDC.
- Artesunate/pyronaridine (Pyramax) FDC.

#### Non-ACTs

- Malarone (atovaquone/proguanil) FDC: this is very expensive and usually only used where there is artemisinin resistance, or for prophylaxis in western travellers.
- Quinine tablets in IV, IM and rectal forms: for true treatment failures.
- Chloroquine: only for non-*P. falciparum* malaria.
- Primaquine and its derivatives (tafenoquine): for radical treatment of *P. vivax* (and *P. falciparum* in elimination areas).

#### Paediatric formulations

- AS/AQ infant dose is dispersible, and suitable for children who weigh 4.5–8 kg.
- Paediatric Coartem® (AM/LM) is dispersible and available as cherry-flavoured tablets for children who weigh 5–25 kg.
- Artequin (Mepha) FDC AS/MQ is available as mango-flavoured pellets/granules that can be swallowed directly without water. It is not WHO prequalified.
- AS/MG FDC produced in Brazil for Drugs for Neglected Diseases (DNDi).

#### Drugs frequently available but not WHO prequalified

- ASMQ Artequin (also in paediatric granules).
- Artemisinin/piperazine (Artequick).
- Artemisinin and naphthoquine.

#### Drugs in development

- Artemisone (partner drug not yet decided).
- Synthetic AS called OZ (Sanofi Aventis).
- Semi-synthetic artemisinin (One World Health).

#### Advice for carers

Discuss preventive efforts with carers (e.g. bed net at night, ideally impregnated with insecticide). Give LLIN if possible.

Tell the mother to return after 2 days if fever persists, and earlier if the child deteriorates.

If the child is repeatedly vomiting and the area is remote and admission to hospital difficult, give rectal artesunate until the vomiting settles. Then give a full 3-day course of ACT.

#### Management of severe malaria

**Severe malaria is a complex multi-system disease that constitutes a medical emergency.**

Mortality approaches 100% without treatment, and death often occurs within the first few hours. Prompt initiation of antimalarial treatment in peripheral healthcare facilities and comprehensive management in hospital are necessary to prevent deaths.

Neurological sequelae of cerebral malaria affect about 10% of African children who survive cerebral malaria. These sequelae are severe and permanent in up to 19 000 children annually, and include spastic paresis and epilepsy.

Care should be provided within 15 minutes of arrival at a healthcare facility. Triage systems should be in place in health centres and hospitals to pick up severely ill patients, referral should be rapid, and emergency facilities must be instituted in hospitals, with a high standard of medical and nursing care available 24 hours a day.

Any seriously ill or unconscious patient in a malaria-endemic area must be tested for malaria by RDT (remember that parasites may not be present in the peripheral blood of a patient with cerebral malaria). Malaria should be assumed in any child with severe anaemia, convulsions, hyperpyrexia and/or hypoglycaemia either in hospital or in a peripheral healthcare facility.

Even if a diagnostic test is not available, **the patient should be given an antimalarial drug (IV, IM or rectally, depending on the skill of the staff in the facility) before transfer to the hospital.** This can be repeated if transfer is impossible or is delayed for more than 12 hours. A note of what has been given should be sent with the patient as soon as transfer can be arranged.

**If any doubt exists, it is safer to treat than not to treat before transfer.**

#### Immediate measures (in hospital)

- Vital signs: temperature, pulse, blood pressure, and respiratory rate and depth.
- State of hydration.
- Estimate or ideally measure body weight. Estimate of weight by age in well-nourished children:
  - For an infant up to 1 year of age, birth weight doubles by 5 months and triples by 1 year.
  - For children over 1 year, use the following formula: weight (kg) = 2 (age in years + 4).

Be careful in HIV-endemic areas where body weights are often very different from those derived by this formula. Weigh the child if at all possible.

- Level of consciousness (AVPU or Glasgow or Adelaide coma scales) (see Section 5.16.A).
- The depth of coma may be assessed rapidly in children using the coma scale for children or by observing the response to standard vocal or painful stimuli (rub your knuckles on the child's sternum; if there is no response, apply firm pressure on the thumbnail bed with a horizontal pencil).
- RDT and malaria smear (thick and thin film) for diagnosis and for continued monitoring of the progress of the

disease. **Do not wait for a malaria smear result before initiating treatment, as it can take up to an hour. If the RDT is positive, commence treatment immediately.**

- Perform lumbar puncture if the patient is unconscious to eliminate meningitis if there are no contraindications. **Contraindications include papilloedema or suspicion of raised intracranial pressure (irregular breathing and pupillary responses, posturing), bleeding problems or respiratory difficulty such that flexing the back would compromise respiration. In such a situation, give IV antibiotics to treat meningitis as well as malaria.**
- Measurement of glucose (finger prick), haemoglobin and haematocrit (packed cell volume, PCV).
- Group and cross-match blood and search for a suitable donor.

### Parenteral IV or IM treatment

In Africa and many other regions, sodium artesunate or quinine are the drugs of choice for severe malaria. In South-East Asia and the Amazon Basin, quinine is no longer always effective and should be accompanied by doxycycline in adults or clindamycin in children. Large trials in mainly Asian Adults (SEAQUMAT study) and in African Children (AQUAMAT study) have proved that parenteral artesunate reduces mortality by over 30% and should be used in preference to quinine.

Initially give treatment intravenously, if possible; otherwise use the IM route. Change to oral therapy as soon as possible.

Especially in the malaria-endemic areas of Africa, the following initial antimalarial medicines are recommended. Artesunate has been shown to reduce mortality compared with quinine, but it is important to use whichever drug is available locally.

- artesunate IV or IM
- artemether IM (its absorption may be erratic in children in shock).
- quinine (IV infusion or divided IM injection)

### First-line antimalarial drugs

#### Sodium artesunate IV or IM

Give 2.4 mg/kg IV (by slow injection) or IM on admission (time 0), followed by 2.4 mg/kg IV or IM at 12 hours and again at 24 hours, and then once daily for a minimum of 3 days until the child can take oral treatment with an ACT.

#### OR second choice

##### Artemether IM

Give 3.2 mg/kg IM as loading dose, then 1.6 mg/kg IM once daily (every 24 hours) for a minimum of three days until oral treatment can be taken. Use a 1 mL tuberculin syringe to give the small injection volume (note: absorption may be erratic and therefore only use if quinine and artesunate are not available) and if shocked do not use this drug as absorption is too unreliable.

#### Intravenous IV quinine (quinine dihydrochloride)

This is the second choice, to be used if sodium artesunate is not available. Give 20 mg/kg quinine dihydrochloride (maximum 1.4 grams) in 5% glucose at a concentration of 1 mg of quinine to 1 mL of 5% glucose over 2–4 hours (never more rapidly than over 2 hours). If possible use an in-line infusion chamber (100–150 mL) to ensure that the

loading dose does not go in too quickly. Alternatively, ensure that the IV giving bag contains only the amount needed for each dose. There is a major risk of cardiac side effects if it is infused too quickly.

Subsequently give 10 mg/kg in 10 mL/kg fluid (5% glucose) IV every 12 hours for 24 hours, or longer if the child remains unconscious. These latter doses **must** be given over at least 2 hours.

**Never give quinine as an IV bolus. The infusion rate must not exceed a total of 5 mg quinine salt/kg/hour.**

**If safe control over the rate of infusion of IV quinine is not possible (e.g. there are insufficient or only untrained nursing staff available), give a loading dose intramuscularly (with initial doses of 10 mg/kg quinine salt IM at 0 and 4 hours and then 12-hourly).**

For IM injections, dilute the quinine solution to allow better absorption and less pain.

As soon as the child is able to take medication orally, switch to quinine tablets 10 mg/kg every 8 hours for a total of 7 days, or the locally available first-line ACT treatment for malaria.

#### Side effects:

- Common: cinchonism (tinnitus, hearing loss, nausea and vomiting, uneasiness, restlessness, dizziness, blurring of vision).
- Uncommon: hypoglycaemia, although this is a common complication of severe malaria.
- Serious cardiovascular problems (QT prolongation on the ECG) and neurological toxicity are rare.
- If overdosed by mistake with quinine tablets, give activated charcoal orally or by nasogastric tube as a suspension in water (1 gram/kg).

#### Chloroquine IV

This drug should never be used to treat severe falciparum malaria but only cases of non-resistant vivax or ovale malaria. Give 5 mg base/kg every 6 hours for a total of 25 mg base/kg (five doses) as an infusion in 5% glucose (give over 2 to 4 hours).

### Antimalarial treatment after IV or IM regimes have ended

Following parenteral administration, usually for a minimum of 24 hours or until the child can take oral drugs, the treatment of severe malaria must be completed by giving a full course of one of the artemisinin-based combination therapies (ACT) described below. In some parts of the world, oral quinine combined with clindamycin to complete 7 days of treatment is used

The following ACTs are recommended:

- artemether plus lumefantrine
- artesunate plus amodiaquine
- artesunate plus sulfadoxine-pyrimethamine
- dihydroartemisinin plus piperazine
- artemether plus clindamycin
- artesunate plus mefloquine.

The choice of ACT in a particular country or region will be based on the level of resistance of the partner medicine in the combination.

In areas of multi-drug resistance (e.g. East Asia), artesunate plus mefloquine, or artemether plus lumefantrine, or dihydroartemisinin plus piperazine are recommended. In

areas without multi-drug resistance (mainly Africa), any of the ACTs, including those containing amodiaquine, may still be effective. Every country has a national malaria policy in which the first-line therapy is described and should be used.

**If possible avoid using mefloquine if the patient has presented with an impaired conscious level.**

#### **Treatment for HIV-infected patients with *P. falciparum* malaria**

- Patients with HIV infection who develop malaria should receive prompt effective antimalarial treatment regimens as recommended above.
- **Treatment with ACT involving sulfadoxine-pyrimethamine should not be given to HIV-infected patients who are receiving co-trimoxazole (trimethoprim plus sulfamethoxazole) prophylaxis.**
- Treatment of HIV-infected patients who are on zidovudine or efavirenz should, if possible, avoid amodiaquine-containing ACT regimens.

#### **Treatment of *P. falciparum* malaria in malnourished patients**

Although there are many reasons why antimalarial pharmacokinetics may differ between malnourished patients and those who are well nourished, there is insufficient evidence to change current mg/kg body weight dosing recommendations.

Always check local guidelines on drug sensitivities.

**With all antimalarial drugs, change to an oral therapy when the child can tolerate it.**

#### **Additional treatment where needed**

- Insert a nasogastric tube to minimise the risk of aspiration pneumonia if the patient's level of consciousness is low. **This can also be used to give food to prevent hypoglycaemia if the child is unconscious for a long period and is unable to eat. Alternatively, sucrose (sugar) can be placed under the tongue.**
- Insert an IV cannula and restore the circulating volume.
  - **Fluids should be given with caution** and the need for them assessed on an individual basis after ascertaining the nutritional status and degree of dehydration present.
  - In general, **children with metabolic acidosis who have not previously received parenteral fluids are dehydrated and should be managed accordingly.**
- Give oxygen if SpO<sub>2</sub> is < 94% (to keep SpO<sub>2</sub> in the range 94–100%) or if there is respiratory distress and no pulse oximeter available.
- Treat severe anaemia with a safe blood transfusion if the child is showing signs of decompensation.
- Give anticonvulsants (diazepam is preferred) if the patient is convulsing (see below) to prevent long-term neurological damage (see Section 5.16.E). Convulsions associated with cerebral malaria should be distinguished from febrile convulsions common in children under 4 years of age. The child usually recovers rapidly, within a few minutes, from a febrile convulsion. Convulsions in malaria are common before or after the onset of coma. They are significantly associated with morbidity and sequelae. They may present in a very subtle way. Important signs include intermittent nystagmus, salivation, minor twitching of a single digit or a corner of the mouth, and an irregular breathing pattern.

Prophylactic anticonvulsants have been recommended in the past, but recent evidence suggests that **phenobarbital may be harmful in this situation.**

- Paracetamol, 15 mg/kg of body weight 4-hourly, may also be given orally or rectally as an antipyretic.
- Use tepid sponging and fanning to try to keep the rectal temperature below 39°C. Relatives are usually happy to do this when instructed.
- High-dose IV or IM antibiotics should be given routinely to an unconscious or shocked patient.
- Avoid using harmful ancillary drugs.

**The patient will need intensive nursing care at least until they regain consciousness. They may urgently need glucose or a blood transfusion if hypoglycaemia or haemolysis is severe.**

#### **Management of associated causes of mortality in severe malaria**

Some children with *P. falciparum* malaria go on to develop altered consciousness, severe anaemia, acidosis, or any combination of these. Where transmission of *P. falciparum* is endemic, malaria is the commonest cause of coma in children, especially in those aged 1–5 years.

#### **Cerebral malaria (coma, confusion and convulsions)**

Coma develops rapidly, often within 1 or 2 days of onset of fever, and sometimes within hours. Convulsions are usual and may be repeated. Clinical features suggest a metabolic encephalopathy, with raised intracranial pressure. Opisthotonos, decorticate or decerebrate posturing, hypotonia and conjugate eye movements are common. Oculovestibular reflexes and pupillary responses are usually intact. Papilloedema is found in a small minority of cases. A unique retinopathy with patchy retinal whitening and pallor of vessels is found. In fatal cases, brain swelling is commonly present at autopsy, but cerebral herniation is not usually found even in patients who have undergone lumbar puncture.

Hypoglycaemia, acidosis, hyperpyrexia and convulsions (sometimes undetectable without EEG) are common accompaniments of cerebral malaria, and require appropriate management (see below).

No physical signs are diagnostic of coma due to malaria, and incidental parasitaemia is common in endemic areas, so other causes of coma, especially hypoglycaemia and meningitis, must always be carefully sought, and if necessary treated on the basis of presumptive diagnosis.

Even with optimal treatment, the case fatality rate is 15–30%, and about 10% of survivors have residual neurological sequelae (hemiparesis, spasticity, cerebellar ataxia) that may partially or completely resolve over time.

#### **Investigations**

- Blood glucose levels (e.g. by blood glucose stick test).
- Lumbar puncture if meningitis is suspected; contraindications include papilloedema or suspicion of raised intracranial pressure (irregular breathing and abnormal pupillary responses, posturing), or respiratory difficulty such that flexing the back would compromise respiration. **In such a situation, give IV antibiotics to treat meningitis as well as malaria.**

## Management

### Coma

Ensure that the airway is open at all times and that the patient is breathing adequately. Give oxygen by face mask with a reservoir or nasal cannulae (to keep SpO<sub>2</sub> in the range 94–98% if a pulse oximeter is available). If the child stops breathing, give assisted ventilation with a bag-mask of suitable size (500 mL or 1600 mL).

Ensure that a bag-mask is available at all times.

Nurse the patient in the recovery position to avoid aspiration of secretions or vomit.

Exclude other treatable causes of coma (e.g. hypoglycaemia, bacterial meningitis).

- Treat convulsions (see Section 5.16.A on coma and Section 5.16.E on convulsions).
- Treat hypoglycaemia.

### Convulsions

Convulsions are common before and after the onset of coma.

- Ensure that the airway is open, and give oxygen by face mask with a reservoir or nasal cannulae.
- If the child stops breathing, give assisted ventilation with a bag-mask of suitable size (500 mL or 1600 mL).
- Examine all children with convulsions for hyperpyrexia and hypoglycaemia. Treat hypoglycaemia with IV or oral glucose if identified on blood testing, but also treat as for hypoglycaemia if blood glucose levels cannot be measured and the child is drowsy, unconscious or fitting (see below).
- Give anticonvulsant treatment with rectal diazepam or paraldehyde or IM paraldehyde.
- If the patient has a fever of  $\geq 39^{\circ}\text{C}$  ( $\geq 102.2^{\circ}\text{F}$ ), give paracetamol rectally (if available).
- Treat seizures lasting for more than 5 minutes with drugs.

**Ensure that a bag-mask is available at all times in case of apnoea following the use of diazepam. Apnoea is usually short-lived and improves quickly with ventilation via bag and mask.**

**Note that seizure activity needs to be looked for carefully, as it may appear as just a twitching of the thumb or mouth.**

- Give IV diazepam:
  - **Children:** 300 microgram/kg of body weight as an IV infusion over 2 minutes or 400–500 microgram/kg of body weight intra-rectally. This dose can be repeated after 10–15 minutes if still fitting.
  - **Pregnant girls:** 10 mg rectally or by slow IV injection. This dose can be repeated after 10–15 minutes if still fitting.
  - Do not exceed 10 mg per dose.
- Alternatively, paraldehyde 0.1 mL/kg of body weight may be given by deep IM injection or 0.8 mL/kg of body weight (maximum 20 mL) intra-rectally using a sterile glass syringe (a disposable plastic syringe may be used provided that the injection is given immediately after the paraldehyde is drawn up, and the syringe is never reused).

### Hypoglycaemia

Hypoglycaemia is common and is due to poor intake, increased metabolic needs of the patient and parasites and impaired hepatic gluconeogenesis. It is easily overlooked

because clinical signs may mimic those of cerebral malaria.

Check for hypoglycaemia in **all** patients who are unconscious, in shock or deteriorating. Also regularly (every hour in the first instance) check pregnant girls, children under 5 years, and the malnourished, and all patients receiving quinine.

Hypoglycaemia is defined as blood glucose levels  $< 2.5$  mmol/litre ( $< 45$  mg/dl).

**Prevent hypoglycaemia** with a maintenance quantity of 5% glucose in 0.9% Ringer-lactate or Hartmann's solution (50 mL of 50% glucose in a 500-mL bag). If the child develops hypoglycaemia despite this, give maintenance as 10% glucose in 0.9% Ringer-lactate or Hartmann's solution (100 mL of 50% glucose in a 500-mL bag). Do not exceed maintenance fluid requirements for the child's weight (see Section 9 Appendix). If the child develops signs of fluid overload, stop the infusion; repeat the 10% glucose boluses (5 mL/kg) if there is hypoglycaemia identified by making regular checks of blood glucose levels.

If IV access is not possible and the child is hypoglycaemic, place an intra-osseous needle (see Section 8.4.B).

Treat hypoglycaemia or suspected hypoglycaemia with an IV glucose infusion or bolus:

- **Children:** 1 mL/kg of 50% dextrose, diluted with four times the volume of infusion fluid (usually Ringer-lactate or Hartmann's solution) infused over 5 minutes **or** 5 mL/kg of 10% glucose as a bolus.
- **Pregnant girls:** 50 mL of 50% dextrose diluted with an equal volume of infusion fluid (usually Ringer-lactate or Hartmann's solution) over 15 minutes (irritating to veins).

Re-test 15 minutes after completion of the infusion, and repeat the infusion if blood glucose remains low. Repeat until blood glucose recovers, then infuse with 5–10% glucose in Ringer-lactate or Hartmann's solution (according to hypoglycaemia risk) to prevent recurrence. Ensure regular feeding when oral intake can be sustained. Fluids used to treat hypoglycaemia must be included in daily fluid requirements.

**If blood glucose levels cannot be measured and hypoglycaemia is a possibility, always give IV glucose as described above.**

If the child is still unable to swallow after 48 hours, start nasogastric feeds. If a gag reflex is present and the child is able to swallow, feed them as soon as this is possible. For young children breastfeed every 3 hours if possible, or give milk feeds of 15 mL/kg 3-hourly if the child can swallow. If they are not able to feed without risk of aspiration, give milk, especially breast milk, by nasogastric tube or sugar sublingually (see Section 5.8.B). Continue to monitor the blood glucose levels, and treat accordingly (as described above) if these are found to be  $< 2.5$  mmol/litre or  $< 45$  mg/dL.

**Hypoglycaemia is a major cause of death in severe malaria patients, especially in young children and pregnant girls. Remember that quinine will potentiate hypoglycaemia. Young children should receive regular feeding, including by nasogastric tube, if they are unable to take oral foods.**

### Severe anaemia

This is indicated by severe palmar pallor, often with a fast pulse rate, difficult breathing, confusion or restlessness. Signs of heart failure such as gallop rhythm, enlarged liver

and, rarely, pulmonary oedema (fast breathing, fine basal crackles on auscultation) may be present (see above).

Severe haemolytic anaemia is defined as < 5 grams of haemoglobin/dL or haematocrit < 15%.

Severe anaemia may be the presenting feature in malaria. Patients with severe anaemia, especially pregnant girls, should be tested for malaria.

Give a safe blood transfusion as soon as possible to:

- all children or pregnant girls with a haematocrit of  $\leq$  12% or Hb of  $\leq$  4 g/dL
- less severely anaemic children (haematocrit > 12–15%; Hb 4–5 g/dL) with any of the following:
  - clinically detectable dehydration (as well as rehydrating orally if possible)
  - shock
  - impaired consciousness
  - deep and laboured breathing
  - heart failure
  - very high levels of parasitaemia (> 10% of red blood cells parasitised).

Give packed cells (10–20 mL/kg body weight for children and 500 mL for pregnant girls), if available, over three to four hours in preference to whole blood. Allow red blood cells to settle at the bottom of the bag, and stop the infusion when the cells have been used.

If not available, give fresh whole blood (20 mL/kg body weight) over 3–4 hours.

A diuretic is not usually indicated (unless pulmonary oedema or fluid overload is developing), because many of these children have a low blood volume (hypovolaemia).

Check the respiratory rate and pulse rate every 15 minutes. If one of them rises, transfuse more slowly. If there is any evidence of fluid overload due to the blood transfusion, give IV furosemide (1–2 mg/kg body weight) up to a maximum total of 20 mg for children, and give 40 mg IV for pregnant girls.

After the transfusion, if the haemoglobin level remains low, repeat the transfusion.

**In severely malnourished children, fluid overload is a common and serious complication. Give whole blood (10 mL/kg body weight rather than 20 mL/kg) once, and only repeat the transfusion if there are no signs of overload.**

Perform microscopy following transfusion, and repeat or extend antimalarial treatment if parasitaemia is increasing.

#### Respiratory distress due to acidosis

This presents with deep laboured breathing while the chest is clear on auscultation, sometimes accompanied by lower chest wall indrawing. It is caused by systemic metabolic acidosis (frequently lactic acidosis) and may develop in a fully conscious child, but more often in children with cerebral malaria or severe anaemia. Always exclude other causes, such as pneumonia or pulmonary oedema.

Metabolic acidosis in severe malaria has been attributed to the combined effects of several factors that reduce oxygen delivery to tissues:

- Increased production of lactic acid by parasites (through direct stimulation by cytokines).
- Decreased clearance by the liver.
- Marked reductions in the deformability of uninfected red blood cells may compromise blood flow through tissues.
- Dehydration and hypovolaemia can exacerbate microvascular obstruction by reducing perfusion pressure.

- Destruction of red blood cells and anaemia further compromise oxygen delivery.
- Mean venous blood lactate concentrations have been found to be almost twice as high in fatal cases as in survivors, and to correlate with levels of tumour necrosis factor and interleukin 1-alpha. The lactate concentrations fell rapidly in survivors but fell only slightly, or rose, in fatal cases. Sustained hyperlactataemia has been found to be the best overall prognostic indicator of outcome.

#### Treatment

Give oxygen to all patients (even if they are not hypoxaemic), and if a pulse oximeter is available keep SpO<sub>2</sub> in the range 94–100%.

Correct reversible causes of acidosis, especially dehydration and severe anaemia.

- If Hb is  $\geq$  5 g/dL, give 10 mL/kg of 0.9% Ringer-lactate or Hartmann's solution IV as a bolus and then reassess.
- If haemoglobin level is < 5 grams/dL, give whole blood (10 mL/kg) over 30 minutes, and a further 10 mL/kg over 1–2 hours without diuretics. Check the respiratory rate and pulse rate every 15 minutes. If either of these shows any rise, transfuse more slowly to avoid precipitating pulmonary oedema (see Section 1.7).
- Monitor ECG for cardiac arrhythmias if possible.
- The use of sodium bicarbonate is controversial.

#### Respiratory distress due to pulmonary oedema

This is different to that due to acidosis, and there is usually more chest recession, hypoxaemia (cyanosis, SpO<sub>2</sub> < 94%), basal lung crepitations, enlarging liver, gallop rhythm, and raised jugular venous pressure. It may be due to fluid overload, often in the presence of severe anaemia. The most effective treatment is to tilt the bed of the patient head up so that the venous blood flow to the heart is reduced. If the bed cannot be tilted, sit the patient up, give furosemide 1 mg/kg for children and 40 mg IV for pregnant girls, and proceed with a careful transfusion of packed blood cells. Repeat furosemide as needed.

#### Respiratory distress due to pulmonary aspiration or pneumonia

**Prevent aspiration pneumonia if possible, because it can be fatal.** Place the comatose patient in the recovery position and ensure that the airway is open. If it is safe to intubate and maintain this, do so in order to protect the airway if the patient is unconscious (U on the APVU scale, or Glasgow Coma Scale score of < 9).

- Give oxygen if the SaO<sub>2</sub> is < 94% or, if pulse oximetry is not available, if there is cyanosis, severe lower chest wall indrawing or a respiratory rate of  $\geq$  70 breaths/minute. Keep SpO<sub>2</sub> 94–100%. Give IM or IV antibiotics as described for pneumonia (see Section 5.3.A), and add in metronidazole 7.5 mg/kg 8 hourly (maximum individual dose 500 mg) until the patient can take these orally, for a total of 7 days.

#### Shock

Most children with malaria have warm peripheries. Shock is unusual in malaria (algid malaria). Some patients may have a cold clammy skin. Some of them may be in shock (increased heart rate, cold extremities, weak pulse, capillary refill time longer than 3 seconds, low blood pressure (late sign)). These features are not usually due to malaria alone.

If shock is present, consider septicaemia, do a blood culture and start a broad-spectrum antibiotic IV (penicillin and gentamicin or cefotaxime or ceftriaxone) in addition to antimalarial drugs.

Management (see Section 5.5) includes fluid replacement as follows:

- **Children:** Give Ringer-lactate or Hartmann's solution IV, 10 mL/kg as a rapid bolus. Reassess, and if the patient is no better, or improving but still in shock, consider further 10 mL/kg boluses.
- **Pregnant girls:** Give Ringer-lactate or Hartmann's solution IV, 500 mL as a rapid bolus, then reassess.

If there is no improvement in capillary refill or tachycardia, repeat the infusion once or twice more, as required.

Give broad-spectrum antibiotics to treat septicaemia and any associated infections.

### Acute renal failure

Acute renal failure (ARF) is defined as an abrupt decline in the renal regulation of water, electrolytes and acid-base balance, and continues to be an important factor contributing to the morbidity and mortality of malaria patients (see Section 5.6.C). Oliguria or anuria is often associated with jaundice, anaemia and bleeding disorders.

**Note that ARF is uncommon in children, and dehydration is a more common cause of poor urine output.**

- The basic principles of management are avoidance of life-threatening complications, maintenance of fluid and electrolyte balance, and nutritional support.
- Urinary catheterisation can be helpful if it can be safely undertaken, so that urine output can be accurately measured. Alternatively, weigh nappies in young children.
- Acute renal failure is suspected when the **hourly** urine output is less than 1 mL/kg of body weight/hour. Blood levels of urea and creatinine are usually raised.
- Make sure that the patient is adequately hydrated, but avoid overload, which will precipitate pulmonary oedema if the kidneys cannot excrete excess water.
- If urine output continues to be low despite adequate hydration, peripheral perfusion and normal blood pressure, give furosemide 1 mg/kg and repeat as required.
- If renal failure is established, restrict fluid to insensible loss (30 mL/kg/day) plus urine output and other fluid losses (e.g. vomit, diarrhoea).
- Consider peritoneal dialysis (if available) or ideally haemodialysis.

### Abnormal bleeding

- Transfuse with fresh blood.
- Give vitamin K, 250–300 microgram/kg (maximum 10 mg) IV.
- Avoid IM injections and non-steroidal anti-inflammatory drugs (NSAIDs).

### Coexisting infections

Treat any associated pneumonia, dysentery, etc.

### Summary of supportive care for the treatment of severe malaria in hospital

- If the patient is unconscious, maintain a clear airway. Nurse them in the recovery position to avoid aspiration pneumonia, and turn them 2-hourly.
- Do not allow the child to lie in a wet bed, and provide

special care for pressure points. Turn the patient every 2 hours.

- Give oxygen for patients who are in respiratory distress or in shock.
- In children with no dehydration, ensure that they receive their daily fluid requirements, but take care not to exceed the recommended limits (see Section 9 Appendix). Be particularly careful when fluids are given IV.
- Treat convulsions and hypoglycaemia.
- If you cannot exclude meningitis, give an appropriate antibiotic intravenously.
- If there is deep or laboured breathing suggestive of acidosis, give one bolus of 10 mL/kg IV fluid (normal Ringer-lactate or Hartmann's) to correct hypovolaemia and reassess. A second bolus may be required.
- During rehydration, examine frequently for fluid overload (increased liver size is probably the best sign, as well as gallop rhythm, fine crackles at the lung bases, raised jugular venous pressure and eyelid oedema in infants).
- In infants, if possible always use an in-line infusion chamber for IV rehydration. If this is not available and supervision is poor, empty the IV fluid bag until only 200–300 mL is remaining then if it all goes in quickly it will be less harmful than if the whole bag is being infused.
- If necessary, use a nasogastric tube to rehydrate the patient.
- Avoid giving drugs like corticosteroids and other anti-inflammatory drugs, urea, invert glucose, low-molecular dextran, heparin, adrenaline (epinephrine), prostacyclin and cyclosporine, as they do not treat malaria and can be harmful.
- Give safe blood transfusion where necessary, with careful monitoring to prevent fluid overload. Packed cells should be used in children and pregnant girls where possible. If overload is suspected, give a single dose of furosemide.
- If the patient is unconscious and you cannot exclude meningitis or the child is in shock, administer a broad-spectrum antibiotic to manage septicaemia, pneumonia or meningitis, which are often associated with cerebral malaria.

### Summary of monitoring

- Check the patient regularly, at least every 3 hours. A doctor (if available) should see the patient at least twice a day.
- The rate of IV infusion should be checked hourly.
- Patients with cold extremities, hypoglycaemia on admission, respiratory distress and/or deep coma are at highest risk of death. It is particularly important that these children are kept under very close observation.
- Monitor and report immediately any change in the level of consciousness, convulsions, or changes in the patient's behaviour.
- Monitor the temperature, pulse rate and respiratory rate (and if possible the blood pressure) every 6 hours for at least the first 48 hours.
- Fluid balance charts: unconscious patients may be catheterised in order to measure urine output and facilitate correct fluid balance, and to detect possible renal failure.
- Frequent measurement of blood glucose levels (every hour, especially when receiving quinine and/or where the level of consciousness does not improve).
- If the patient is conscious, regularly (4-hourly) determine

blood glucose levels to exclude hypoglycaemia if the patient is not eating well. This is especially important in young children and pregnant women, and in those patients who are receiving quinine therapy.

- Check haemoglobin levels and haematocrit daily.
- Check plasma urea and electrolytes where possible, and take blood gas and lactate measurements (if available).
- Check the rate of IV infusion regularly. If available, use a giving chamber with a volume of 100–150 mL. Be very careful about over-infusion of fluids from a 500-mL or 1-litre bottle or bag, especially if the child is not supervised all the time. Partially empty the IV bottle or bag. If the risk of over-infusion cannot be ruled out, rehydration using a nasogastric tube may be safer.
- Keep a careful record of fluid intake (including IV) and urine output (should be at least 1 mL/kg/hour).
- Undertake a daily slide to determine the level of parasitaemia and to monitor treatment efficacy.
- Regular haemoglobin measurement. The frequency will depend on the rate of red blood cell breakdown. This may be very rapid in cases of high parasite density.

#### On discharge from hospital

When the child or pregnant girl is due to leave hospital, talk with the relatives and carers to ensure that:

- the patient sleeps under a net (LLIN); if not, provide one
- the patient completes any outstanding treatment
- the carers and relatives recognise symptoms and where to get treatment for simple malaria in future
- the family knows to give extra meals to make up for the poor nutrition during the illness
- the family know when to bring the patient for further check-ups and arrange a follow-up appointment.

Examine for any neurological sequelae and advise the family on how to manage these and the possible prognosis. Arrange a physiotherapy session if necessary. Good follow-up is important.

#### Management of non-severe anaemia

If anaemia associated with malaria is not severe (defined as a haemoglobin level of 6–9.3 grams/dL), treat as follows. Give iron once daily in combination with folic acid (one tablet contains ferrous sulphate 200 mg, equivalent to 60 mg of elemental iron) plus 250 micrograms/kg/day of folic acid. Give 3–6 mg/kg (maximum 200 mg) of elemental iron in 2–3 divided doses and for folic acid give 250 microgram/kg once daily (usually one 5 mg tablet). Stress the importance of keeping the tablets out of reach of young children. Iron poisoning is very dangerous.

If the child is taking sulfadoxine-pyrimethamine for malaria, or co-trimoxazole for HIV prophylaxis, do not give folic acid until 2 weeks later (it interferes with antimalarial action).

**TABLE 6.3.A.D.1 Dose of ferrous fumarate 140 mg/5 mL in children**

Weight	Dose
3–6 kg	1 mL
6–10 kg	1.25 mL
10–15 kg	2.0 mL
15–20 kg	2.5 mL
20–30 kg	4 mL

An alternative for a young child is iron syrup (ferrous fumarate) 140 mg in 5 mL and equivalent to 45 mg of iron. Give once daily (see Table 6.3.A.d.1).

Plus separate folic acid 250 micrograms/kg/day.

Treat for 3 months where possible (1 month to correct anaemia and 1–3 months to build iron stores).

#### Patients with HIV infection

Patients with HIV infection who develop malaria should receive prompt effective antimalarial treatment regimens as recommended above.

**However, treatment with an ACT involving sulfadoxine-pyrimethamine should not be given to HIV-infected patients receiving co-trimoxazole (trimethoprim plus sulfamethoxazole) prophylaxis.**

**Treatment in HIV-infected patients on zidovudine (AZT) or efavirenz should, if possible, avoid amodiaquine-containing ACT regimens. Amodiaquine can cause anaemia in G6PD deficiency, and AZT may also cause anaemia.**

#### Infection with *P. vivax*, *P. ovale* and *P. malariae*

Of the four species of *Plasmodium* that affect humans, only *P. vivax* and *P. ovale* form hypnozoites, parasite stages in the liver, which can result in multiple relapses of infection weeks to months after the primary infection. Thus a single infection causes repeated bouts of illness. Ideally, the objective of treating malaria caused by *P. vivax* and *P. ovale* is to cure (radical cure) both the blood stage and the liver stage infections, and thereby prevent recrudescence and relapse, respectively. **However, primaquine which is used to produce a radical cure is contraindicated in children under 4 years of age.**

#### Diagnosis

- Microscopy using a Giemsa-stained quality-assured thin film.
- pLDH tests can detect all species of malaria. Combination tests are now available that combine HRP2 and pLDH to detect both *P. falciparum* and non-*P. falciparum* malaria.

#### Treatment

Both *P. ovale* and *P. malariae* are regarded as very sensitive to chloroquine, although there is a single recent report of chloroquine resistance in *P. malariae*.

*P. vivax* is generally still sensitive to chloroquine, although resistance is prevalent and increasing in some areas (notably Indonesia, Peru and Oceania). Resistance to pyrimethamine has increased rapidly in some areas, and sulfadoxine/pyrimethamine is consequently ineffective. There are insufficient data on current susceptibility to proguanil and chlorproguanil, although resistance to proguanil was selected rapidly when it was first used in *P. vivax*-endemic areas.

In general, *P. vivax* is sensitive to all of the other antimalarial drugs, and slightly less sensitive to mefloquine (although mefloquine is still effective). In contrast to *P. falciparum*, asexual stages of *P. vivax* are susceptible to primaquine. Thus chloroquine plus primaquine can be considered as a combination treatment. The only drugs with significant activity against the hypnozoites are the 8-aminoquinolines (bulaquine, primaquine and tafenoquine).

**Treatment of uncomplicated *P. vivax***

For chloroquine-sensitive *P. vivax* malaria (i.e. in most places where *P. vivax* is prevalent), oral chloroquine at a total dose of 25 mg base/kg body weight for a course of treatment is effective and well tolerated. Lower total doses are not recommended, as these might encourage the emergence of resistance. Chloroquine is given in an initial dose of 10 mg base/kg body weight followed by either 5 mg/kg body weight at 6 hours, 24 hours and 48 hours or, more commonly, by 10 mg/kg body weight on the second day and 5 mg/kg body weight on the third day.

Recent studies have also demonstrated the efficacy of the recommended ACTs in the treatment of *P. vivax* malaria. The exception to this is artesunate plus sulfadoxine-pyrimethamine.

For treatment of chloroquine-resistant *P. vivax* malaria, amodiaquine, mefloquine and quinine are effective. ACTs based on either amodiaquine, mefloquine or piperaquine, rather than monotherapy, are the recommended treatment of choice.

For the complete (radical) removal of *P. vivax* infection, primaquine is required, but is contraindicated in children under 4 years of age and in pregnant women and girls.

**Treatment of uncomplicated malaria caused by *P. ovale* and *P. malariae***

Treat with chloroquine as described for *P. vivax* above.

**Prevention of malaria**

Most important is the prevention of mosquito bites. All children, all pregnant girls and all patients who have had a recent bout of malaria should be provided with an insecticide-impregnated bed net.

Drugs for prophylaxis depend on the region and sensitivity of the malarial parasite.

This is important for:

- children with sickle-cell disease: chloroquine 5 mg/kg weekly
- children or adults who return to an endemic area after an absence of over 1 year, even if they are originally from that region
- non-immune individuals: people from non-endemic areas.

**Intermittent preventive treatment for malaria in infants (ITPi) and children (ITPc, now called seasonal malaria chemoprevention, SMC)****ITPi**

- Malaria cases can be reduced by 30% in infants during the first 12 months of life using this safe, affordable and simple tool. It can be implemented via existing vaccination programmes run by the WHO.
- For infants, a treatment dose of sulfadoxine/pyrimethamine (SP) should be given three times at the time of each immunisation, beginning at 2 months (DTP2), 3 months (DTP3) and 9 months (measles and yellow fever). Each tablet of SP contains 500 mg sulfadoxine and 25 mg pyrimethamine, and for infants the following sizes for each dose are: a quarter tablet for children weighing less than 5 kg, and a half tablet for children weighing 5–10 kg.

**SMC**

- For children living in areas where transmission is highly seasonal (e.g. in Mali, Senegal, Niger and northern Nigeria), aged 1–6 years, a single dose of one tablet of SP plus three doses of one tablet/day for 3 days of amodiaquine (200 mg) is given once a month during the malaria transmission season.
- Tablets are crushed and suspended in water and given by spoon. Side effects are very rare. Minor gastrointestinal side effects may occur.
- For areas in which there is resistance to SP, piperaquine may be used instead of SP.

ITPi and SMC are recommended in addition to treated bed nets in areas of moderate to high levels of malaria transmission and low to moderate levels of parasite resistance to SP.

**Preventive treatment for malaria in pregnant girls and women (see Section 2.8.D)****Follow-up care for anaemia**

- If moderate or severe anaemia has been documented, give home treatment with a daily dose of iron/folate tablet or iron syrup for 3 months where possible (it takes 2–4 weeks to correct the anaemia and 1–3 months to build up iron stores).
- **However, if the child is taking sulfadoxine-pyrimethamine for malaria, do not give iron tablets that contain folate until a follow-up visit in 2 weeks. The folate may interfere with the action of this antimalarial drug.**
- If the child is over 1 year and has not had mebendazole/albendazole in the previous 6 months, give one dose of mebendazole (500 mg) for possible hookworm or whipworm infestation (see Section 6.3.C.a). Advise the mother about good feeding practices.
- Omit iron in any child with severe malnutrition in the acute phase.
- A study in Malawi showed that many children who were so anaemic as to require a blood transfusion died within 6 months of discharge from hospital. Prophylactic anti-malarial drugs (coArtem) at 1 month and 2 months post discharge prevented many readmissions and deaths.

**Follow-up care after malaria has been treated**

- Ask the mother to return if the fever returns or persists after 2 days of treatment, or if the child's condition gets worse in any way.
- If this happens, reassess the child to exclude the possibility of other causes of fever.
- Check whether the child actually took the full course of treatment, and repeat a blood smear. If the treatment was not taken, repeat it. If it was taken but the blood smear is still positive (remember that an RDT can remain positive for up to 6 weeks after the initial infection), and the child is not seriously ill, re-treat with first-line drugs.
- If the child returns within 2 weeks, give a full course of oral quinine.
- If the child is severely ill, refer them to a hospital for inpatient treatment.

## 6.3.B Other protozoal infections

### Introduction

The organisms collectively termed **protozoa** are not closely related to each other. They do have some similarities when viewed under a microscope, as they are largely unicellular and motile, although with exceptions.

### Toxoplasmosis

Toxoplasmosis is caused by infection with a common parasite called *Toxoplasma gondii*. *T. gondii* can be found in:

- undercooked or raw meat
- cured meat
- unpasteurised goats' milk
- cat faeces.

It cannot be passed from person to person apart from mother to unborn child.

During acute toxoplasmosis, symptoms are often influenza-like (swollen lymph nodes, or muscle aches and pains that last for a month or more).

Swollen lymph nodes are commonly found in the neck or under the chin, followed by the axillae and the inguinal region. Swelling may occur at different times after the initial infection, persist, and/or recur for various times independently of antiparasitic treatment. It is usually found at single sites in adults, but in children multiple sites may be more common. Enlarged lymph nodes will resolve within 1–2 months in 60% of patients. However, 25% of patients take 2–4 months to return to normal, and a few take longer than this.

Young children and immunocompromised patients, such as those with HIV/AIDS, may develop severe toxoplasmosis. This can cause encephalitis or necrotising retinochoroiditis.

Infants can develop a congenital infection acquired *in utero*. The key features are fever, rash, petechiae, lymphadenopathy, hepatosplenomegaly, jaundice, hydrocephalus or microcephaly, microphthalmia, epilepsy and chorioretinitis.

### Management

Congenital toxoplasmosis in newborns and immunocompromised children with HIV infection can be treated for a year with pyrimethamine (with additional folic acid) plus sulfadiazine. This treatment requires expert management.

### Amoebiasis

Infection by *Entamoeba histolytica* is acquired from human hosts via contaminated food, water or direct contact. Most infected children are asymptomatic, but some have systemic illness. This can last for many weeks. The disease presents with acute diarrhoea with colicky abdominal pains. A small proportion have bloody diarrhoea with a fever, and rarely intestinal perforation with peritonitis or haemorrhage may occur.

The diagnosis can be confirmed by observing the amoebae in a fresh stool or following a biopsy of the ulcers at sigmoidoscopy.

Amoebic liver abscesses occur in less than 1% of infected individuals. They present with fever, abdominal

pain, and a tender liver sometimes with a palpable mass. The liver abscess often occurs without gastrointestinal symptoms and with negative stools. The diagnosis can be confirmed by ultrasound scan or **CT scan (if available)**.

Treatment is required for those with systemic illnesses, those with diarrhoea due to invasive ulceration and those with liver abscesses.

- Metronidazole is the drug of choice and is well absorbed orally: 7.5 mg/kg three times daily for 5–10 days (maximum daily dose 400 mg).
- If the abscess is very large and particularly if there is concern that it may rupture, it may require aspiration under careful ultrasound support.
- After the acute treatment of a liver abscess, diloxanide should be used immediately following the course of metronidazole in order to remove all amoebae from the bowel.
- The dose of diloxanide is:
  - 1 month to 12 years of age: 6.6 mg/kg three times daily for 10 days
  - > 12 years of age: 500 mg three times daily for 10 days.

### Cryptosporidiosis

*Cryptosporidium parvum* can be acquired from infected human or animal hosts and from contaminated water and food.

It causes an acute gastroenteritis, which is self-limiting in most children. The enteritis is associated with watery diarrhoea, nausea and colicky abdominal pains. It lasts for approximately 2 weeks. In otherwise healthy children it does not usually require treatment with antimicrobial drugs unless it persists or is associated with systemic illness, in which case azithromycin may be effective.

In children with AIDS it can produce a protracted and severe illness involving major weight loss, in which case it can be treated with azithromycin. Avoid azithromycin in patients with liver disease.

The dose of azithromycin is:

- 6 months to 12 years of age: 10 mg/kg once daily for 3 days or longer in AIDS.

### Giardiasis

Infection by *Giardia lamblia* can be acquired from infected human or animal hosts and from contaminated water and food. The organisms live in the duodenum.

The infection may be asymptomatic or it can produce an acute gastroenteritis with watery stools, colicky abdominal pains and nausea. It can also produce a chronic diarrhoeal illness with malabsorption and colicky abdominal pain lasting for many months.

Diagnosis is best made from examining a fresh stool. Sometimes more than one examination will be necessary.

- Metronidazole (at the doses described for amoebiasis above) is appropriate in the chronic form of the infection. The acute form usually resolves without treatment.

## 6.3.C Helminth infections

### 6.3.C.a Worms

#### BOX 6.3.C.A.1 Minimum standards

- Faecal microscopy and egg count.
- Anoscopy.
- Eosinophil count and chest X-ray if available.
- Mebendazole, albendazole and ivermectin.
- Topical thiabendazole.

#### Introduction

In low-resource countries, children presenting to medical facilities may harbour intestinal helminthiasis (worms) or their juvenile forms (larvae) in other organs. Often this situation may exist without the presence of any signs or symptoms. In such situations ill health or the risk of serious complications is directly related to the number of parasites in a child; although children bearing heavy loads of parasites are in a minority. These patients will often present for other reasons, without their heavy worm infections being recognised.

#### Parasitology of worms

There are three important groups of helminth infections:

- 1 **Cestodes:** Beef tapeworm (*Taenia saginata*) and pig tapeworm (*Taenia solium*).
- 2 **Nematodes:** Roundworms (*Ascaris* species), hookworms (*Ancylostoma duodenale*), whipworms (*Trichuris* species) and threadworms (*Enterobius* species).
  - *Ascaris lumbricoides* is the commonest human roundworm. Adult worms are whitish pink, several millimetres (mm) wide and up to 30 centimetres (cm) long, which may live for years in the small intestine. They are often seen in stool or vomit. Transmission is by ingestion of embryonated eggs from soil. Adult worms shed their eggs in faeces. The ill effects of ascariasis are largely indirect and rare (e.g. a worm in the common bile duct). The probability of this obstruction increases with worm load.
  - Hookworms are of two species, *Necator americanus* (the New World hookworm) and *Ancylostoma duodenale*. Both adult forms are hair-like, about 1 cm long, with cutting plates at the mouth end. *Ancylostoma* is generally the more virulent pathogen. Both species occur widely, with overlap, and the differences between them can be ignored by clinicians without a special interest in this subject. They have invasive larvae, and both skin penetration and ingestion of embryonated eggs are involved in transmission. Sustained blood loss in the small intestine leads to an accumulating risk of anaemia. In children, protein-losing enteropathy and systemic secondary effects of chronic inflammation are equally important.
  - *Trichuris trichiura* commonly known as the whipworm can be up to 4 cm long with thickness of a hair except at the tail end which is wider. Transmission is similar to *Ascaris* but maturation occurs only in

the gut without tissue invasion beyond the mucosa. Its ill effects are related to worm load and may lead to a form of colitis with systemic secondary effects of chronic inflammation. This intensity of infection occurs only in a small minority of children.

- *Enterobius vermicularis* is an intestinal helminth which is spread in the form of embryonated eggs by personal contact among children. It is largely harmless but can cause secondary infection in the vaginal introitus.
  - *Strongyloides stercoralis* is capable of independent existence in the soil. It is an opportunistic parasite of several mammals, including humans. Person-to-person spread occurs with probability related to intimacy of contact. Although it is acquired in childhood, its most devastating (often fatal) effects occur only when filariform larvae become disseminated through asexual reproduction in the host. This happens if host immunity breaks down, for example with severe malnutrition or malignancy in later life. Surprisingly, disseminated strongyloidiasis is not associated with HIV infection, although it is associated with another retrovirus, HTLV1.
- 3 **Trematodes** or flukes, which include blood flukes (e.g. schistosomiasis) (see Section 6.3.C.c) and biliary tract, lung and gut flukes.

#### Diagnosis

The main clues to heavy parasitosis are in growth, nutrition and in the case of hookworm, anaemia. Gastrointestinal symptoms also occur. Often a presumptive diagnosis is based on manifestations suggestive of worm infections. An increasing number of studies on the effects of helminth infections on cognitive function and general physical fitness have added to the case for community control of these infections as an important public health measure.

#### Investigations

##### **Investigation for adult worms in the intestine**

Except for *Enterobius*, this depends on the examination of stool. Full laboratory details are beyond the scope of this manual, but for *Ascaris*, hookworm and *Trichuris*, examination by the Kato (modified Kato or Kato-Katz) method is recommended. This requires only microscope slides, a standard hole in a flat spatula with which a 50 mg stool sample is squashed on to the slide, cellophane, glycerol and a stain such as malachite green. A microscopic count of eggs per gram of stool gives an indication of the intensity of infection.

*Enterobius* (thread worm) eggs are only occasionally seen in stool because they adhere to perianal skin where the female worm has deposited them. They can be picked up on sticky tape and transferred to a glass slide. Specific diagnosis of *Enterobius* is not really necessary in any case,

**TABLE 6.3.C.A.1** Diagnosis of helminth infections due to the presence of adult worms

Symptom or sign	Likely species of adult worm in the viscera
Short stature, not growing	<i>Trichuris</i> or hookworm
Mild or moderate muscle wasting	<i>Trichuris</i> or hookworm
Anaemia, microcytic hypochromic	Hookworm or severe trichuriasis; not <i>Ascaris</i>
Hypoproteinaemia, possible oedema	Hookworm or severe trichuriasis or disseminated strongyloidiasis: not <i>Ascaris</i>
Pica, especially eating soil (geophagia)	Any or all helminths
Colicky abdominal pain	<i>Ascaris</i> : common but a weak correlation
Intestinal obstruction	<i>Ascaris</i> : a quite common surgical emergency
Jaundice and/or pancreatitis	<i>Ascaris</i> : uncommon
Laryngeal obstruction	<i>Ascaris</i> : rare
Vomiting up worms	<i>Ascaris</i> : common
Chronic diarrhoea	<i>Trichuris</i> or severe hookworm or strongyloidiasis
Defecating during sleep	<i>Trichuris</i>
Blood and mucus in stool	<i>Trichuris</i>
Rectal prolapse	<i>Trichuris</i>
Finger clubbing	Intense trichuriasis or hookworm; not <i>Ascaris</i>
Perianal itching	<i>Enterobius</i>
Vulvovaginitis	<i>Enterobius</i>

as it is reasonable to treat the patient and family when it is suspected, without proving the presence of the worm (see below).

The most effective way to establish that *Trichuris* infection is intense is to see the worms on prolapsed rectal mucosa or to perform anoscopy. An otoscope with a wide-aperture speculum can be used for anoscopy in young children. The worms are usually confined to the caecum, so if they have reached the lower rectal mucosa the infection must be intense.

*Strongyloides* is a rare cause of illness in young children, although it becomes more significant in adolescence in some regions. Microscopy has a low sensitivity, and the stool requires culture by special techniques. Serology is not widely available and also lacks specificity (see Section 6.3.C.h).

#### Investigation for migrating larvae

Eosinophilia is characteristic of this stage with 20–50% of the leucocytes being eosinophils in some cases. By contrast, eosinophilia is not a constant feature of established infection with adult worms and so is a useless diagnostic marker for intestinal infection.

The chest X-ray may show a flaring shadow spreading out from the hila.

Serology is diagnostically useful in visceral larva migrans (*Toxocara* infection), but is only undertaken in special centres or research laboratories.

Diagnosis of cutaneous larva migrans (dog hookworm

**TABLE 6.3.C.A.2** Illness due to larvae rather than adult worms

Symptom or sign	Likely species of larvae in the viscera
Cough and wheeze	<i>Toxocara canis</i> or <i>T. cati</i> (dog or cat roundworm) Also <i>Ascaris</i> and hookworm
Hepatomegaly	<i>Toxocara</i>
Lymphadenopathy	<i>Toxocara</i>
Leucocytosis with extreme eosinophilia	<i>Toxocara</i>
Epilepsy or encephalopathy	<i>Toxocara</i> (rare)
Uveitis or proliferative retinitis	<i>Toxocara</i> (younger children escape in endemic areas: naive strangers are more susceptible)

infection picked up from skin–ground contact) is purely clinical. The key is to think of it when looking at a patch of itchy pyoderma; the red line has often disappeared under the scratching.

It is not clear how much of the total burden of cough, wheezing and dyspnoea in a child population in an endemic zone is due to the pulmonary migration of helminth larvae. Factors that make the symptoms more severe are migration of children naive to *Ascaris* or hookworm infection into the endemic area, and zoonotic larvae (*Toxocara*) which cannot complete their migration but die in their human hosts.

#### Treatment

The broad-spectrum antihelmintics, mebendazole and albendazole, are drugs which combine great efficacy with an almost complete absence of side effects in ordinary use. They are the drugs of choice for ascariasis, hookworm infection, trichuriasis and enterobiasis. Albendazole is as effective as thiabendazole for visceral larva migrans, and with fewer side effects. However, visceral larva migrans is a self-limiting condition where symptoms and signs resolve in 3 months. Thiabendazole is still useful for cutaneous larva migrans in a topical preparation (10% in aqueous cream; the pharmacist may be able to make this on site, see Regimens below). Ivermectin is recommended for strongyloidiasis, but albendazole remains useful and is preferable to thiabendazole because it is less toxic.

#### Mebendazole

This is most commonly available as 100 mg tablets, but is also produced as a 20 mg/5 mL liquid and a 500 mg tablet. The tablets are chewable and reasonably palatable. The 500 mg tablet is useful for mass campaigns against *Trichuris* or hookworm. It is not approved for use in children under 2 years of age, but clinical judgement should be used in a symptomatic child. **It is considered unsafe in pregnancy or lactation.**

#### Threadworms and pinworms

Oral dose:

- Children from 6 months up to 10 kg body weight: Give 50 mg as a single dose; if reinfection occurs a second dose may be needed after 2 weeks.
- Children over 1 year of age or more than 10 kg body weight: Give 100 mg as a single dose; if reinfection occurs a second dose may be needed after 2 weeks.

### Whipworms, roundworms and hookworms

Oral dose:

- Children from 6 months up to 10kg body weight: Give 50mg twice daily for 3 days.
- Children over 1 year of age or more than 10kg body weight: Give 100mg twice daily for 3 days.

### Capillariasis

Oral dose:

- Children over 2 years of age: Give 200mg twice daily for 20 days.

### Echinococcus (mebendazole is second-line therapy, albendazole is preferred)

Oral dose:

- Child over 2 years of age: Give 15mg/kg/dose three times daily.

### Toxocariasis: visceral larva migrans (mebendazole is second-line therapy, albendazole is preferred)

Oral dose:

- Children over 2 years of age: Give 100–200mg twice daily for 5 days, although doses of up to 1 gram/day have been used for 21 days. Severe disease may warrant corticosteroid use.

### Trichinosis (gastrointestinal phase of illness only)

Oral dose:

- Children over 2 years of age: 5 mg/kg (maximum 200mg) twice daily with food for 7 days; severe infection may require concomitant corticosteroid use; late-phase antihelmintic therapy is not indicated.

### Albendazole

This drug is closely related to mebendazole, with similar pharmacokinetics. It has superior efficacy to mebendazole in systemically invasive conditions, and is more effective against migrating larvae. It is available as 200mg tablets or 200mg/5mL liquid. Cautions are as for mebendazole, noting its greater systemic absorption.

### Hookworms, roundworms, pinworms and threadworms (ancylostomiasis, necatoriasis, ascariasis and enterobiasis)

Oral dose:

- Children aged 12 months to 2 years: Give 200mg as a single dose.
- Children over 2 years or 10kg: Give 400mg as a single dose before food. Treatment may be repeated in 3 weeks.

### Echinococcus

Oral dose:

- 7.5mg/kg twice daily (maximum dose 400mg twice daily). Given continuously for up to 2 years.

### Tapeworm (taeniasis) and strongyloidiasis

Oral dose:

- Children under 10kg: Give 200mg daily before food for 3 days.
- Children over 10kg: Give 400mg daily before food for 3 days. Treatment may be repeated in 3 weeks.

### Neurocysticercosis

Oral dose:

- Children under 60kg: Give 7.5mg/kg (maximum dose 400mg) twice daily after food for 7–30 days.

### Whipworm (trichuriasis)

Oral dose:

- Children over 2 years of age: Give 200–400mg as a single dose, or in heavier infections, 400mg daily for 3 days. Treatment may be repeated in 3 weeks.

### Filariasis for community eradication programmes in combination with diethylcarbamazine or ivermectin

Oral dose:

- Children under 10kg: Give 200mg once annually for 5 years.
- Children over 10kg: Give 400mg annually for 5 years.

### Hairworm (trichostrongyliasis)

Oral dose:

- Child over 10kg: Give 400mg as a single dose.

### Cutaneous larva migrans

Oral dose:

- Children over 10kg: Give 400mg as a single dose, or 400mg daily for 3 days.

### Visceral larva migrans (toxocariasis)

Oral dose:

- Child of all ages: Give 10mg/kg daily (maximum 400mg daily) for 5 days.

### Trichinosis

Oral dose:

- Children over 10kg: Give 400mg daily for 8–14 days.

For topical treatment of cutaneous larva migrans, thiabendazole tablets can be crushed and mixed with aqueous cream or 1% hydrocortisone cream or ointment to a concentration of 10% thiabendazole.

### In places or situations where only the older drugs are available

Details and dosages are not given here. The manufacturers' recommendations may be followed, but these drugs are inferior to mebendazole and albendazole, and should be replaced if possible.

- Piperazine is effective against *Ascaris* and *Enterobius*. It has no action on *Trichuris* or hookworm, and is toxic in children prone to epileptic seizures.
- Levamisole is effective against *Ascaris* and is fairly useful effective in hookworm infection (especially *Necator americanus*); to be used in mass control programmes.
- Thiabendazole has limited effectiveness in trichuriasis and is useful in strongyloidiasis, toxocariasis and cutaneous larva migrans.
- Pyrantel is effective against *Ascaris* and *Enterobius*, with some action against *Necator americanus* and less against *Ancylostoma duodenale*. Only if combined with oxtel does the preparation affect *Trichuris*.

### Further reading

WHO's programme 'Action against worms' <http://evidence.action.org/deworming/>

### 6.3.C.b Hydatid disease

#### BOX 6.3.C.B.1 Minimum standards

- Ultrasound/radiology.
- Albendazole.
- Percutaneous aspiration, injection with hypertonic saline and re-aspiration (PAIR).
- Surgical excision.

#### Introduction

The adult stage of the tapeworm *Echinococcus granulosus* lives in the gut of dogs and certain other carnivores. The usual intermediate hosts are herbivores. **Humans may become an accidental intermediate host for the cystic stage of the parasite following ingestion of eggs in dog faeces contaminating the fingers, food or water.** Because of the slow rate of growth of hydatid cysts, symptoms from infection in childhood often present in adulthood. Many cysts remain asymptomatic, eventually calcify and become sterile.

#### Epidemiology

The disease is widespread in sheep-farming countries and wherever there is intimate contact between humans and dogs or other canids, and where dogs scavenge dead animals or offal. There is a high incidence in the Turkana region of Kenya.

#### Clinical features

- Cysts may occur in virtually any organ.
- Many cysts are asymptomatic but may be palpable if they are large or superficial.
- Abdomen:
  - Palpable mass: liver (60% of all cysts), spleen, other intra-abdominal cysts.
  - Communication with the biliary tract: cholangitis, rigors, jaundice.
  - Abdominal pain.
  - Rupture from trauma.
- Chest:
  - Lungs (25% of cysts).
  - Pleuritic pain and cough.
  - Often asymptomatic, detected on chest X-ray.
- Other areas:
  - Brain: space-occupying lesions (3–5% in some countries).
  - Bone cysts: pathological fractures, respond poorly to chemotherapy.
  - Cyst rupture may cause anaphylaxis and/or spread by 'seeding' of daughter scolices (heads of immature worms).

#### Diagnosis

- Ultrasound is effective in detecting liver and abdominal cysts. The presence of a separated membrane or daughter cysts makes the diagnosis highly likely. The condition needs to be differentiated from simple hepatic cysts.

- Plain X-ray for lung or bone cysts. CT or MRI (if available) is also useful (e.g. for brain cysts).
- Eosinophilia is present in around 20% of cases. This may be due to cyst leakage or rupture.
- Serology: specific IgG ELISA AgB (antigen-B-rich fraction) (if available) is most sensitive. Serology lacks sensitivity for extra-hepatic cysts (note that false-positive results are obtained in cysticercosis).
- A urine antigen detection test appears promising.

#### Treatment

Calcified cysts require no treatment.

#### Medical treatment

- Albendazole is useful for patients with inoperable, widespread or numerous cysts, and for patients unfit for surgery.
- Continuous treatment is now recommended (for up to 2 years). Its duration depends on the lesion's response. The dose is 7.5 mg/kg orally twice daily. The maximum dose is 400 mg twice daily.
- The absorption of albendazole is enhanced if it is taken with fatty meals.
- Albendazole plus praziquantel has greater protoscolicidal activity. The combination is successful for inoperable spinal, pelvic, abdominal, thoracic or hepatic hydatid, and as an adjunct to surgery.
- Anthelmintics may reduce the need for surgery in uncomplicated pulmonary cysts.
- Patients undergoing surgery or PAIR should receive pre-operative albendazole (for 1–3 months) with or without praziquantel.

#### Percutaneous aspiration under ultrasound control

Puncture, aspiration, injection, re-aspiration (PAIR):

- The patient should be on albendazole for at least 4 weeks prior to PAIR.
- Following initial aspiration of the cyst, hypertonic saline is injected into the cyst and re-aspirated after 20 minutes.
- Percutaneous aspiration combined with an 8-week course of albendazole is more effective than either treatment alone.
- Laparoscopic treatment of liver and spleen hydatid is also effective.
- Contraindications to PAIR include cysts in the CNS or heart, and cysts communicating with the biliary tree, abdominal cavity, urinary tract or bronchi.

#### Surgery

Surgical removal is standard treatment if the lesion is accessible but is unsuitable for PAIR. The procedure is as follows:

- The patient should be on albendazole for at least 4 weeks prior to surgery.
- Pack around the cyst and avoid spillage of the cyst contents (there is a risk of anaphylaxis and seeding).
- Drain the cyst, replace fluid with hypertonic saline, drain again, and then remove the cyst capsule.

- High rates of recurrence and of surgical complications are recorded in inexperienced hands.
- It is important to avoid hypertonic saline entering the bile ducts, as this may cause sclerosing cholangitis.

### Prevention

- Ensure disposal of infected herbivore carcasses and offal.
- Treat dogs with praziquantel.
- Maintain strict hygiene, and protect food and water from contamination.

### 6.3.C.c Schistosomiasis

#### BOX 6.3.C.C.1 Minimum standards

- Public health measures to improve water and sanitation.
- Urine and faecal microscopy
- Praziquantel.

### Introduction

Schistosomiasis occurs in areas of the world where there is a combination of warm fresh water containing specific snails, and urinary and/or faecal excretion of *Schistosoma* eggs by humans.

### Parasite and life cycle

Eggs are passed from humans in stool or urine into freshwater containing snails, *Bulinus* (*S. haematobium*), *Biomphalaria* (*S. mansoni*) and *Oncomelania* (*S. japonicum*). Miracidia hatch from the eggs, penetrate the snail, and replicate into cercariae (larval forms) which are then released into the water.

The cercaria penetrates the skin (or pharyngeal mucosa) of humans, loses its tail and becomes a schistosomula, which is then transported to the lung capillaries. It reaches the left side of the heart and is distributed throughout the body. Those that reach the portal system develop into mature worms about 1 cm in length in the liver.

Adult males and females copulate and migrate in pairs to their preferred egg-laying sites, *S. haematobium* to the vesical veins and pelvic plexus, and *S. mansoni* to the superior and inferior mesenteric veins.

Female flukes produce eggs daily throughout their average 3- to 4-year lifespan. Most eggs pass through the vessel wall, and about 50% reach the lumen of the urinary tract or intestine and are excreted. Those that remain in the tissues provoke an immune reaction which causes the disease. Some eggs are transported to the liver and some reach the general circulation.

### Pathogenesis

Pathogenesis can be divided into four stages.

- 1 **Dermatitis.** An itchy papular rash 'swimmers itch' lasting one to two days may develop as a result of humoral immune reaction to invading cercariae and schistosomulae. However, it is more likely to be due to avian schistosoma (non-pathogenic to man). Older children and adults develop a degree of resistance to this stage of invasion.

- 2 **Katayama fever** (2–8 weeks). A humoral reaction to adult worms and eggs results in an acute illness associated with formation of immune complexes. Symptoms include fever, rigors, malaise, diarrhoea, cough, hepatosplenomegaly and marked eosinophilia. It is a self-limiting disease.
- 3 **Established disease** (usually after 2 months). A T-cell delayed-hypersensitivity response to eggs deposited in tissue results in granuloma formation. If the worm load is reduced by drug therapy at this stage, granulomata may resolve, leaving little disease.
- 4 **Fibrotic complications.** Repeated infections without treatment eventually result in fibrosis, for example of the ureter and bladder (*S. haematobium*) and liver (*S. mansoni*). There is little response to drug therapy at this stage.

TABLE 6.3.C.C.1 Schistosomiasis: geographical areas (the commonest species and areas are shown in bold type)

Schistosoma species	Disease	Area
<b><i>S. haematobium</i></b>	Urinary tract	<b>Africa</b> , Middle East
<b><i>S. mansoni</i></b>	Intestines, liver	<b>Africa</b> , Middle East, <b>South America</b>
<i>S. intercalatum</i>	Intestines, liver	Central and West Africa, uncommon
<b><i>S. japonicum</i></b>	Intestines, liver	<b>China</b> , <b>Indonesia</b> , <b>Philippines</b>
<i>S. mekongi</i>	Intestines, liver	Laos, Kampuchea, small number of foci

### Epidemiology

- Schistosomiasis affects at least 240 million people worldwide, and more than 700 million people live in endemic areas.
- Schistosomiasis is associated with communities living near swamps, rivers, irrigation canals and rice fields, who have poor hygiene and sanitary facilities and lack a ready supply of clean water.
- Infection is highest in children (5–14 years) who are an important reservoir of infection because of their indiscriminate excretion habits near and in water.
- Infections decrease after puberty, but adults are still at risk when farming or washing clothes.

## Clinical features

**TABLE 6.3.C.C.2** Symptoms and complications of *S. haematobium* and *S. mansoni*

Initial stage	<i>S. haematobium</i>	<i>S. mansoni</i>	Comments
Swimmers' itch	Terminal haematuria	Bloody diarrhoea Anaemia	<i>S. japonicum</i> is similar to <i>S. mansoni</i>
Katayama fever	Obstructive uropathy Calcification of bladder and lower ureters Bladder calculi	Hepatic fibrosis Portal hypertension Ascites Colonic polyposis Nephropathy	Hepatic fibrosis is most often seen with <i>S. mansoni</i> Katayama fever is more severe with <i>S. japonicum</i>

### *S. haematobium*

This causes urinary schistosomiasis.

- Terminal haematuria, there may be dysuria.
- In a minority of children, frequent untreated infections eventually lead to structural disorder of the bladder and lower ureter, resulting in obstructive uropathy, hypertension and chronic renal failure.
- Obstruction can be demonstrated by ultrasonography and intravenous pyelogram. Adequate treatment in the early stages may be followed by resolution of ureteric lesions.

### *S. mansoni*

This causes intestinal schistosomiasis along with other species, namely *S. intercalatum*, *S. japonicum* and *S. mekongi*.

- Bloody diarrhoea. In long-standing cases there is severe iron-deficient anaemia, and even heart failure (due to anaemia).
- Protein-losing enteropathy with hypoalbuminaemia may result from colonic granulomatous disease and polyps.
- The left lobe of the liver is enlarged more than the right lobe. Ascites may occur. Liver function is usually well preserved.
- Marked splenomegaly due to portal hypertension is associated with pancytopenia.
- Haematemesis from oesophageal varices is the final event which influences the prognosis.
- Ultrasonography is useful for grading the degree of peri-portal fibrosis and in differential diagnosis from other liver diseases.
- Acute and long-term management of oesophageal varices requires endoscopy and decisions regarding sclerotherapy (see Section 5.7.B on liver disease).
- Nephropathy due to immune complex disease may manifest with microscopic haematuria and proteinuria or nephrotic syndrome. Nephrotic syndrome has a poor prognosis, especially if associated with amyloid disease (see Section 5.6.A).

### Salmonella infection

Schistosoma worms may harbour *Salmonella* species, including *S. typhi*, which cannot be eradicated until the schistosomiasis is treated. This phenomenon occurs in both *S. haematobium* and *S. mansoni* infections. *Salmonella* may cause a reversible nephritis in *S. mansoni* infection.

### Complications common to *S. haematobium* and *S. mansoni*

- Spinal cord myelopathy (less common with *S. haematobium*).
- Brain granulomata (more common with *S. japonicum*, less common with *S. haematobium*).
- Pulmonary hypertension (less common with *S. haematobium*).
- Chronic *Salmonella* infection.

### Diagnosis

#### Microscopy of urine or faeces

##### *S. haematobium*

A midday specimen is best. Urine should be sedimented or filtered. Viability of the eggs (and thus requirement for treatment) can be established by looking for miracidia, which hatch when eggs are put in boiled water that has been cooled.

##### *S. mansoni*

If stool smear is negative on microscopy, a concentration method must be undertaken. Miracidial hatching techniques are also available.

#### Rectal biopsy

Rectal biopsy to demonstrate the presence of eggs is undertaken if urine and faeces are negative.

#### Serology

Serology is of little value for diagnosis in indigenous patients, but may be useful in the non-immune (e.g. tourists to an endemic area). Antigen tests are being developed.

### Treatment

Praziquantel is effective against all human *Schistosoma* species, and is the only available drug treatment. Treatment at least three times in childhood usually prevents adult disease.

Praziquantel is given at a dose of 40 mg/kg in two divided doses given 4–6 hours apart on one day. It can also be given as a single dose of 40 mg/kg. For heavy *S. mansoni* infection and for *S. japonicum* infection, 60 mg/kg is advised, given in two doses 4–6 hours apart. Repeat urine or stool examination should be done at 3–4 months.

Praziquantel is safe during pregnancy. The safety of praziquantel in children under 4 years of age has not been established, but this drug can be used to treat individually infected children.

Side effects include dizziness, drowsiness, skin reactions, fever, headache and vomiting.

### Prevention

Control of schistosomiasis is very difficult. Measures include

regular mass treatment of communities and improvement in water supply, sanitation and hygiene. Mollusciciding (use of chemicals to kill the snails) is usually impractical and too expensive for general use.

## 6.3.C.d Fascioliasis (liver fluke infections)

### BOX 6.3.C.D.1 Minimum standards

- Vector control.
- Triclabendazole (preferred) or Bithional.

### Introduction

This disease is caused by *Fasciola hepatica* and *Fasciola gigantica*, and occurs in sheep- and cattle-rearing areas worldwide, especially South America.

Freshwater snails act as the intermediate amplifying hosts, liberating free-swimming cercariae which encyst as metacercariae on water plants. Humans are infected following ingestion of metacercarial cysts on raw aquatic plants (e.g. watercress) or from contaminated water. Following ingestion, the larvae emerge in the duodenum, penetrate the intestinal wall, migrate via the peritoneal cavity to the liver, penetrate the liver capsule, and after 3–4 months mature into adults in the bile ducts.

### Clinical features

Infections may be asymptomatic. Acute presentations occur 6–12 weeks after infection. Fluke migration may be associated with fever, malaise, abdominal pain, weight loss, urticaria, cough and wheeze. In chronic presentations, symptoms may be minimal or may be due to recurrent cholangitis, intermittent biliary obstruction or anaemia.

Ectopic flukes may cause granuloma or abscess formation in various organs, and also present as migrating skin nodules.

### Investigations

- Eosinophilia is common.
- Liver ultrasound is often normal.
- CT of the liver (if available) may reveal hypodense lesions.
- Serology may be helpful in established *F. hepatica* infections, but is less reliable for *F. gigantica*. Fasciola excretory–secretory (FES) antigen detection in faeces is available for *F. hepatica*.
- In established infections, eggs may be found in faeces.

### Treatment

**Triclabendazole** is the drug of choice for *F. hepatica* and *F. gigantica* infections. One dose of 10 mg/kg taken with food is usually effective, but should be repeated after 12 hours in severe infections. Expulsion of dead or damaged flukes may cause biliary colic 3–7 days after treatment; the colic responds well to antispasmodics. Triclabendazole resistance has been reported in Ireland, the UK and Australia.

**Bithional**, 30–50 mg/kg/day in three divided doses on alternate days for 10–15 days was the preferred treatment previously. Side effects include mild gastrointestinal upset and pruritus.

**Nitazoxanide** may be effective.

**Praziquantel is unreliable** in the treatment of fascioliasis.

### Prevention and control

- Avoid potentially contaminated watercress and other aquatic plants.
- Treat herbivores.
- Undertake snail control.

## 6.3.C.e Dracunculiasis (guinea-worm disease)

### BOX 6.3.C.E.1 Minimum standards

- Early identification of blister and worm emergence.
- Removal of worm and prevention of secondary infection.
- Filtering of water.
- Temephos to kill *Cyclops* species.

### Introduction

Guinea-worm disease is transmitted exclusively by drinking stagnant water contaminated with tiny water fleas (*Cyclops* species) that carry infective guinea-worm larvae. Once ingested, the larvae mature into worms, growing up to 1 metre in length. Humans are the only known reservoirs for the disease.

About 1 year after infection, a very painful blister forms, 90% of the time on the lower leg, and one or more worms emerge accompanied by a burning sensation. To soothe the burning pain, patients often immerse the infected area in water. The worm then releases thousands of larvae into the water, contaminating the water and bringing the infective cycle full circle.

### Epidemiology

The main source of infection is stagnant water sources such as ponds and sometimes shallow or step wells. 'Man-made' ponds are the main source of transmission.

Only four African countries (Chad, Ethiopia, Mali and

South Sudan) are known to be affected, with the majority of cases in South Sudan.

Guinea-worm disease is seasonal, occurring with two broad patterns found in endemic areas of Africa, depending on climatic factors. In the Sahelian zone, transmission generally occurs in the rainy season (from May to August). In the humid savanna and forest zone, the peak occurs in the dry season (from September to January).

A successful eradication programme for guinea-worm disease consists of several preventive strategies, such as ensuring wider access to safe drinking-water supplies, filtration of drinking water (with cloth filters) to prevent infection, intense surveillance and control to detect every case within 24 hours of the emergence of the worm(s), treatment of ponds with the larvicide temephos that kills the water fleas, and promoting health education and behaviour change.

Early case detection (when the patient feels the initial pain) is vital in order to contain the disease. There are thousands of village volunteers in the remaining endemic countries who are trained to find new cases, take care of them and report them to the area supervisor.

### Clinical effects

Once a new case is identified, the wound must be disinfected and bandaged to help to prevent secondary infection. The worm should be gently pulled out a few inches every day until all of it has been removed. Many

patients are unable to leave their beds for a month after the emergence of the worm.

Guinea-worm disease is not fatal, but infected people cannot work or attend school for months. Since the peak transmission period often coincides with the agricultural season, fields are left untended and food production declines. In Mali, guinea-worm disease is called 'the disease of the empty granary'. As adults lie sick, older children must take on the household chores and miss months of schooling. Younger children may miss vital vaccinations.

### Prevention

- Effective surveillance to detect all cases within 24 hours of worm emergence.
- **Ensure access to safe drinking water, and convert unsafe sources to safe ones.**
- Construction of copings around well heads or installation of boreholes with hand pumps.
- **There must be regular and systematic filtering of drinking water derived from ponds and shallow unprotected wells, or from surface water.** Fine-meshed cloth or, better still, a filter made from a 0.15-mm nylon mesh, is all that is needed to filter out the *Cyclops* species from the drinking water.
- Treatment of unsafe water sources with temephos to kill the *Cyclops* species.
- Health education and social mobilisation to encourage affected communities to adopt healthy behaviour with regard to use of drinking water.

## 6.3.C.f Filariasis

### BOX 6.3.C.F.1 Minimum standards

- Treatment of endemic communities.
- Control of mosquitoes (the vector).
- Diethylcarbamazine citrate (DEC), albendazole, doxycycline and ivermectin.

### Introduction

This painful and profoundly disfiguring disease is usually acquired in childhood.

The disease is caused by three species of thread-like nematode worms, known as filariae, namely *Wuchereria bancrofti*, *Brugia malayi* and *Brugia timori*. Around 90% of infections are caused by *Wuchereria bancrofti* and most of the remainder by *Brugia malayi*. About 120 million people are affected worldwide (of whom 60% live in South-East Asia and 30% live in Africa).

### Life cycle of filariae

Filariae are transmitted by mosquitoes. When a mosquito with infective-stage larvae takes a blood meal, the parasites are deposited through the person's skin, from which they enter the body. These larvae then migrate to the lymphatic vessels and develop into adult worms over a period of 6–12 months, causing damage to and dilatation of the lymphatic vessels. The adult filariae live for several years in the human host. During this time they produce millions of immature microfilariae that circulate in the peripheral

blood and are ingested by mosquitoes that bite the infected human. The larval forms further develop inside the mosquito before becoming infectious to humans. Thus a cycle of transmission is established.

Threadlike adult worms of *Wuchereria bancrofti* live in the lymphatics (groin, scrotum, arm). Male worms are about 3–4 cm in length, and female worms 8–10 cm. The male and female worms together form 'nests' in the lymphatic system. Females release thousands of microfilariae into the peripheral blood periodically every day, synchronising with the biting habits of the predominant local mosquito vector. Nocturnal periodicity is commonest, except in some Polynesian islands where microfilariae are more numerous by day.

*Brugia malayi* has two main forms: the nocturnal periodic form in swampy areas from India to Korea and Japan, and the nocturnal sub-periodic form in the damp forests of South-East Asia. The parasites of *B. malayi* are transmitted by various species of the genus *Mansonia*, and in some areas anopheline mosquitoes are responsible for transmitting infection. Brugian parasites are confined to areas of East and South Asia, notably India, Indonesia, Malaysia and the Philippines.

An estimated 120 million people in tropical and sub-tropical areas are infected, of whom almost 25 million men have genital disease (most commonly hydrocoele) and almost 15 million, mostly women, have lymphoedema or elephantiasis of the leg.

### Diagnosis

Eosinophilia is common in the acute stages. Examination of thick smears of 20–60 microlitres of blood from a finger tip or filtration of 1 mL of intravenous blood and examination of the filtrate can reveal the microfilariae provided that the concentration is high (> 100 microfilariae/mL). Concentration techniques can improve sensitivity (e.g. Nuclepore filtration).

Samples should be appropriately timed (usually between 22.00 and 02.00 hours for *W. bancrofti*).

A variety of more sensitive diagnostic techniques are now available, including complement fixation tests for circulating *W. bancrofti* antigen (e.g. an ELISA 'TropBio-test') and a rapid finger-prick immunochromatographic card test (Amrad ICT, Binax). The rapid ICT has a high sensitivity and specificity and is currently the preferred diagnostic test for *W. bancrofti*. It is also used for monitoring the success of mass drug programmes. The test requires 100 microlitres of finger-prick blood drawn at any time, day or night.

### Clinical features

The majority of infected people are asymptomatic, but virtually all have subclinical lymphatic damage, and up to 40% have kidney damage, with proteinuria and haematuria.

Inflammatory episodes associated with lymphatic filariasis involve:

- responses to the parasite itself
- the effects of secondary bacterial infection
- sometimes inflammatory mediators associated with endosymbiotic bacteria (*Wolbachia*).

Endosymbiotic bacteria infect most species of filarial nematodes that are pathogenic to humans, and contribute to the damage done by the filaria. Further characterisation of the *Wolbachia*–nematode relationship might allow the development of new therapeutic approaches to these parasitic diseases.

Acute episodes of local inflammation involving the skin, lymph nodes and lymphatic vessels often accompany chronic lymphoedema or elephantiasis (see below). Some of these episodes are caused by the body's immune response to the parasite, but many are the result of bacterial skin

infections, linked to the partial loss of the body's normal defences as a result of underlying lymphatic damage.

**Careful cleansing is extremely helpful in healing the infected areas and in both slowing and even reversing much of the damage that has already occurred.**

Acute symptoms may recur several times a year in three forms:

- 1 Acute filarial fever without lymphadenitis.
- 2 Acute filarial lymphangitis (AFL) follows the death of an adult worm, causing an inflammatory nodule or cord with lymphangitis spreading away from the affected node. This is usually mild, but may develop into an abscess.

Acute dermatolymphangioadenitis (ADLA) resembles cellulitis or erysipelas, and is often associated with secondary bacterial infection and impaired lymphatic flow, ascending lymphangitis and limb oedema. ADLA is more common than AFL, and is an important cause of lymphoedema and elephantiasis.

Chronic lymphatic filariasis may develop over months or years even without a history of acute symptoms. Lymphatic obstruction eventually leads to **elephantiasis**, most commonly affecting the legs, scrotum, arms and breast. Recurrent secondary bacterial skin infections (often streptococcal) cause acute pain and fever, and may be complicated by acute glomerulonephritis.

Other presentations of lymphatic filariasis include:

- hydrocoele, usually unilateral
- swelling of the scrotum
- acute epididymitis
- funiculitis (inflammation of the spermatic cord)
- monoarthritis
- glomerulonephritis
- chyluria, chylous diarrhoea, chylous ascites (due to rupture of dilated lymphatics). (Malabsorption of fat-soluble vitamins may complicate chylous diarrhoea.)

Brugian filariasis is usually less severe than Bancroftian filariasis.

The most severe symptoms generally appear in adults, and in males more often than in females. In endemic communities, around 10–50% of men suffer genital damage

**TABLE 6.3.C.F.1 Recommended treatment strategies for mass drug distribution, individual drug administration, and morbidity control and treatment of lymphatic filariasis**

Mass drug administration		Individual drug administration	Morbidity control and treatment
Africa	Rest of world		
IVM + ALB for at least 5 years	DEC + ALB for at least 5 years	(a) DEC (with or without ALB) 6 mg/kg single dose <sup>1</sup> (b) DEC 12-day course of 6 mg/kg per day in two or three divided doses <b>or</b> (c) doxycycline 200 mg/day for 4 weeks followed by one dose IV or IM	Lymphoedema: hygiene, physiotherapy, doxycycline 200 mg/day for 6 weeks Hydrocoele: surgical hydrocoelectomy, doxycycline 200 mg/day for 6 weeks Tropical pulmonary eosinophilia: doxycycline 200 mg/day for 4 weeks followed by one dose IV or IM

Based on Taylor M *et al.* (2010) *Lancet*, **376**, 1175–85.

<sup>1</sup> If the patient continues to live in an endemic area, or is less than 8 years of age (contraindication of doxycycline).

ALB, Albendazole; DEC, diethylcarbamazine (omit if there is onchocerciasis co-infection or a risk of serious adverse events with *Loa loa*); IVM, ivermectin (omit if there is a risk of serious adverse events with *Loa loa*).

Doxycycline: the doses above are suitable for children aged ≥ 8 years and weighing > 45 kg. Children aged ≥ 8 years but weighing < 45 kg should receive 4.4 mg/kg/day. Doxycycline should not be used for children < 8 years.

(hydrocoele and elephantiasis of the penis and scrotum). Elephantiasis of the entire leg or arm, the vulva and the breast may affect up to 10% of men and women.

In endemic areas, chronic and acute manifestations of filariasis tend to develop more often and sooner in refugees or newcomers than in local populations. Lymphoedema may develop within 6 months, and elephantiasis as soon as 1 year after arrival.

### **Tropical pulmonary eosinophilia (TPE)**

A hypersensitivity response to microfilariae in the lungs can develop in some patients, causing cough and wheeze, especially at night. There may also be an enlarged liver, spleen and lymph nodes. Chest X-ray may show diffuse miliary shadows. Untreated TPE may progress to irreversible lung fibrosis. The condition is usually associated with high eosinophilia and high microfilaria titres. Microfilariae are usually absent from peripheral blood, but the rapid antigen test is usually positive.

### **Treatment and control of filariasis**

A number of antihelmintic agents are effective, although care must be taken in the choice of antihelmintic depending on the risk of co-infection with onchocerciasis and/or *Loa loa*. Mass drug administration is an important strategy in community control. The treatment and control options are summarised in Table 6.3.C.F.1.

#### **Treating endemic communities** (see Table 6.3.C.F.1)

The goal is to eliminate microfilariae from the blood of infected individuals in order to interrupt the cycle of transmission by mosquitoes. A single dose of diethylcarbamazine citrate (DEC) has the same long-term (1-year) effect in decreasing levels of microfilaraemia as the formerly recommended 12-day regimen of DEC. More importantly, the use of single doses of two drugs administered together (optimally albendazole with DEC or ivermectin) is 99% effective in removing microfilariae from the blood for a full year

after treatment. The following recommended drug regimens need to be administered once a year for at least 5 years, with coverage of at least 65% of the total at-risk population:

- 6 mg/kg of body weight diethylcarbamazine citrate (DEC) + 400 mg albendazole,
- or
- 150 micrograms/kg of body weight ivermectin + 400 mg albendazole (in areas that are also endemic for onchocerciasis).

### **Treating individuals**

Most problems result from bacterial and fungal 'super-infection' of tissues, linked to compromised lymphatic function caused by earlier filarial infection. Antibiotics against streptococcal and other bacterial infections are important. Surgical procedures are available to correct hydrocoele.

Because secondary bacterial infections play an important role in precipitating acute adeno-lymphangitis episodes and progression of lymphoedema, simple hygiene (either alone or in combination with antibiotic treatment) plays an important role in preventing episodes of acute disease and in the management of lymphoedema. Daily washing of affected limbs with soap and safe water to prevent secondary infection, combined with simple exercises, elevation of the limb, and treatment of cracks and entry points, provides significant relief from acute episodes and slows progression of the disease.

### **Vector control**

Avoidance of mosquito bites through personal protection measures or community-level vector control is the best option for preventing lymphatic filariasis. If possible, malaria and lymphatic filariasis vector control should be integrated. Periodic examination of blood for infection and initiation of the above treatment is essential.

## **6.3.C.g Onchocerciasis**

### **BOX 6.3.C.G.1 Minimum standards**

- Rapid diagnostic tests.
- Ivermectin and doxycycline.

### **Introduction**

Onchocerciasis is caused by the filarial worm *Onchocerca volvulus*, and is an important cause of blindness and skin disease in tropical Africa, Yemen and Central and South America. It is transmitted by the bite of blackflies (*Simulium* species).

### **Epidemiology**

This infection mainly affects people living or working near fast-flowing rivers (*Simulium* breeding sites), but may be more widely distributed by flies carried on winds.

### **Pathology**

Adult worms evade the host immune response and cause few symptoms. The main problems are the result of

immunological reactions to dying and dead microfilariae and their endosymbiotic bacteria (*Wolbachia*), which release bacterial mediators that trigger the innate immune system. In addition, activated eosinophils release cellular proteins that cause connective tissue damage.

Onchocerciasis may increase the risk of HIV-1 sero-conversion. Treatment of onchocerciasis is associated with reduced HIV-1 viral replication. Onchodermatitis is more severe in HIV-positive patients.

### **Clinical features**

The incubation period is usually 15–18 months. Infected patients may be asymptomatic. Palpable firm painless subcutaneous nodules (intertwined adult worms), several centimetres in diameter, may be most obvious over bony prominences.

### Skin disease

A variety of different skin manifestations are seen, usually with a significant degree of overlap:

- Acute papular onchodermatitis (APOD): an intensely itchy papular rash, sometimes with local oedema.
- Chronic papular onchodermatitis (CPOD): larger pruritic (itchy) hyperpigmented papules.
- Lichenified onchodermatitis (LOD): discrete or confluent pruritic hyperpigmented papulonodular plaques, often with lymphadenopathy.

Severe itching may give rise to excoriation and secondary bacterial infection. Healing is associated with progressive hyperpigmentation, blackening and thickening of the skin.

Unrelenting itching may result in chronic sleep disturbance, poor concentration and depression.

Heavy infections in childhood can impair growth. After some years, skin atrophy and depigmentation give a wrinkled prematurely aged appearance (presbydermia). Patchy depigmentation, especially of the legs, results in a 'leopard-skin' appearance.

Inguinal or femoral lymphadenopathy may give rise to the so-called 'hanging groin' appearance.

### Eye disease

Early symptoms include itching, redness and excess lacrimation. Late disease leads to varying degrees of loss of vision, and eventually to blindness.

#### Anterior eye disease

- Punctate keratitis due to death of microfilariae in the cornea may appear as a reversible 'snow-flake' opacity.
- Pannus forms as blood vessels invade the cornea from the sides and below. The pannus may cover the pupil (sclerosing keratitis) and cause blindness.
- Iritis leads to a loss of the pigment frill and to synechiae that cause a deformed, often pear-shaped pupil. Secondary cataracts occasionally result.

#### Posterior eye disease

- Chorioretinitis with pigmentary changes.
- Optic atrophy.
- 'Tunnel vision' and various other forms of visual loss may become evident in young adults.

### Diagnosis

- Skin snips in saline examined under the microscope for microfilariae.
- Slit-lamp examination for microfilariae in the anterior chamber of the eye.
- Rapid diagnostic tests. A new luciferase immunoprecipitation systems (LIPS) assay has 100% sensitivity and specificity for *O. volvulus* using a rapid 15-minute format (QLIPS).
- Biochemical methods: Recent advances include a serum antibody test card using recombinant antigen to detect *O. volvulus*-specific IgG4 in finger-prick whole-blood specimens, a triple-antigen indirect ELISA rapid-format card test, and a highly sensitive and specific urine antigen dipstick test.
- Surgery: Subcutaneous nodules can be removed to demonstrate adult worms, or aspirated with a needle to look for microfilariae.

- DEC patch test: Diethylcarbamazine (DEC), although no longer recommended for the treatment of onchocerciasis because of the risk of provoking a Mazzotti reaction (see below), may be used in the following manner in patients with repeatedly negative skin snips, where other diagnostic techniques are unavailable. A 1-cm square of filter paper soaked in a solution of DEC is applied to the skin of the patient. If positive, this will provoke intense localised itching and inflammation at the site of application. DEC patch testing of children aged 3–5 years is advocated as an effective low-cost method for monitoring the endemicity and transmission of onchocerciasis in Africa.
- **Warning: A DEC patch test may precipitate a full-blown Mazzotti reaction.** This consists of microfilaria death resulting in an intensely itchy papular rash, may be accompanied by fever, limb oedema, hypotension and worsening of eye damage, and may be fatal. It is commonly associated with the use of oral DEC, and is rarely caused by ivermectin.

### Treatment

**Ivermectin** kills microfilariae by immobilising them so that they are carried away via the lymphatics.

**Warning: Ivermectin may precipitate meningoencephalitis or renal failure in patients who have *Loa loa* with a high microfilaraemia (> 2500 microfilariae/mL).**

It is therefore important to exclude *Loa loa* if there is any possibility of co-infection, before giving ivermectin.

**Doxycycline** kills the endosymbiotic *Wolbachia*, resulting in the slow, less pathogenic death of the microfilariae. The drug also blocks worm embryogenesis and has a significant macrofilaricidal effect. Contraindications to doxycycline include age less than 9 years, pregnancy and breastfeeding.

#### Treatment of individual patients

Provided that the patient does not have a high *Loa loa* microfilaraemia, and ivermectin (or doxycycline) is not otherwise contraindicated, the following options are available:

- If the patient will continue to live in an endemic area, or is less than 9 years old and weighs more than 15 kg, give **ivermectin** 150 micrograms/kg every 3–6 months.
- If interruption of worm embryogenesis and cessation of microfilariae production is desired, give **doxycycline** 200mg/day for 4 weeks, or 100mg/day for 6 weeks, followed by one dose of **ivermectin** after 4–6 months (children aged > 9 years).
- If a strong macrofilaricidal effect is desired, give **doxycycline** 200mg/day for 6 weeks, followed by one dose of ivermectin after 4–6 months.

Patients with onchocerciasis who do have a high *Loa loa* microfilaraemia may be treated with **doxycycline** 200 mg daily for 6 weeks, unless contraindicated. If they are under 9 years of age, in which case doxycycline is contraindicated, *Loa loa* microfilaraemia must be reduced by treatment with **albendazole** prior to treatment with **ivermectin**.

Surgical removal of head nodules (nodulectomy) was advised in the past in an attempt to reduce the likelihood of eye disease. There is no guarantee that this will eliminate the risk of eye disease, because not all nodules are evident, and the remaining nodules continue to produce

microfilariae. Improved drug treatment has reduced the justification for nodulectomy.

### Control

There has been rapid progress in the past 30 years, largely due to successful international public–private partnerships, sustained funding for regional programmes, and technical advances.

Initial efforts in vector control using the organophosphate larvicide **temephos** proved inadequate.

A major breakthrough came with Merck's donation of ivermectin. Thereafter larviciding was abandoned in favour of regular mass drug treatment.

The African Programme for Onchocerciasis Control

(APOC) is a Community-Directed Treatment with Ivermectin (CDTI) programme that aims to treat over 90 million people annually in 19 countries, protecting an at-risk population of 115 million, and should prevent over 40 000 cases of blindness every year. High-risk foci of *Loa loa* are currently excluded from community ivermectin programmes.

The Onchocerciasis Elimination Programme for the Americas (OEPA) adopts a similar approach to APOC, except that ivermectin is administered twice a year until transmission has been interrupted. By the end of 2012, transmission of the infection, judged by surveys following WHO guidelines, had been interrupted or eliminated in four of the six endemic countries in the WHO Americas Region.

## 6.3.C.h Strongyloidiasis

### BOX 6.3.C.H.1 Minimum standards

- Hygiene, sanitation and shoes are useful in prevention.
- Ivermectin is the treatment of choice.
- Albendazole.

### Introduction

This parasite affects 50–100 million people worldwide, and occurs in warm, wet, tropical and subtropical regions where sanitation is poor. *Strongyloides stercoralis* is the main species infecting humans. However, *Strongyloides fülleborni*, which is principally a parasite of primates, also occurs in humans in Africa and Papua New Guinea.

Human infection is due to percutaneous penetration of filariform larvae in contaminated soil. Filariform larvae travel via the lungs to the small intestine, where they develop into adults and penetrate the duodenal and jejunal mucosa. Fertilised females produce eggs which hatch in the intestinal mucosa and release the first-stage rhabditiform larvae, which are excreted in faeces. In favourable conditions, the rhabditiform larvae transform into infectious filariform larvae within 48 hours, and remain viable in the soil for weeks.

An important feature of *Strongyloides* is auto-infection. This occurs when rhabditiform larvae transform into infectious dwarf filariform larvae in the gut lumen and penetrate the mucosa or the peri-anal skin. Infection may persist for decades without further exposure. Person-to-person transmission may also occur.

### Clinical features

Initial skin penetration may cause itching, urticaria and sometimes a snake-like (serpiginous) rash. Migration through the lungs may cause cough, wheeze and evidence of pneumonitis. Invasion of the small bowel may cause abdominal pain, vomiting, malabsorption and paralytic ileus.

Chronic infection is often asymptomatic, but may cause intermittent abdominal pain, diarrhoea and urticaria. Malabsorption and a protein-losing enteropathy may occur. A transient, intensely itchy serpiginous rash, known as 'larva currens' or 'creeping eruption', may appear on the trunk, buttocks or elsewhere.

Episodic pneumonitis and, more rarely, a reactive arthritis may occur.

### *Strongyloides* hyperinfection syndrome

One of the major dangers associated with *Strongyloides* infection occurs as a result of massive auto-infection. Risk factors include immunosuppression induced by various drugs, including corticosteroids, or associated with diseases such as malignancies (particularly leukaemia and lymphoma), severe malnutrition and severe infections, including advanced AIDS and human T-cell leukaemia virus type 1 (HTLV-1).

Hyperinfection syndrome may present with severe diarrhoea, often with blood in the stool. Bowel inflammation with micro-perforations may give rise to paralytic ileus, peritonitis and Gram-negative septicaemia. Proliferation and dissemination of larvae and enteropathogens may cause widespread pathology, including endocarditis, pneumonitis and meningitis.

All patients with a history of possible exposure to *Strongyloides* should be screened before being treated with any drugs that cause immunosuppression. Those at significant risk should be treated empirically even if investigations are negative.

### Investigations

Eggs are rarely found in the stool, and larvae may be difficult to identify. Stool culture (e.g. on charcoal or agar) is recommended.

Larvae may be seen in duodenal aspirates or using the string capsule technique (Enterotest).

Larvae may also be found in sputum, CSF and urine in hyper-infection syndrome.

Serology is useful for immune-competent patients who are not normally resident in an endemic area. However, interpretation of a positive test may be a problem due to cross-reactions with filarial antigens.

Eosinophilia is common in immune-competent patients, but may be absent in hyperinfection syndrome.

### Treatment

Ivermectin is the drug of choice for children over 5 years old

or weighing more than 15 kg. An oral dose of 200 micrograms/kg/day for 2 days gives excellent results.

Albendazole 400 mg every 12 hours for 7 days may also be effective, and can be used in children over 2 years of age.

Hyperinfection syndrome can be very difficult to manage. There may be problems with administration or absorption of oral medication, and no IV or IM preparations of ivermectin or albendazole are licensed for use in humans. However, parenteral ivermectin, available as a veterinary preparation,

has been administered subcutaneously in the successful treatment of *Strongyloides* hyperinfection. Patients with hyper-infection syndrome also require treatment for Gram-negative septicaemia.

#### **Prevention and control**

- Improve hygiene and sanitation.
- Wear shoes.
- Avoid contact with contaminated soil.

# Section 7

## Major injuries in pregnancy and childhood

# 7.1 Wounds and their management

## BOX 7.1.1 Minimum standards

- Analgesia.
- Sutures.
- Adhesive strips/tissue glues.
- Human anti-tetanus immunoglobulin.
- Tetanus toxoid (or DTP, Td).
- Antibiotics.

## Management of major injuries using the APLS/ATLS system

Before wounds are treated, if there are other injuries, the whole patient must be assessed according to the APLS/ATLS system (see also Section 1.11).

### Primary survey and resuscitation

- Assess:
  - Airway and cervical spine control
  - Breathing
  - Circulation and haemorrhage control
  - Disability
  - Exposure.
- Identify and correct life-threatening abnormalities.
- Resuscitate and stabilise vital functions.

### Secondary survey and emergency treatments

Remember that if simple resuscitative measures do not stabilise the child, operative intervention may be necessary before a formal secondary survey is done. In the secondary survey, determine the full extent of all injuries to the head, face, neck, chest, abdomen, pelvis, spine and extremities.

Have an emergency treatment plan to give emergency treatments in order of priority.

### Definitive care

The definitive care of major injuries, which include wounds, is often carried out by teams that have not been involved in the resuscitation and emergency treatments. Good communication is essential, using:

- legible and detailed notes
- prompt and efficient transfer to a unit which can provide the definitive care (this may be an inter-hospital transfer)
- a clear handover summary.

## Wounds

### Definition

In a medico-legal context, to wound is to destroy, however superficially or minutely, a bodily surface, be it skin or mucous membrane. A contusion (bruise) is excluded.

### Nature of injuries causing wounds

- Kinetic energy (impacts): from any object of any material purposefully or accidentally impacting.
- Heat: from any heated solid, liquid or gas.

- Cold: from any cooled solid, liquid or gas.
- Chemical: acids and alkalis predominate.
- Electrical: can cause significant internal injury.

### Types of wounds

- Abrasion: friction injury, also known as graze.
- Laceration: blunt injury.
- Incision: injury from a sharp object.
- Stab: injury from a knife, scissors, screwdriver, poker, etc., usually penetrating in nature.
- Needlestick.
- Bite: human or animal (see Sections 6.2.H and 7.5).
- Firearm: shotgun, rifle, revolver or pistol (see Section 7.3.H).
- Blast (see Section 7.3.G).
- Burn (see Section 7.3.I.a and I.b).

**It is important to remember that a variety of types of wounds may coexist following a single incident.**

### Assessment of minor wounds

Assessment of each wound should include the following:

- nature of the injury causing the wound
- type of wound
- wound site: size, shape, position and depth
- relevant motor function
- relevant sensation
- circulation distal to the wound.

Associated features include the following:

- erythema (redness)
- oedema (swelling)
- contusion (bruise)
- **surgical emphysema: this needs urgent specialist care**
- tenderness: if this extends beyond the area of the wound, a fracture may be present (see Section 7.2)
- pain.

General assessment includes the following:

- allergies
- immunisation status
- intercurrent illness
- medication
- past medical history
- time of last meal.

### General principles

- After assessment of pain, give appropriate analgesia (see Section 1.15).
- If a radiopaque foreign body may be present, arrange an X-ray.
- The most important local treatment for all wounds is vigorous cleaning with sterile saline to remove dirt and possible pathogenic organisms (after analgesia).

- Local, regional or general anaesthesia may be needed to achieve optimal cleaning (see Section 1.24).
- Superficial palpable foreign bodies should be removed as soon as possible.
- Removal of deeper foreign bodies may need specialist advice.
- **Dead or damaged tissue must be excised.** Specialist advice is needed if this involves more than a very small area of skin or mucous membrane.
- If tendons or nerves have been damaged, specialised care is needed.

### Tetanus prevention

Give tetanus prophylaxis if the patient is **not immunised** or is **not fully immunised** (full immunisation is 5 doses of

tetanus toxoid: 3 for the primary immunisation in infancy, one before school entry and one before leaving school). Wounds particularly prone to tetanus are those sustained more than six hours prior to presentation, those of puncture type, those with much devitalised tissue, those that appear septic, those associated with a compound fracture or foreign body and those contaminated with soil or dung. These wounds may need human anti-tetanus immunoglobulin (HATI), 250–500 units IM, depending on the patient's tetanus status and the degree of contamination or devitalisation of the wound.

If the child has received anti-tetanus immunisation in the past, a single extra dose of tetanus toxoid IM (or, if they are due additional immunisation boosters, the relevant combination) should be given.

**TABLE 7.1.1** Need for tetanus immunoglobulin and/or tetanus toxoid after a wound

History of tetanus vaccination		Type of wound	Tetanus vaccine booster (see below)	Tetanus immunoglobulin
≥ 3 doses	< 5 years since last dose	All wounds	No	No
	5–10 years since last dose	Clean minor wounds	No	No
		All other wounds	Yes	No
	> 10 years since last dose	All wounds	Yes	No
< 3 doses or uncertain	Clean minor wounds	Yes	No	
	All other wounds	Yes	Yes	

Note: if a patient has not completed the 5 tetanus doses when they are injured, it is likely they have also not completed other immunisation schedules. If possible give a combined immunisation comprising, for example, DTaP, DTP or DTaP – IPV for young children and Td for older children or adults according to local immunisation schedules.

### Antibiotics

There is no substitute for thorough cleaning of wounds and for careful debridement of any devitalised tissue. However, in addition to cleaning and to tetanus prophylaxis, some wounds will need antibiotics. These will include wounds that have presented late and already are infected. Do not close these wounds but pack with sterile gauze dampened with sterile normal saline and review after antibiotic treatment for possible delayed primary closure after excision of the wound edges if feasible, or secondary closure.

Oral antibiotics to choose include flu/cloxacillin 25–50 mg/kg four times a day or co-amoxycylav 125/31 mg three times a day for 1–6 years or 250/62 mg three times a day for 6–12 years. Co-amoxycylav is effective in bite injuries. A five day course is usually sufficient.

### Specific injuries

#### Abrasions

- After thorough cleaning and debridement, leave abrasions exposed or cover them for 5 days with vaseline gauze.
- If debris is left in an abrasion, epithelium will grow over it and 'tattooing' will occur.

#### Lacerations and incisions

- Only clean fresh wounds should be closed immediately, preferably only less than 6 hours old, certainly less than 12 hours old.

#### ● Distal-based flap lacerations may need specialist care if the blood supply is poor.

- To close superficial wounds, adhesive strips and tissue glues are excellent, but these must not be used for deeper wounds, in which cavities will be created and healing will not occur.
- Close deeper wounds in layers without tension.
- Close skin with interrupted sutures, ideally using monofilament material.
- If the wound is compound (associated with a fracture), an antibiotic should be given to prevent osteomyelitis (see Section 5.17).
- Arrange for removal of sutures at the times shown in Table 7.1.2.
- Younger patients heal more quickly. Malnourished patients take longer to heal.

**TABLE 7.1.2** Times for removal of sutures

Site	Days
Face	4
Scalp and neck	5–7
Hand (flexor surface)	5–7
Trunk and arms (not extensor surfaces)	5–7
Legs (not extensor surfaces)	7–10
Hands (extensor surfaces)	7–10
Elbows and knees	10–14

#### Fingertip injuries

- Preserve maximum length.
- If the tip is amputated distal to the bone, regeneration will occur if the wound is kept clean and moist under paraffin gauze dressings changed weekly.

- Other principles of treatment are the same as for lacerations and incised wounds.

### **Tongue lacerations**

- Most stop bleeding spontaneously and do not need sutures.
- Repair under general anaesthesia if there is profuse bleeding or the full thickness of tongue is involved.
- Use absorbable sutures.

### **Stab wounds**

- **Stabbing may cause serious penetrating injuries to deep structures, which may lead to rapid death from haemorrhage or air embolus.**
- The external dimensions of a stab wound may be deceptively small compared with the damage to underlying structures.
- Superficial stab wounds are treated in the same way as lacerations and incised wounds.
- Patients with penetrating wounds need resuscitation and emergency exploration under general anaesthesia.
- Never remove the penetrating object until the patient has been resuscitated and is in a secure surgical environment with cross-matched blood available.

### **Needlestick injuries**

- If there is **skin puncture**, encourage bleeding and wash the wound thoroughly with plenty of soap and water. Dry the wound and apply a dry dressing if appropriate.
- If there is only **skin contact**, wash the wound with plenty of soap and water but do not scrub it. Scrubbing may damage the skin.
- If there is **splashing into the mouth**, rinse with plenty of water.
- If there is **splashing into the eye**, rinse with plenty of water. Obtain the help of a colleague to do this.

- If the identity of the donor (the person whose blood is on the needle) is known, try to find out whether that person has hepatitis B and/or HIV infection.
- Consider immunisation for hepatitis B and triple therapy for HIV if these are available.

### **Complications of wounds**

#### **Retained foreign body**

- This will cause swelling beneath the wound.
- Secondary infection is more likely if there is a retained foreign body. If the foreign body is superficial, it must be removed by a competent surgeon under local anaesthetic. A general anaesthetic will be required if the foreign body is deeply placed and/or in an area with important structures, such as the hand or face.

#### **Infection**

- Tetanus: this is most likely to occur if the wound has been contaminated with soil and/or manure and the child is not fully immunised (see above).
- Bacterial. Prophylactic antibiotics such as flu/cloxacillin or co-amoxycylav should be considered in cases where wounds have been contaminated, **but this does not lessen the need for thorough cleaning of such wounds.**
- Antibiotic doses: flu/cloxacillin 25–50 mg/kg four times a day or co-amoxycylav 125/31 mg three times a day for 1–6 years or 250/62 mg three times a day for 6–12 years. Co-amoxycylav is effective in bite injuries. A five day course is usually sufficient.

#### **Delayed healing**

- This may be due to poor apposition of the edges, malnutrition and/or infection.
- Excision of the edges of the wound and secondary suture may be helpful, except in malnutrition.

## **7.2 Fractures in children**

### **BOX 7.2.1 Minimum standards**

- X-rays.
- Splints.
- Plaster of Paris bandages.
- Traction.
- External and internal fixation.
- Physiotherapy.

### **Introduction**

As any parent knows, all children are susceptible to injury. However, children in resource-limited countries are probably more at risk than their developed-world counterparts, as they often live in less regulated and protective environments. Once injured, there may be a considerable delay

in their presentation to a healthcare facility, a situation that can complicate and restrict treatment options.

Scarce X-ray resources and a limited range of treatment modalities can then further complicate treatment of paediatric fractures.

However, on a more optimistic note it can be said that paediatric fractures are often more 'forgiving' when compared to those of the adult; they are often easier to reduce, less requiring of internal fixation, are quicker to unite and, due to the potential for remodelling with continued skeletal growth greater degrees of mal-union can be tolerated.

### **Diagnosis**

Certain features of the history and examination may suggest the presence of a fracture:

- history of a significant traumatic event
- swelling
- bruising
- deformity
- loss of function: inability to move or weight-bear
- bony crepitus at the fracture site
- consider the possibility of child abuse (see Section 7.6) if the fracture appears inconsistent with the history given or with the child's developmental status.

### Open fractures

Open fractures occur where the fracture site communicates with a laceration or break in the skin relating to it. There is potential for the introduction of contaminants and resultant infection. Often open fractures are the result of a greater degree of violence than is the case for closed fractures.

Open fractures are graded according to the Gustilo classification:

- grade 1: skin wound of < 1 cm with minimal soft-tissue injury
- grade 2: skin wound of > 1 cm, with moderate soft tissue injury
- grade 3: these wounds typically involve a far greater degree of violence and energy transfer. This is further subdivided into:
  - A: extensive wound > 10 cm with crushed tissue and contamination but for which soft-tissue coverage is usually possible.
  - B: extensive wound > 10 cm, again with crushed tissue and contamination, but where it is not thought that local soft-tissue coverage is possible, and therefore a **regional** or **free** flap may be necessary.
  - C: any open fracture with an associated major vascular injury requiring repair for limb salvage.

Treatment is dictated by the extent of soft-tissue injury as reflected in the above grading system. The initial priority is a thorough debridement and copious irrigation of the fracture site in order to reduce the burden of contamination and lower the risk of infective sequelae. Once this has been done, some form of stabilisation is necessary. Internal fixation of open fractures carries a considerable risk of infection. Safer options are plaster application (with or without windowing to expose the wound) or external fixation.

It is often useful for a photograph of an open fracture to be taken by the initial assessor (perhaps on a mobile phone) so that the wound can remain covered until the patient is in the operating theatre. It helps to prevent frequent opening of the dressings and infection.

### Compartment syndrome

The associated soft-tissue injury and subsequent swelling leads to an elevation of interstitial pressure within a closed fascial compartment, which results in microvascular compromise. If left untreated, tissue necrosis will occur. The commonest site is in the lower leg, but compartment syndromes can also occur in the thigh, foot and upper limb. The signs and symptoms of compartment syndrome include the following:

- a hard woody swollen extremity
- severe pain on passive movement
- tingling or burning sensations (paraesthesia) in the skin
- pain out of proportion to the severity of the fracture and not relieved by splinting or analgesia

- numbness or paralysis (loss of movement) and absent distal pulses are late signs.

Although it is possible to monitor intra-compartment pressures, such technology will rarely be available. The alternative is to have a high index of suspicion for fractures involving significant soft-tissue injury, and regularly review the clinical condition of the limb.

Treatment of compartment syndrome is by prompt surgical fasciotomies to decompress the affected compartments. In the lower leg there are four muscular compartments separated by strong fascia:

- 1 the lateral compartment containing the peroneal muscles
- 2 the anterior compartment containing the dorsiflexor muscles of the ankle and toes
- 3 the superficial posterior compartment containing the gastrocnemius and soleus muscles
- 4 the deep posterior compartment containing the deep plantar flexors of the ankle and toes.

The lateral and anterior compartments can be decompressed through the same antero-lateral longitudinal incision. A single postero-medial incision can be used for the deep and superficial posterior compartments. In each case the fascial envelope containing the muscle group must be incised along its length in order to permit swelling and prevent the build-up of pressure within the compartment.

### X-rays

X-rays are the most useful and specific diagnostic modality. Where possible, two orthogonal X-rays (at 90 degrees to each other) should be obtained, ideally including the joints above and below the suspected fracture site. Terms relating to fracture appearance on X-ray include the following:

- transverse: at 90 degrees to the long axis of the bone
- oblique: other than the above
- simple: involving a single fracture line
- comminuted: involving bony fragmentation
- greenstick: visible fracture at only one cortex on the X-ray view. Greenstick fractures are only seen in paediatric fractures, due to the flexible nature of paediatric bone; this implies intact periosteum along the opposite side to the fracture and is a good prognostic sign.

### Salter-Harris classification

This relates to the X-ray pattern of fractures occurring around the epiphysis, or growth plate, of a bone. Such fractures occur in about 15–20% of major long bone fractures and 34% of hand fractures in childhood.

There are five grades, with increasingly poor prognosis for fracture outcome with increasing grade because of an increasing degree of damage to the growth plate. This will lead to limb shortening as the child grows.

- 1 Fracture across the epiphyseal line, not extending into the epiphysis or metaphysis. This occurs when the growth plate is very thick, and thus tends to be seen in young children. Healing is rapid and complications are rare.
- 2 Fracture across the epiphyseal line extending into the metaphysis, but not into the epiphysis. This usually occurs in children over the age of 10 years. Healing is usually rapid and there is rarely growth disturbance.
- 3 Fracture extending completely across the epiphyseal line

- and into the epiphysis. This type of fracture can occur at any age and is associated with a poor prognosis.
- 4 Fracture extending from the metaphysis through the growth plate and into the epiphysis. This type of fracture occurs when the growth plate is partially fused, and it has a poorer prognosis.
  - 5 Crush injury to the growth plate. This is caused by severe axial loading during a fall from a height. Inevitably there is partial destruction of the epiphyseal plate, and thus a considerable risk of growth disturbance.

### Treatment of fractures

- **Reduce** the fracture (if displaced).
- **Hold** the fracture while bony healing occurs.
- **Rehabilitate:** restore function and range of motion.

The potential for remodelling with continued skeletal growth is more marked in younger children. It occurs to a greater degree in the plane of movement of the affected joint. As a result of remodelling, angular deformity can gradually resolve with growth, and thus accurate initial reduction is not mandatory. In contrast, it is important to accurately reduce intra-articular fractures in order to prevent secondary arthritis.

Children will often be unable to tolerate reduction under local anaesthesia. General anaesthetic will usually be required (see Section 1.24).

Once reduced, the fracture needs to be held in position while bony union occurs.

During reduction of fractures, particularly in the lower limb, rotation of the limb should be checked clinically and compared with the opposite limb. X-rays, although useful for judging angulation, length and translation, are not very helpful for judging rotation.

### Splintage

Splintage of a fracture involves immobilising the fracture, thereby preventing relative motion of the bone ends. In the

**FIGURE 7.2.1** Slings and splints for childhood fractures. From the Merck Manual Home Health Handbook, edited by Robert Porter. © 2010-11 Merck Sharp & Dohme Corp., a subsidiary of Merck & Co, Inc, Whitehouse Station, NJ. Available at: [www.merckmanuals.com/home/](http://www.merckmanuals.com/home/) (accessed 5/8/14).

acute phase, this will help to relieve the pain associated with the fracture. In the longer term, the fracture stability conferred by the splint will help to promote bony union.

The commonest form of splintage uses plaster of Paris bandages (see plastercraft below). If these are not available preformed, then it is possible to make them from crepe bandages and calcium sulphate. The bandages can be applied in the form of a complete (circumferential) cast or as a backslab, along only one side of the injured limb.

In any situation where swelling is anticipated, a complete cast should either be bivalved or split down to skin along its length.

In some circumstances, plaster of Paris may not be available. If this is the case, splints can often be fashioned from locally available materials. One example of this is the use of strips of bamboo and bandaging.

The splint should be applied with the limb in the position of function. Then if stiffness does occur the limb will still have some use. For the elbow, this position is 90 degrees of flexion. For the ankle, a position of neutral plantar/dorsiflexion (the sole of the foot at 90 degrees to the lower leg) is preferred.

### Plastercraft

Before starting to apply a plaster, all of the necessary equipment should be ready to hand. The limb should be covered in stockinette, if available, and then cotton wool. Bony prominences (ankle malleoli, fibular head, wrist, olecranon) should be covered with extra padding to prevent pressure sores.

The plaster bandage should be immersed in water for about 5 seconds, by which time bubbles should have stopped rising from the plaster. Cold water is usually best, but hot water causes the plaster to set faster, so the temperature should be adjusted according to need.

For plaster slabs, the length required should have been premeasured and then the slab made up in readiness, most slabs requiring a thickness of between 5 and 10 layers of plaster bandage. Once dipped, the slab should be applied to the limb over the layer of cotton wool and then bandaged into place.

For circumferential casts, the bandage should be unwound half a turn before dipping, with the roll held in one hand and the free end in the other. After immersion, excess water should be allowed to fall from the plaster, but it should not be wrung or squeezed, as this will result in a plaster that is too dry to make a good cast. The plaster bandage can then be wound around the injured limb, with each turn overlapping the previous one by about two-thirds. Twists and turns in the plaster should be avoided, as these can constrict the limb. Once the plaster bandage has been applied, the limb should be held still until the plaster sets.

If proprietary plaster of Paris bandages are not available, it is possible to make them using gauze bandages and plaster. Medicinal-grade plaster (calcium sulphate PBC) is ideal, but failing this, building plaster can be used. The plaster should be sprinkled on to an unrolled bandage that is **just damp** (so that the plaster adheres). The bandage can then be rolled up and used in a similar way to a commercially available plaster bandage.

Once set, a useful technique is to write, with broad marker pen, the details of the fracture on the plaster cast as a so-called 'fracture passport'. These details can include the date of the fracture, the date when the plaster was

applied, the intended date of removal, and even a sketch of the fracture configuration itself. This information can be invaluable for subsequent care, as notes and X-rays can easily be mislaid or lost.

Wedging of the plaster can be useful for improving reduction of the fracture.

### Traction

An alternative to splintage is traction. By exerting a pull along the axis of the injured bone, traction helps to effect reduction and maintain alignment. Traction can either represent a definitive mode of treatment and be maintained until bony union, or be temporary, being maintained only until the fracture is stable enough to be treated in a plaster cast. Several types of traction exist.

- **Skin traction:** Traction is exerted on the limb by means of a bandage (usually adhesive) applied around the limb.
- **Balanced traction:** Traction of the more distal part of the limb is maintained by reaction against a more proximal structure. The classic example is the Thomas' splint for femoral fractures, where the splint is braced against the ipsilateral ischial tuberosity.
- **Skeletal traction:** Traction is exerted by means of a pin inserted into bone distal to the fracture. An example is a traction pin inserted through the proximal tibia as treatment for a femoral fracture. In the paediatric context, care should be exercised to avoid growth plates when inserting the traction pins.

Traction methods of treatment are most applicable to fractures of the lower limb, but there are occasional circumstances in which these methods are used in the upper limb. One example is temporary skin traction for a supracondylar fracture of the humerus.

### External fixation

This involves stabilising the fracture by means of an external scaffold which is fixed to the bones proximal and distal to the fracture by means of threaded pins. It is relevant to unstable compound fractures, particularly those with extensive soft-tissue wounding. Several different types of fixator exist. The pins can be sited away from bone growth plates and the fracture reduced prior to the linking bar being tightened. Following application of the fixator, the pin tracks must be cleaned daily with saline in order to prevent the build-up of crust, infection of the track and secondary osteomyelitis. The fixator can remain in position until bony union occurs, or be replaced by a plaster cast once the fracture becomes stable enough to tolerate this and/or the soft-tissue wound heals.

A variant of external fixation is percutaneous K-wiring, usually used in conjunction with plaster casting. Particularly relevant to peri-articular fractures, this involves the insertion of smooth K-wires across the fracture line in order to prevent secondary displacement. The external ends of the wires should be bent to prevent migration. The wires can be removed once fracture stability permits, typically at 2–3 weeks. In the absence of K-wires, improvisation using long K-wires-type needles is possible.

### Internal fixation

This involves the use of screws, plates and other types of metalwork to rigidly hold the reduction of a fracture.

Although these techniques permit accurate stable reduction, there is an associated risk of infection of the fixation device. Thus, when considering this form of treatment, the following should be borne in mind:

- The fracture should warrant internal fixation, as opposed to splintage, traction or external fixation.
- There should be an adequate supply of the metalwork in a full range of sizes and the required instruments for their insertion. For a sustainable fracture treatment philosophy, **a constant supply of fixation devices needs to be available.**
- The surgeon should be trained in the application of the device and in the surgical approach necessary for it.
- The fixation devices and tools should be sterile and the level of asepsis in the operating theatre must be high.
- In some cases, intra-operative X-ray guidance (fluoroscopy) is necessary for accurate fixation.
- Intramedullary methods of fixation, popular in well-resourced countries for the fixation of adult long bone fractures, are rarely appropriate in paediatric cases, as they violate the epiphyseal plates, potentially resulting in growth disturbance.

The decision to use this method of fixation will be based on a risk-benefit analysis with consideration given to the fracture configuration, the age of the child, the operative resources available and the training of the surgeon involved.

### Ongoing fracture care

Once reduction and stabilisation of the fracture have occurred, ongoing care is required to monitor the progress of the fracture to union. The treating physician should document the treatment provided and estimate the duration of immobilisation needed. Where the provision of notes and X-rays is limited, one suggestion is to draw the fracture on the surface of the plaster cast along with the intended date of removal.

At initial follow-up, the quality of the plaster cast should be inspected and X-rays taken (where possible) to ensure that secondary displacement has not occurred. The overall duration of immobilisation required is dependent upon the age of the patient and the fracture configuration. Determination of bony union involves the removal of the plaster cast or external fixation device (after an appropriate time period during which union would have been predicted to occur) and the gentle stressing of the fracture site. The presence of persistent tenderness, swelling or abnormal movement all indicate that union has yet to occur. The extent of fracture callus on X-ray is also indicative of the state of union.

### Rehabilitation

Children rarely need dedicated physical therapy following fracture healing. They should be encouraged to move their joints through a full range of motion, and exercises should be prescribed to restore muscle bulk.

### Specific fractures

#### Femoral shaft

Closed femoral shaft fractures in children are usually best treated with traction, with the type dependent on the age of the child. Typically the duration required is 1 week per

year of age, but this can be shortened by transfer into a plaster hip spica once fracture stability permits.

- Age 0–2 years and weight under 12 kg: Gallows traction, thighs in 45-degree flexion and hips 30-degree abduction. Limb length inequality is seldom a problem as fracture does not shorten excessively. Shortening of up to 1.5 cm and angulation of up to 30 degrees is acceptable. Early spica casting is often possible. **This fracture is associated with non-accidental injury in 50–80% of cases at this age.**
- Age 2–10 years: Skin traction, either in the 90/90 position (hip and knee flexed to 90 degrees) or Perkins type (straight traction). Alternatively, especially in the older members of this group, skeletal traction through a distal femoral traction pin; again either in the 90/90 position or straight. Up to 2 cm of bayonet shortening can be tolerated with no adverse effects. Early spica casting can be used if the position is acceptable. With skin traction the weight used should not exceed 5 kg, but with skeletal traction up to 10% of body weight can be applied.
- Age 10–15 years: Skeletal traction, either in 90/90 position or straight. There is a much greater risk of shortening in this group, and less potential for subsequent growth acceleration and length equalisation.
- Above the age of 15 years, children can be treated as adults.

### Tibial shaft

Closed tibial shaft fractures in children are usually uncomplicated, and can be treated satisfactorily with closed reduction and long leg cast application.

- The cast should be applied with the knee in 5–10 degrees of flexion.
- In comparison to the femur there is less potential for overgrowth and thus it is important to maintain the fracture out to length, that is, to ensure that the length of the fractured limb is the same length as the uninjured side. Acceptable degrees of shortening are 5–10 mm in the 0–5 years age group, but aim for none in any older age group.
- Acceptable axial alignment is less than 10 degrees of recurvatum (where the apex of the fracture site points posteriorly) and less than 5 degrees of varus or valgus angulation.
- As union progresses it may be possible to convert the long leg cast to a patellar tendon bearing cast after 3 weeks.
- Undisplaced fractures in children aged 1–5 years can often be treated in below-knee casts or even below-knee plaster cylinders.

### Distal humeral

Supracondylar fractures of the humerus have the highest rate of complications and some of the poorest results of treatment of all paediatric fractures. They are also difficult to diagnose without an X-ray. The peak incidence is at the age of 6 or 7 years.

- The vast majority (98%) are extension type, featuring a posteriorly displaced distal part. Only 2% are flexion type, resulting from a fall on to the point of the elbow.
- A careful assessment of distal vascularity should be made. In fractures with posterolateral displacement, the medial humeral spike can tether the brachial artery.
- If distal pulses are absent, closed reduction should be

attempted. If this fails to restore pulses, immediate open reduction and surgical exploration of the brachial artery should be performed.

- In other displaced fractures with palpable distal pulses, closed reduction should be attempted, possibly combined with percutaneous pin fixation for unstable fractures.
- Acceptable reductions will have no more than 4 degrees of varus as determined by Baumann's angle on the antero-posterior radiograph. Additionally, the axis of the capitellum should be at 45 degrees to the humeral shaft.
- If an acceptable position is not obtained, this may be an indication for open reduction and percutaneous K-wire fixation.
- Alternatively, the limb can be placed on traction in extension. As the swelling subsides, it will become easier to effect a closed reduction (with or without K-wiring).
- Once reduced, an above-elbow plaster backslab should be applied with the elbow flexed. Flexion above 90 degrees will assist in maintaining the reduction of extension-type fractures, but care should be taken to ensure that distal pulses are maintained.
- Ideally, X-rays should be taken on a weekly basis to ensure that reduction is maintained. The plaster cast can be completed once swelling has resolved, and percutaneous wires can be removed after 3 weeks.
- The typical duration of immobilisation necessary for union is 4–5 weeks in the 0–5 years age group and 6–7 weeks in the 5–10 years age group.

### Forearm fractures

- Both types of bone paediatric forearm fractures typically result from the indirect violence of a fall on an outstretched hand. They may be greenstick or complete. If the periosteal sleeve is disrupted the fractures may be unstable.
- X-rays should include the wrist and elbow, as the integrity of the proximal and distal radio-ulnar joints needs to be determined.
- Be aware of the possibility of a Monteggia fracture, which consists of dislocation of the radial head along with fracture of the ulna.
- In contrast to adult forearm fractures, the majority of these injuries can be treated by closed reduction and plaster immobilisation.
- Up to the age of 9 years, acceptable reduction can be defined as anything less than 15 degrees of displacement and 45 degrees of malrotation.
- Above 9 years, at least bayonet apposition is required with less than 30 degrees of malrotation, less than 10 degrees angulation if the fracture is proximal or less than 15 degrees if it is distal.
- Immediately following fracture union, there may be a cosmetic deformity if the above reduction criteria are utilised, but this deformity should remodel if there is over 2 years of skeletal growth remaining.
- Following reduction, an assessment of forearm supination and pronation should be undertaken to ensure that there is no block.
- The arm should be immobilised in an above-elbow cast with the elbow flexed to 90 degrees. Opinion varies as to the position of the wrist in the cast. Some surgeons place the wrist in neutral supination/pronation for all fractures, others placing it in supination for proximal

third fractures, neutral for middle third and pronation for distal third.

- Follow-up X-rays should be taken at 1- and 2-week intervals following manipulation to ensure that secondary displacement has not occurred. If displacement does occur, re-manipulation can be attempted.
- Some very unstable fractures may prove difficult to treat by closed methods. These may benefit from intramedullary pinning (Rush pins) or cross K-wiring if facilities exist for this (**intra-operative fluoroscopy is required**).

#### Distal radial ('wrist') fractures

- Children's distal radial fractures are usually the result of a fall on the outstretched hand, and are rarely intra-articular.
- Common types include the following:
  - Galeazzi fracture (isolated fracture of the distal radius) implies associated disruption of the distal radio-ulnar joint.
  - Physeal fracture (pattern of injury described by the Salter-Harris classification)
  - Torus (buckling of the cortex on the compression side of the fracture without angulation).
  - Greenstick fracture (incomplete fracture).

- In children these fractures can almost always be treated with closed reduction and plaster immobilisation.
- The reduction manoeuvre is to hyperextend the wrist, followed by traction and 'hinging' of the distal fragment over the fracture site.
- Acceptable reduction can be defined as anything less than complete displacement and slight angulation. As in forearm fractures, cosmetic deformity should remodel if more than 2 years of skeletal growth remain.
- Check X-rays should be taken at 1 and 2 weeks post-reduction to exclude secondary displacement.
- The duration of immobilisation required depends upon the fracture configuration and the age of the child, but is typically 3–5 weeks.

#### Conclusions

- Most paediatric fractures can be treated by closed methods.
- Very often the periosteal sleeve will be intact, leading to enhanced fracture stability.
- Completely accurate reduction is not always necessary, as children's bones have the potential to remodel with continued skeletal growth.

## 7.3 Life-threatening trauma

### 7.3.A Structured approach to trauma in pregnancy and childhood

#### BOX 7.3.A.1 Minimum standards

- Triage.
- Structured approach: primary assessment and resuscitation, and then secondary assessment and emergency treatment.
- Availability of emergency surgery or safe transport system.
- Oxygen.
- Blood transfusion service.
- Chest drain.
- Analgesia.
- High-dependency care.
- Tetanus immunoglobulin and toxoid.
- Mannitol or hypertonic saline.
- Tranexamic acid.

#### Introduction

Most regions of the world are experiencing an epidemic of trauma, but the most serious increase has been in the resource-limited countries.

Proliferation of roads and increased use of vehicles have led to an increase in injuries and deaths, and many

peripheral medical facilities find themselves faced with multiple casualties from bus crashes or other disasters. Severe burns and drownings have always been more common in middle- and low-income countries.

There are a number of important differences between high- and low-income countries:

- use of open fires and kerosene stoves for cooking and heating
- unsafe water storage practices and unsupervised play in water courses, lakes and ponds by young children
- poor or absent flood defences, making poor people much more vulnerable to natural disasters
- poorly maintained road networks and vehicles, contributing to a higher injury rate per distance travelled in low-income countries
- the absence of a paramedic-manned emergency ambulance service to give life-saving medical care at the scene
- the great distances over which the injured may have to be transported, and therefore the time taken for them to reach medical care, thus losing the opportunity to prevent secondary damage caused by hypoxia and hypovolaemia
- the absence of appropriate equipment, supplies, and the

necessary knowledge and skills to manage the injured once they have arrived at a healthcare facility

- the absence of skilled people to operate and service equipment.

**Prevention of trauma is by far the best and most cost-effective way forward, but accident prevention has not yet had much impact in low-income countries.**

Trauma is the commonest cause of death in children over the age of 5 years in high-income countries, and it is increasing in absolute numbers as well as in ranking in low- and middle-income countries. In the World Health Organization (WHO) 2008 report 'World Report on Child Injury Prevention', the death rate in under 20 year olds from injury was 12.2 per 100 000 in high income countries while in low and middle income countries, the figure was 41.7 per 100 000.

Trauma is also a major cause of disability, especially following head injury, burns and drownings. In high-income countries, road accidents and falls predominate; in low-income countries road traffic accidents are increasing, but there has been no fall in the number of burns, falls and drownings.

Children are less likely than adults to suffer from serious penetrating injuries, although in cities where stabbings and shootings are common, or in armed conflict, such violence spills over into childhood. Intentional injury, in the form of child abuse, also contributes to a significant degree to childhood trauma (see Section 7.6).

The patterns of injury and the physiological consequences can be quite different in children compared with adults, reflecting their different size and shape, the elasticity of their body tissues, and the immaturity of their physiological systems.

The key principles of managing major trauma are to

**Treat the greatest threat to life first**

Do no further harm

AVOID: hypoxia, hypercapnia, hypovolaemia, hypoglycaemia and hypothermia

By following a structured approach, problems will be identified and managed in order of priority. The key steps are outlined in the primary assessment and resuscitation, enabling identification and treatment of life-threatening injuries. The secondary assessment identifies all other injuries, and provides emergency treatment for them.

Structured approach

- Primary assessment and resuscitation
- Secondary assessment and emergency treatment
- Definitive care

Primary assessment

- Airway and control of haemorrhage (and cervical spine control)
- Breathing
- Circulation and continued haemorrhage control

If there is more than one injured patient, then treat the patients in order of priority (see Section 1.10).

## Management of major trauma

**A team leader should be in overall charge of resuscitating a child or pregnant woman or girl who is suffering from major trauma.**

### Primary assessment and resuscitation

During the primary assessment, assess and resuscitate in sequence – Airway, Breathing and Circulation (ABC) – as these, if compromised, can be an immediate threat to life.

Although the patient may have obvious severe injuries, the clinician's first task is to prevent further deterioration of the patient's condition by ensuring that vital organs, especially the heart and the brain, are supplied with oxygenated blood by ensuring an open airway, adequate breathing and circulation. This is what is meant by **primary assessment and resuscitation**.

Although ABC management is described sequentially, if there are sufficient trained clinicians present, they can be managed at the same time. If there are limited personnel, the approach must be A then B then C. If there is only one trained person available, make use of untrained staff such as ward orderlies or relatives to perform tasks under your supervision. For example, if there is visible severe exsanguinating haemorrhage, once you have identified and controlled it, the ward orderly can continue to apply the pressure while you open the airway and give oxygen, etc. You will need to continually monitor the untrained person's actions to make sure that they are still effective.

**The first priority is establishment or maintenance of airway opening, and control of any obvious life-threatening haemorrhage.**

Primary Assessment and Resuscitation:

**Airway** and control of exsanguinating haemorrhage (plus cervical spine control, if appropriate)

**Breathing**

**Circulation**

**Stop visible external exsanguinating bleeding**, if any, by applying direct pressure. This bleeding will be from a superficial artery or large vein. Minor bleeding can be left until the vital ABC have been assessed and resuscitated. Internal bleeding will be dealt with first in 'C' by replacing fluid, and then, if necessary, by emergency surgery.

### Open and maintain the airway

We assess the airway patency by assessing its function, which is to allow air to pass through it into the lungs. If the airway is blocked, the lungs will not receive air.

The approach is similar to that used for managing any airway, in that you must:

LOOK for chest movement

- LISTEN for breath sounds
- FEEL for exhaled air
- Talk to the patient

If the patient is conscious, a rapid way to assess the airway is to ask them to speak, using the question 'Are you all right?'

A patient who can speak (or, in the case of a baby, who can cry) must have a clear airway.

If the patient is unconscious, airway obstruction is most commonly due to obstruction by the tongue.

The signs of airway obstruction may include:

- snoring or gurgling
- stridor or abnormal breath sounds
- agitation (hypoxia)
- using the accessory muscles of ventilation/paradoxical chest movements
- cyanosis.

### Cervical spine protection

In countries where there is no trained emergency ambulance service available to rescue trauma victims at the scene, the risk of an unstable cervical fracture causing permanent spinal cord damage, and subsequent paresis occurring before the patient is brought to medical attention, is high. Therefore any cervical fracture presenting to a medical facility after being brought in by passers-by is likely to be stable.

Fortunately, unstable cervical spinal fractures are relatively uncommon. They are more likely to occur as a result of very severe road traffic accidents or falls from a significant height.

**Protect the cervical spine with collar, sand bags and tape if the patient is likely to have an unstable cervical spine.**

Definitive treatment requires specialist surgery, and health services in many low-income countries may struggle to access the appropriate service for their population.

It is important to recognise that although protection of the cervical spine may occasionally be beneficial, the opening and maintaining of a clear airway benefits every patient and is an absolute priority.

### Cervical spine immobilisation

The cervical spine can be mobilised in three ways:

- 1 In-line stabilisation: the spine is held in the neutral position (the same as the airway position for an infant; see Section 1.12) by the clinician's hands on either side of the patient's head, ensuring that the ears are not covered, as the patient must be able to hear to be reassured and informed. This position must be held until the collar and/or blocks are in place.
- 2 A cervical collar can be placed around the neck. Before placing the collar, gently feel around the back of the patient's neck to ascertain if there is any midline tenderness and/or a 'step' indicating a fracture or if there is any bleeding. Collars are manufactured in several sizes to fit different sized patients. They are measured according to the manufacturer's instruction and then gently slid under the neck at the back. The shaped part is placed under the chin at the front, and the collar is fastened with the 'Velcro' tape fastening. This should leave the patient with a firmly held neck in a neutral position. The collar is used by itself in the combative patient, and in conjunction with blocks or sandbags in the unconscious or cooperative patient (i.e. one who will remain still).
- 3 Sandbags or blocks and tape are usually added after the collar has been fitted. They cannot be used in combative patients as their movements to free themselves will

cause more injury. They are essential in the unconscious patient who has a possibility of neck injury. These objects are placed on either side of the patient's head to prevent lateral movement, and held in place with two tapes, one across the patient's forehead and the other across the chin part of the cervical collar.

### Management of the airway

- **Head tilt/chin lift or jaw thrust.** Jaw thrust is recommended in trauma, as it does not require any neck movement. However, if a jaw thrust is unsuccessful, try chin lift with some head tilt. **A closed airway will always be potentially fatal, so the airway takes priority.**
- **Suction/removal of blood, vomit or a foreign body,** if any, but only under direct vision. Do not blindly suck in the mouth or pharynx.
- **If there is no improvement, place an oropharyngeal airway.** Avoid using a nasopharyngeal airway if base of skull injury is suspected.
- **If the airway is still obstructed, a definitive airway by intubation or surgical airway may be needed.**
- Identify the 'at-risk' airway:
  - Altered level of consciousness will fail to protect the airway.
  - Vomiting, with risk of aspiration, is a major risk in pregnancy.
  - Facial trauma, including burns, will continue to worsen as the tissues swell.

**Once the airway is open, give high-flow oxygen using a mask and reservoir.**

If the airway cannot be maintained and/or protected, consider the need for **advanced airway management.**

Indications for advanced techniques for securing the airway (intubation or surgical airway) include:

- persistent airway obstruction
- a conscious level of  $\leq 8$  on the Glasgow Coma Scale, or 'P' or 'U' on the AVPU scale (see below for both)
- penetrating neck trauma with haematoma (expanding)
- apnoea
- hypoxia
- severe head injury
- chest trauma
- maxillofacial injury.

Intubation techniques should ideally be performed by an experienced anaesthetist. A surgical airway is best performed by an ENT surgeon, but general surgeons will have been trained even if they are not experienced in the technique. The technique of emergency cricothyrotomy can be performed by any emergency clinician (see below).

For intubation, the following sequence should be followed:

- 1 Pre-oxygenation with 100% oxygen, with manual lung inflation if required.
- 2 Administration of a carefully judged, reduced dose of an anaesthetic induction agent.
- 3 Application of cricoid pressure.
- 4 Suxamethonium 1–2 mg/kg.
- 5 Intubation with a correctly sized tracheal tube.

### Confirmation of correct placement of the endotracheal tube

Signs such as chest movement and auscultation remain helpful, but are occasionally misleading, especially in inexperienced hands. The most reliable evidence is to see the tube pass through the vocal cords. The correct size is a tube that can be placed easily through the cords with only a small leak. Intubation of the right main bronchus is best avoided by carefully placing the tube only 2–3 cm below the cords, and noting the length at the teeth before checking by auscultation, which is best done in the left and right lower axillae. **Capnography (if available) is a useful adjunct to help to confirm correct tube placement.**

### Indications for surgical cricothyrotomy

- Inability to open or clear the airway, and the patient losing consciousness due to cerebral hypoxia (usually also cyanosed and bradycardic).
- Inability to ventilate the lungs despite high-level CPAP via a bag-valve-mask system and 100% oxygen through a reservoir attached to the bag.
- Inability to intubate through the larynx, either because this is not possible or due to lack of experience.

### Method

- 1 Place the patient in a supine position.
- 2 If there is no risk of neck injury, consider extending the neck to improve access. Otherwise, maintain a neutral alignment.
- 3 Identify the cricothyroid membrane (see Figure 7.3.A.1).
- 4 Prepare the skin, and, if the patient is conscious, infiltrate with local anaesthetic.
- 5 Place a hand on the neck to stabilise the cricothyroid membrane, and to protect the lateral vascular structures from injury.
- 6 Make a small vertical incision in the skin, and press the lateral edges of the incision outwards, to minimise bleeding.
- 7 Make a transverse incision through the cricothyroid membrane, being careful not to damage the cricoid cartilage.
- 8 Insert a tracheal spreader, or use the handle of the scalpel by inserting it through the incision and twisting it through 90 degrees to open the airway.
- 9 Insert an appropriately sized endotracheal or tracheostomy tube.
- 10 Ventilate the patient and check that this is effective.
- 11 Secure the tube to prevent dislodgement.

**FIGURE 7.3.A.1** Anatomy of neck, showing landmarks for surgical cricothyrotomy.

### Complications of surgical cricothyrotomy

These include the following:

- asphyxia
- aspiration (e.g. blood)
- laceration of the trachea
- laceration of the oesophagus
- haemorrhage or haematoma formation
- mediastinal emphysema
- subsequent glottic stenosis
- creation of a false passage into the tissues
- subsequent subglottic stenosis or oedema.

### Primary assessment and resuscitation: Breathing

After management of the airway, the patient's breathing should be assessed. The same approach is adopted as for the patient suffering a serious illness.

### Assessment of breathing

- Effort: recession, rate, added noises, accessory muscles, alar flaring.
- Efficacy: breath sounds, chest expansion, abdominal excursion.
- Adequacy: heart rate, skin colour (look for cyanosis), mental status.
- A pulse oximeter is very useful to monitor oxygenation adequacy (SaO<sub>2</sub>).

### Unequal breath sounds or poor oxygenation:

- Pneumothorax or haemothorax.
- Misplaced or blocked endotracheal tube.

**Looking** at the respiratory rate and chest expansion is essential. In addition to the signs listed above, check whether any of the following are present:

- penetrating injury
- presence of flail chest
- sucking chest wounds.

**Listen** for breath sound character and equality:

- pneumothorax (decreased breath sounds on site of injury)
- detection of abnormal sounds in the chest.

**Feel** for:

- tracheal shift (sign of tension pneumothorax on side away from the deviation)
- broken ribs
- subcutaneous emphysema.

**Percuss:**

- percussion is useful for diagnosis of **haemothorax** (dull on affected side) and **pneumothorax** (hyper-resonant on affected side).

### Continue giving high-flow oxygen (15 litres/minute) in all cases.

Careful examination of the trachea, neck veins and chest may indicate the presence of pleural collections of air or blood. Tension pneumothorax should be treated immediately with needle thoracocentesis in the second intercostal space in the mid-clavicular line.

**Needle thoracocentesis**

This procedure is used for the rapidly deteriorating patient who has a life-threatening tension pneumothorax. If it is used with a patient who does not have a tension pneumothorax, there is a 10–20% risk of producing a pneumothorax or causing damage to the lung, or both. In such cases immediate subsequent insertion of a chest drain is mandatory.

- 1 Identify the second intercostal space in the mid-clavicular line on the side of the pneumothorax (the **opposite** side to the direction of tracheal deviation, and the **same** side as the hyper-resonance).
- 2 Swab the chest wall with surgical prep or an alcohol swab.
- 3 Attach the syringe to the over-needle venous cannula.
- 4 Insert the cannula into the chest wall, just above the rib below, aspirating all the time.
- 5 If air is aspirated, remove the needle, leaving the plastic cannula in place. Alternatively, insert the over-needle venous cannula without a syringe and note a 'hiss' of air on relief of the tension pneumothorax when the metal stylet is removed from the plastic cannula.
- 6 Tape the open cannula in place and proceed to chest drain insertion as soon as possible.

**Complications of needle thoracocentesis**

- Local cellulitis.
- Local haematoma.
- Pleural infection.
- Empyema.
- Pneumothorax.

**Ventilation**

Provide assisted ventilation if needed to patients with breathing problems, using a bag and mask with a reservoir attached, or by intubation and intermittent positive pressure ventilation. **Do not persist with intubation attempts without oxygenating the patient.**

**Look for and treat the following:**

- airway obstruction (see above)
- tension pneumothorax
- open pneumothorax
- haemothorax
- flail chest
- cardiac tamponade.

See below for details.

**TABLE 7.3.A.1 Serious chest trauma: signs and treatment**

Breathing problem	Clinical signs	Treatment
Tension pneumothorax	<ul style="list-style-type: none"> <li>● Decreased air entry on side of pneumothorax</li> <li>● Decreased chest movement on side of pneumothorax</li> <li>● Hyper-resonance to percussion on side of pneumothorax</li> <li>● Tracheal deviation away from side of pneumothorax</li> <li>● Hypoxic shocked patient</li> <li>● Full neck veins</li> </ul>	High-flow oxygen Needle thoracocentesis Chest drain insertion
Open pneumothorax	<ul style="list-style-type: none"> <li>● Penetrating chest wound with signs of pneumothorax</li> <li>● Sucking or blowing chest wound</li> </ul>	High-flow oxygen Chest drain Wound occlusion on three sides
Massive haemothorax: blood in pleural space	<ul style="list-style-type: none"> <li>● Decreased chest movement</li> <li>● Decreased air entry</li> <li>● Dullness to percussion</li> <li>● Shock and hypoxia</li> <li>● Collapsed neck veins</li> </ul>	High-flow oxygen Venous access and IV volume replacement Chest drain (a haemothorax of 500–1500 mL that stops bleeding after insertion of an intercostal catheter can generally be treated by closed drainage alone; a haemothorax of greater than 1500–2000 mL, or with continued bleeding of more than 200–300 mL/hour, may be an indication for further investigation, such as thoracotomy)
Flail chest: paradoxical movement of a chest wall segment associated with underlying lung contusion	<ul style="list-style-type: none"> <li>● Rare in children because they have an elastic chest wall</li> <li>● Decreased efficiency of breathing</li> </ul>	Oxygen and pain relief May need intubation and ventilation Transfer if feasible
Cardiac tamponade: blood in pericardial sac causing a decrease in cardiac output	<ul style="list-style-type: none"> <li>● Shock associated with penetrating or blunt chest trauma</li> <li>● Faint apex beat and/or muffled heart sounds</li> <li>● Distended neck veins</li> </ul>	Oxygen IV access and IV fluids Emergency needle pericardiocentesis ( <i>see</i> Section 8.4.C: may need to be repeated) Consider transfer if feasible

## Primary assessment and resuscitation: Circulation

### Assessment of circulation

Circulatory assessment includes identification of actual and potential sources of blood loss. Closed fractures and bleeding into the chest, abdomen or pelvis may make it difficult to detect how much blood has been lost. The ability to estimate the percentage blood loss is helpful when planning resuscitation. Remember that a child's circulating blood volume is only 80 mL/kg, so is easily compromised. Blood volume in pregnancy is 100 mL/kg, or 5–7 litres.

TABLE 7.3.A.2 Blood loss in pregnancy

Sign	Percentage blood loss		
	< 25	25–40	> 40
Heart rate	slight increase	moderate increase	marked increase or bradycardia
Systolic BP	normal	normal	beginning to fall
Pulse volume	normal or decreased	seriously decreased	very seriously decreased
Skin*	cool, pale, sweaty	cool, mottled, sweaty	cool and sweaty
Respiratory rate	slight increase	moderate increase	sighing respirations
Mental status	slight agitation	lethargic or uncooperative	only reacts to pain

\* Capillary refill time > 3 seconds.

Note that blood pressure may be normal until up to 50% of the patient's circulatory volume has been lost. The blood pressure is initially well maintained despite continuing bleeding in children and pregnant women and girls. As an indicator of haemorrhage, it can be falsely reassuring. A progressively worsening tachycardia is a more revealing feature.

A monitoring device which records pulse rate, ECG trace and blood pressure is a very useful adjunct if available.

### Resuscitation of circulation

Management is focused on avoiding hypovolaemia and controlling blood loss.

#### Loss of blood is the most common cause of shock in major trauma.

Concealed bleeding severe enough to cause shock can occur into the pleural cavity, abdomen, pelvis and femur. Around 40% of the circulating blood volume can be lost via an open femoral fracture, wherein initial treatment should include pressure, splinting and analgesia.

### Stop bleeding

The first priority is to stop obvious bleeding by applying direct pressure. Do not forget that the patient may have a wound on their back that is bleeding into the bed. To examine the back, the patient should be log-rolled, if indicated.

- **Injuries to the limbs:** tourniquets do not work well and may cause reperfusion syndromes and add to the primary injury. The recommended procedure of 'pressure dressing' is an ill-defined entity. Severe bleeding from high-energy penetrating injuries and amputation wounds can be controlled by sub-fascial gauze pack

placement, plus manual compression on the proximal artery, plus a carefully applied compressive dressing of the entire injured limb.

- **Injuries to the chest:** the most common source of bleeding is chest wall arteries. Immediate placement of a chest tube drain plus intermittent suction plus efficient analgesia (IV ketamine is the drug of choice, if available) expand the lung and seal off the bleeding.

Recent evidence has shown that tranexamic acid can reduce mortality from major haemorrhage in major trauma in adults. It is also now recommended for use in children. The drug should be started as soon as possible, and within the first 3 hours after the trauma, to be effective.

### In pregnancy

The loading dose is 1 gram over 10 minutes followed by an IV infusion of a further 1 gram over 8 hours.

The slow IV bolus dose is given by injecting 1 gram of tranexamic acid into a 100-mL bag of 0.9% saline and letting it run through over about 10–20 minutes (the exact timing is not crucial).

The 8-hour infusion is given by injecting 1 gram of tranexamic acid into a 500-mL bag of 0.9% saline and giving it over 8 hours (approximately 60 mL/hour). If there is a gap between the initial bolus and the subsequent infusion this probably does not matter too much, but ideally one should follow the other.

### In children

The loading dose is 15 mg/kg (maximum 1 gram) diluted in a convenient volume of sodium chloride 0.9% or glucose 5% and given over 10 minutes.

The maintenance infusion rate is 2 mg/kg/hour. The suggested dilution is 500 mg in 500 mL of sodium chloride 0.9% or glucose 5% given at a rate of 2 mL/kg/hour for at least 8 hours, or until bleeding stops.

#### Elevate the legs if the patient is in shock.

### IV fluid resuscitation

The goal is to restore oxygen delivery to the tissues. As the usual problem is loss of blood, fluid resuscitation must be a priority.

- Adequate vascular access must be obtained. This requires the insertion of at least one, and ideally two, large-bore cannulae (14–16 G). Peripheral cut-down or intra-osseous infusion may be necessary.
- Infusion fluids: These should be warmed to body temperature if possible (e.g. pre-warm in a bucket of warmed water or under a relative's clothing). Remember that hypothermia can lead to abnormal blood clotting. Use crystalloids such as Ringer-lactate or Hartmann's solution. Normal (0.9%) saline can be used if these fluids are unavailable, but **be aware that, especially in larger volumes, normal saline causes a hyperchloraemic acidosis which is detrimental to sick or injured patients.**
- Avoid solutions containing ONLY glucose (e.g. 5% Dextrose in water or 5% Dextrose with 1/5N saline, these are dangerous in this situation) but glucose can be added to Ringer-lactate, Hartmann's or N saline if there is evidence of or concern about hypoglycaemia.
- Take blood for Hb, group and cross match and glucose, electrolytes and amylase for urgent analysis.

Not all cases of hypovolaemia require aggressive fluid therapy. In adults, withholding fluids in penetrating trunk trauma before achieving surgical haemostasis has been associated with an improved outcome. The rationale is to avoid pushing up the blood pressure, which hinders clot formation and promotes further bleeding. Aggressive crystalloid fluid replacement can lead to increased fluid requirements, hypothermia, dilution of clotting factors, excessive blood transfusion and its associated immunosuppression. Aim to give sufficient fluid to maintain vital organ perfusion. This can be monitored by monitoring the patient's state of alertness which is a measure of brain perfusion in the absence of a head injury.

On the other hand, in severe head injury, cerebral perfusion is critically dependent on maintaining blood pressure. If the patient has both a severe head injury and major trunk bleeding, the apparently conflicting requirements are best managed by maintaining priorities in ABC order and achieving prompt surgical haemostasis. Beyond this strategic conflict, it should be remembered that the normal blood pressure is lower in children, hypovolaemia mimics head injury, and blood pressure itself is a poor indicator of organ perfusion.

As outlined above, the concept of '**targeted fluid resuscitation**' is important if the cause of hypovolaemic shock is haemorrhage from penetrating injury. Here the initial boluses of IV crystalloids required to treat shock should only be given to keep the vital organs (especially the brain, heart and kidneys) perfused before emergency surgery and blood transfusion is available. Fresh blood is particularly useful to combat the coagulopathy that occurs in major blood loss if specific coagulation components such as platelets are unavailable.

However, it must be borne in mind that penetrating trauma is not common in women and children in civilian life.

We suggest that when giving boluses of crystalloid or blood to patients in shock **due to bleeding** in major trauma, only the amount needed to keep the blood pressure at a level sufficient to perfuse the vital organs should be given. There is no clear evidence to indicate the precise blood pressure that should be achieved in a pregnant woman or child in shock due to haemorrhage. Adequate perfusion of vital organs may best be indicated by **a radial pulse which can be palpated and an alert conscious level (in the patient without a significant head injury)**. **In pregnancy, the adequacy of the fetal heart rate may also be helpful.**

In children under 2–3 years of age, the radial pulse may be difficult to feel, and the presence of a palpable brachial pulse may be the best available indicator at present.

Therefore to maintain a palpable radial pulse in pregnancy, start with IV boluses of 500 mL of crystalloid or ideally blood, and reassess after each bolus.

In children, to maintain a radial or brachial pulse give 10 mL/kg IV boluses of crystalloid or, ideally, blood, and reassess after each bolus.

In the absence of further evidence, it is recommended that in children it is best to start with 10 mL/kg boluses (infusions given as rapidly as possible) of Ringer-lactate or Hartmann's solution or plasma expander with frequent reassessment, rather than the full 20 mL/kg recommended in other life-threatening situations, such as meningococcal sepsis or severe dehydration.

Fluid resuscitation in pregnancy starts with a 500-mL

bolus of Ringer-lactate or Hartmann's solution or plasma expander.

After repeating boluses twice (i.e. 10 mL/kg twice in a child, or 500 mL twice in pregnancy), the transfusion of blood (packed red cells) should be considered. The most important aspect of fluid resuscitation is **the patient's response to the fluid challenge**.

Improvement is indicated by the following:

- a decrease in heart rate
- an increase in systolic blood pressure
- an increase in skin temperature
- faster capillary refill
- improving mental state.

Failure to improve should prompt an urgent search for chest, abdominal or pelvic haemorrhage, with the immediate involvement of an experienced surgeon. Similar volumes may be repeated if there is continuing evidence of haemorrhagic shock, after re-evaluating the state of the circulation.

It is useful to delegate the initial fluid bolus to a member of the trauma team (if a team is available), who attaches the warmed fluid bag to the IV cannula via a three-way tap to which is attached a 20- or 50-mL syringe to give the boluses.

### Blood transfusion

There may be considerable difficulty in getting blood. Remember possible incompatibility, and hepatitis B and HIV risks, even among the patient's own family.

Blood transfusion must be considered when the patient has persistent haemodynamic instability despite fluid (colloid/crystalloid) infusion. If the type-specific or cross-matched blood is not available, type O negative packed red blood cells should be used. Transfusion should be seriously considered if the haemoglobin level is less than 7 grams/dL and if the patient is still bleeding. Blood transfusion is most important, and requires blood to be taken for urgent cross-matching.

**As described above, early surgical involvement is essential.**

### Vascular access

This is essential in all seriously injured patients. A minimum of two relatively large-bore IV cannulae is essential.

**TABLE 7.3.A.3** Infusion IV line flow rates

Colour code	Gauge	Crystalloid flow rate (mL/minute)
Brown	14	240
Grey	16	172
Yellow	17	130
Green	18	76
Pink	20	54
Blue	22	25
Lime green	24	14

Peripheral veins are preferable; the inexperienced should not attempt central venous cannulation. The external jugular vein can be accessed even in shock, but the cannula can become easily displaced and must be very carefully taped in place. A cut-down on the long saphenous vein at the ankle can also be used. If venous access is difficult and is

taking too long, the new intra-osseous EZ-IO drill is simple to operate and can be life-saving (see Section 8.4.C), and **should be available in all emergency departments.**

Central venous cannulation can permit large volumes to be rapidly infused and also permit central venous pressure measurements. It must be undertaken by a skilled person (e.g. an anaesthetist), and a Seldinger technique should be used. The femoral vein is used for children, but not for pregnant women where the internal jugular or subclavian vein may be used. Peripheral venous access can often be established once peripheral perfusion has been improved. Both femoral venous and tibial intra-osseous access are best avoided if there is clinical evidence of a pelvic or abdominal injury. In such cases it is better to secure vascular access above the diaphragm. The upper outer aspect of the humerus can be used for intra-osseous access in that case (see Section 8.4.C).

Blood from a vein or bone marrow should be drawn for typing and cross-matching, haemoglobin, glucose and electrolytes. These tests are clinically accurate on a marrow sample from an intra-osseous approach provided there has not been prior infusion of blood or crystalloid fluid. The infused fluids should be warm. Physiological coagulation works best at normothermia, and haemostasis is difficult at core temperatures below 35°C. Hypothermia in trauma patients is common during protracted improvised outdoor evacuations, even in the tropics. It is easy to cool a patient but difficult to rewarm them, so prevention of hypothermia is essential. IV fluids should have a temperature of 40–42°C (using IV fluids at ‘room temperature’ means cooling!).

### Venous cut-down

#### Anatomical considerations

In adults the primary site for cut-down is over the long saphenous vein above the ankle at a point approximately 2 cm anterior and 2 cm superior to the medial malleolus, **but not if there is significant injury proximal to this site.**

Identify the surface landmarks. These are shown in Table 7.3.A.4.

**TABLE 7.3.A.4** Surface landmarks for cut-down incision

	Saphenous
Infant	Half a finger's breadth superior and anterior to the medial malleolus
Small children	One finger's breadth superior and anterior to the medial malleolus
Older children and pregnant mothers	Two finger breadths superior and anterior to the medial malleolus

- Apply a venous tourniquet proximal to the intended cannulation site.
- Prepare the skin with antiseptic and sterile drapes.
- Infiltrate the area with local anaesthetic (1% lignocaine using a fine 24–25G needle).
- Make a full-thickness transverse incision through the skin.
- By blunt dissection, identify and display the vein.
- Free the vein from its bed and elevate a 2 cm length.
- Pass a dissolvable suture around the proximal end of the vein but do not tie it yet.
- Introduce the plastic cannula (with trocar) through the

venotomy, remove the trocar and secure it in place by tying the proximal ligature.

- Attach the giving set and commence flow at the required rate.
- If possible, close the incision; otherwise apply a sterile dressing and secure the giving set tubing in place.

See also Section 8.4.C.

#### Complications

- Haemorrhage or haematoma.
- Perforation of the posterior wall of the vein.
- Nerve transection.
- Phlebitis.
- Venous thrombosis.

### External jugular venous cannulation

#### Procedure

Place the patient in a head-down position to dilate the vein and reduce the risk of air embolus.

- 1 Place the patient in a 15–30-degree head-down position (or with padding under the shoulders so that the head hangs lower than the shoulders).
- 2 Turn the head away from the site of puncture.
- 3 Clean the skin over the appropriate side of the neck.
- 4 Identify the external jugular vein, which can be seen passing over the sternocleidomastoid muscle at the junction of its middle and lower thirds.
- 5 Have an assistant place their finger at the lower end of the visible part of the vein just above the clavicle. This stabilises it and compresses it so that it remains distended.
- 6 Puncture the skin and enter the vein.
- 7 When free flow of blood is obtained, ensure that no air bubbles are present in the tubing and then attach a giving set.
- 8 Tape the cannula securely in position.

### Other less common causes of shock in major trauma

#### Cardiogenic shock

Inadequate heart function may result from:

- myocardial contusion (bruising)
- cardiac tamponade
- tension pneumothorax (preventing blood from returning to the heart)
- myocardial infarction.

Assessment of the jugular venous pressure is essential in these circumstances. It will be elevated compared with hypovolaemic shock, where it may not be visible.

An ECG should be recorded (if available).

#### Neurogenic shock

This is due to the loss of sympathetic tone, usually resulting from spinal cord injury, with the classical presentation of hypotension without reflex tachycardia or skin vasoconstriction.

#### Tension pneumothorax

See under breathing section above. This can present with shock as well as breathing impairment.

### Primary assessment: neurological failure

#### Head injury is the major cause of death in trauma.

Rapid assessment of the central nervous system for evidence of failure includes determining the AVPU score: AVPU score: A = Alert, V = responds to a Voice, P = response to Pain, U = Unresponsive.

- With a score of 'P' or 'U', intubation should take place in order to maintain and protect the airway. If there is no one skilled in intubation available, the patient should be placed in the recovery position.
- Remember to check for a pain response above the level of the clavicle, as a patient with a spinal injury may not be able to respond by moving their limbs.
- Look for signs indicative of injury (e.g. bruises, lacerations or haematoma) in the head and neck area.
- Examine the pupils for size, equality and reaction to light. Look for other lateralising signs, such as limb weakness or focal seizures.

At this stage, the brain is best cared for by close attention to managing A B and C, and by correction of any hypoglycaemia.

If there is evidence of raised intracranial pressure (RICP):

- Intubate and ventilate to maintain oxygenation, and aim for a pCO<sub>2</sub> of about 4 kPa.
- Maintain systolic blood pressure.

- Nurse the patient in a 30-degree head-up position.
- Contact a neurosurgeon (if available).

Mannitol 0.5 mg/kg should be administered after first excluding intracranial haematoma. If this is not excluded, there will be temporary improvement due to relief of cerebral oedema, but there may be sudden worsening a short time later due to rapid expansion of the haematoma. An alternative is hypertonic saline (see Section 7.3.C).

**Low blood glucose levels are common in child trauma victims, and can cause brain damage. Always check the blood glucose level where possible. If it is not possible to check it, treat any baby or small child immediately with 5 mL/kg of 10% glucose IV.**

**Analgesia in major trauma** (see Section 1.15)

Pain increases fear and distress, makes the patient less able to cooperate, and raises intracranial pressure. If the patient is fully conscious and in severe pain, control of pain is required.

Pain relief takes several different forms:

- Reassurance.
- Splinting of fractures.
- Covering wounds, especially burns.
- Drugs:
  - There is no place for oral or IM medication in a major trauma situation.
  - There are three alternatives in severe trauma: ketamine, morphine and Entonox.

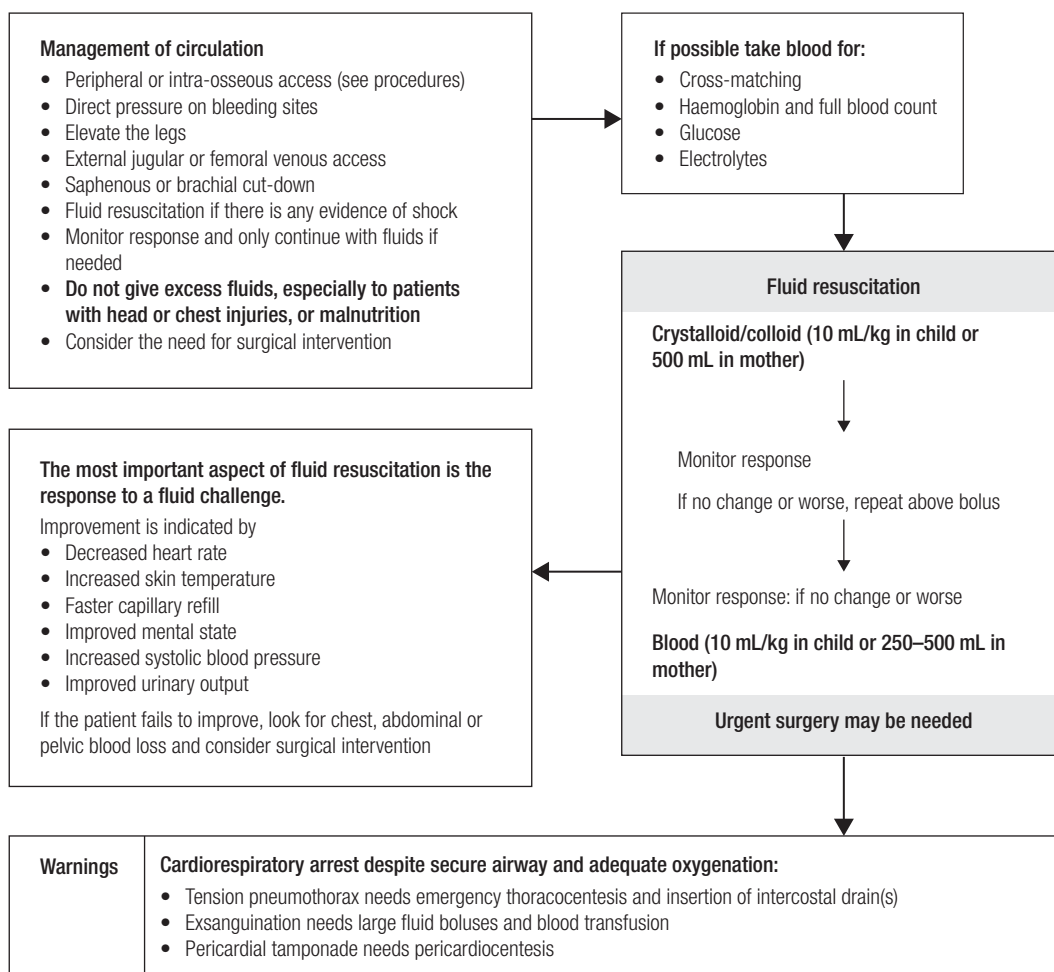

FIGURE 7.3.A.2 Managing the circulation in major trauma.

### Ketamine

The positive inotropic effects of ketamine, and the fact that it does not affect the gag reflex, make this a very helpful analgesic, especially if there is or has been shock. Repeated IV doses of 200 micrograms/kg followed by careful reassessment are usually effective, especially during transfer to a more specialised hospital (if available and relevant).

### Morphine

In major trauma, 100–200 micrograms/kg morphine IV in a child, or 5–10mg in a mother, is the drug of choice, followed by careful reassessment. If the conscious level falls, the effect can be reversed with naloxone, showing whether the effect is caused by the morphine or by a worsening brain injury. If there is respiratory depression, first ventilate with a bag-valve-mask before giving naloxone.

### Entonox

Entonox (a 50:50 mixture of nitrous oxide and oxygen) is useful, especially for limb injuries while splints are being applied. Do not use it in the presence of head, chest or abdominal trauma.

**A head injury is NOT a contraindication to giving morphine unless there is depressed consciousness, when great care is needed.**

## Summary of primary assessment and resuscitation

#### The injured patient should have:

- a team approach with an urgent call for surgical and anaesthetic availability
- a clear airway and 100% oxygen for breathing
- adequate respiration, achieved by manual or mechanical ventilation and chest decompression when indicated
- venous access and an initial fluid challenge, if indicated on circulatory assessment
- blood sent for typing and cross-matching
- identification of the need for life-saving surgery and preparation under way
- identification of any serious head injury, and attention paid to maximising A, B and C
- cervical spine immobilisation, where appropriate

#### Life-threatening injuries identified and treated

Injury	Treatment
Airway obstruction	Head tilt, chin lift and jaw thrust, oropharyngeal airway, intubation or surgical airway
Tension pneumothorax	Needle thoracocentesis and chest drain
Open pneumothorax	Three-sided dressing, then chest drain
Massive haemothorax	IV access, chest drain and blood transfusion
Flail chest	Intubation if needed
Cardiac tamponade	Pericardiocentesis

Before the secondary assessment begins, it should be remembered that:

**ABC and neurological failure components of the primary assessment and resuscitation require constant re-evaluation, as deterioration can be rapid and unexpected.**

**Emergency operative treatment to control life-threatening haemorrhage should be performed promptly, without waiting for non-urgent examination and imaging.**

Identification of all anatomical injuries remains an important goal, but may be overridden by pressing physiological requirements to ensure that oxygenated blood reaches vital organs in sufficient degree. This may require emergency surgery before all non-life-threatening injuries have been identified.

## Secondary assessment and emergency treatment

Secondary assessment and emergency treatment are undertaken only when the patient's ABC's are stable. **If any deterioration occurs during this phase, secondary assessment must be interrupted by another primary assessment and resuscitation.**

Documentation is required for all procedures undertaken. This involves careful examination from head to toe in a systematic way, including a **controlled examination of the back, avoiding spinal movement** by log-rolling (see Section 8.5). Clear documentation of all injuries is required, to serve as the basis of the subsequent management strategy.

Shortly after the primary assessment and resuscitation, various adjuncts help with protecting the patient and monitoring progress.

#### Secondary assessment: adjuncts

- Monitoring ECG, SaO<sub>2</sub> and blood pressure
- Urinary and gastric catheters
- Portable X-rays of chest and pelvis
- Ultrasound of abdomen (if available)
- Adequate pain control (see below)
- Baseline blood tests (especially haemoglobin, cross-matching, biochemistry and clotting)

#### History

- Events before and after incident
- First aid given at scene
- Past medical history
- Medications and allergies
- Immunisation status
- Last food and drink

Adjuncts to the secondary assessment and emergency treatment include:

- ECG, oxygen saturation and blood pressure monitoring (as used in primary assessment and resuscitation).
- Gastric and urinary catheters.
- **Portable** X-rays of the chest, neck and pelvis.

### Head examination

This includes the following:

- scalp and ocular abnormalities
- external ear and tympanic membrane
- periorbital soft-tissue injuries.

**Head injury patients should be suspected of having cervical spine injury until demonstrated otherwise.**

### **Neck examination**

This includes the following:

- looking for a penetrating wound
- subcutaneous emphysema
- tracheal deviation
- neck vein appearance (JVP).

### **Neurological examination**

This includes the following:

- brain function assessment using the AVPU Scale or the Glasgow Coma Scale (GCS)
- spinal cord motor activity
- sensation and reflex.

### **Chest examination**

This includes the following:

- the clavicles and all ribs
- breath sounds and heart sounds
- ECG monitoring (if available).

### **Abdominal examination**

This includes the following:

- look for a penetrating wound of the abdomen requiring surgical exploration
- look for blunt trauma; a nasogastric tube is inserted (but not in the presence of facial trauma)
- rectal examination (but not in children unless absolutely essential)
- insertion of urinary catheter except in children (check for meatal blood before insertion).

### **Examination of pelvis and limbs**

This includes the following:

- pain, tenderness on palpation
- deformity
- wounds.

### **X-rays (if possible and where indicated)**

These include the following:

- chest X-ray and cervical spine films (it is important to see all seven vertebrae)
- pelvic and long bone X-rays
- skull X-rays may be useful to search for fractures when head injury is present without focal neurological deficit if CT is unavailable
- CT scans of the head and abdomen (if available).

## **Head injury**

This remains the commonest cause of death and disability in severe trauma in children, and is dealt with in more detail elsewhere (see Section 7.3.C). The scalp and face are examined for bruising, abrasions, lacerations and evidence of fracture.

Basal skull fracture is manifested by signs such as:

- 'raccoon eyes' (bilateral peri-orbital haematoma), bleeding from the ears or a visible haemotympanum
- Battle's sign (bruising over the mastoid process, which is a relatively late sign)
- CSF leakage from the nose, mouth or ears.

The AVPU Scale score or the Glasgow Coma Scale score is again evaluated (see Section 7.3.C), allowing a dynamic comparison with the primary assessment estimation, unless the child is now intubated and sedated.

As infants and small children are prone to hypoglycaemia, it is important to consider this as a potential cause of altered consciousness (see Section 5.8.B).

Delay in the early assessment of head-injured patients can have devastating consequences in terms of survival and patient outcome. Hypoxia and hypotension double the mortality of head-injured patients.

The following conditions are potentially life-threatening but difficult to treat in district hospitals. It is important to treat what you can with the expertise and resources that you have available, and to triage casualties carefully.

Immediate recognition and early management of the following conditions are essential:

### **Acute extradural haemorrhage**

Classical signs consist of:

- loss of consciousness following a lucid interval, with rapid deterioration
- a rapid rise in intracranial pressure, due to bleeding from the middle meningeal artery
- development of hemiparesis on the opposite side, with a fixed pupil on the same side as the impact area.

The management is surgical, and every effort should be made to do burr-hole decompressions.

### **Acute subdural haematoma**

There is bleeding with clotted blood in the subdural space, accompanied by severe contusion of the underlying brain. This condition results from tearing of bridging veins between the cortex and the dura. Again, surgery is needed, but it requires a neurosurgeon, not burr-holes alone.

The following conditions should be treated with more conservative medical management, as neurosurgery does not usually improve the outcome:

- base-of-skull fractures
- cerebral concussion, with temporarily altered consciousness
- depressed skull fracture: an impaction of fragmented skull that may result in penetration of the underlying dura and brain
- intracerebral haematoma, which may result from acute injury or progressive damage secondary to contusion
- in children, diffuse brain swelling is a more frequent problem than bleeding; again this is managed medically, but apart from ventilation and general supportive therapy, recovery is dependent on the severity of the injury and the effect of the initial physiological support of ABC.

### **Alteration of consciousness is the hallmark of brain injury.**

The most common errors in head injury evaluation and resuscitation are:

- failure to perform ABC and prioritise management
- failure to look beyond the obvious head injury
- failure to assess the baseline neurological examination
- failure to re-evaluate the patient who deteriorates.

## Management of head trauma

The Airway, Breathing and Circulation are stabilised (and the cervical spine immobilised, if possible).

Vital signs are important indicators of the patient's neurological status, and must be monitored and recorded frequently.

The Glasgow Coma Scale (GCS) score is interpreted as follows:

- severe head injury: GCS score is  $\leq 8$
- moderate head injury: GCS score is 9–12
- minor head injury: GCS score is 13–15.

### Remember:

- Deterioration may occur due to bleeding or brain swelling.
- Unequal or dilated pupils may reflect an increase in intracranial pressure.
- Head or brain injury is never the cause of hypotension in the adult trauma patient.
- Sedation should be avoided, as it decreases the level of consciousness, and promotes hypercarbia due to slow breathing with retention of  $\text{CO}_2$ .
- The Cushing response is a late sign, reflecting a lethal rise in intracranial pressure, associated with a poor prognosis. The hallmarks of the Cushing response are:
  - bradycardia
  - hypertension
  - decreased and erratic respiration.

Basic medical management for severe head injuries includes:

- Intubation and ventilation, producing normocapnia ( $\text{pCO}_2$  in the range 4.5–5 kPa, if it is possible to monitor this). This will reduce both intracranial blood volume and intracranial pressure temporarily.
- Sedation with possible paralysis provided that the airway is fully protected by intubation and a means of assisted ventilation present.
- Moderate IV fluid input with diuresis: do not overload.
- Nursing with the head up at an angle of 20 degrees.
- Prevention of hyperthermia/fever.
- Avoidance of hypoglycaemia and electrolyte abnormalities.

## Chest trauma

The majority of chest injuries result from blunt trauma, and are usually associated with injuries in other organ systems.

Approximately 25% of deaths due to trauma are attributed to chest injury. Immediate deaths are essentially due to major disruption of the heart or of the great vessels. Early deaths due to chest trauma include airway obstruction, tension pneumothorax, cardiac tamponade or aspiration.

The majority of patients with thoracic trauma can be managed by simple manoeuvres and do not require surgical treatment.

Respiratory distress may be caused by:

- rib fractures/flail chest
- pneumothorax
- tension pneumothorax
- haemothorax
- pulmonary contusion (bruising)
- open pneumothorax
- aspiration.

Haemorrhagic shock may be due to:

- haemothorax
- haemomediastinum.

The increased compliance of the chest wall in the child is protective, but can make interpretation of the severity of injury difficult. Rib fractures are uncommon in the infant or child, but indicate that significant blunt force has been applied. Moreover, serious chest injury can occur without obvious external signs of trauma. The energy that is not dissipated in breaking the elastic ribs may be transferred to the lungs, to be manifested as pulmonary contusion. Respiratory failure can occur quickly in infants and young children with chest trauma, yet the majority of chest injuries require no more than the insertion of an intercostal drain.

- Thorough re-examination of the chest front and back, using the classical **inspection–palpation–percussion–auscultation approach**, is combined with a chest X-ray.
- Particular attention is directed to the symmetry of chest movement and breath sounds, the presence of surgical emphysema and pain, or instability on compressing the chest.
- Tracheal deviation and altered heart sounds are noted.
- On log-rolling the child, **it is important to reconsider flail chest**, as a posterior floating segment is often poorly tolerated in children.

### Rib fractures

Fractured ribs may occur at the point of impact, and damage to the underlying lung may produce lung bruising or puncture. The ribs usually become fairly stable within 10 days to 2 weeks. Firm healing with callus formation is seen after about 6 weeks.

### Flail chest

The unstable segment moves separately and in an opposite direction from the rest of the thoracic cage during the respiration cycle. Severe respiratory distress may ensue. Treatment is by analgesia, as breathing is painful, and shallow breathing may predispose to pneumonia in this situation. In severe cases, ventilation is needed in children but not usually in adults.

### Pneumothorax

- A **tension pneumothorax** develops when air enters the pleural space but cannot leave, increasing the compression of the underlying lung with each breath. The consequence is progressively increasing intra-thoracic pressure in the affected side, resulting in mediastinal shift. The trachea may be displaced (late sign) and is pushed away from the midline by the air under tension. The patient will become short of breath and hypoxic. Urgent needle decompression (thoracocentesis) is required prior to the insertion of an intercostal drain.
- A **simple pneumothorax** can be diagnosed by X-ray or ultrasound scanning and, although not life-threatening, may be associated with significant underlying lung injury. All traumatic pneumothoraces **require close observation**. Small ones often absorb spontaneously, but larger ones frequently require chest drainage.
- **Open pneumothoraces**, or sucking chest wounds, allow bidirectional flow of air through a chest wall defect. The lung on the affected side is exposed to atmospheric pressure with lung collapse and a shift of the

mediastinum to the uninvolved side. This must be treated rapidly. In compromised patients, intercostal drains, intubation and positive pressure ventilation are often required. Alternatively, they can be treated by applying an occlusive dressing, taped on three sides to serve as a flap valve, followed by insertion of a chest drain remote from the site of injury. A better dressing is the customised Asherman chest seal, which consists of an adhesive ring, similar to that on a colostomy stoma bag, which projects into a pipe-shaped flap valve, resembling that in a Heimlich valve. **Beware of the possibility of a tension pneumothorax developing when one of these is used.**

### **Pulmonary contusion**

This is usually caused by blunt trauma, and may occur in association with rib fractures with or without a flail segment. It is common after chest trauma, and is a potentially life-threatening condition. The onset of symptoms may be slow, progressing over 24 hours post-injury. Pulmonary contusion is likely to occur in cases of high-speed accidents, falls from great heights, and injuries by high-velocity bullets.

Symptoms and signs include:

- dyspnoea
- cyanosis
- sparse or absent breath sounds
- hypoxaemia
- tachycardia.

Treatment involves supplemental oxygen, careful fluid management and particular attention to pain relief. Endotracheal intubation may be necessary in severe cases.

### **Traumatic haemothorax**

This is more common in penetrating than in non-penetrating injuries to the chest. If the haemorrhage is severe, hypovolaemic shock will occur, and also respiratory distress due to compression of the lung on the involved side.

Optimal therapy consists of the placement of a large chest tube and the concomitant replacement of lost blood. In some instances where the bleeding continues and is significant, open chest surgery is necessary to stop the bleeding (see below).

- A haemothorax of 500–1500 mL in pregnancy, or 10–30 mL/kg in a child, that stops bleeding after insertion of an intercostal catheter, can generally be treated by closed drainage alone
- A haemothorax of greater than 1500–2000 mL in pregnancy, or > 30 mL/kg in a child, with continued bleeding of more than 200–300 mL per hour in pregnancy or > 5 mL/kg per hour in a child, is an indication for further investigation e.g. thoracotomy.

The injuries listed below are also possible in severe trauma, but carry a high mortality even in regional centres.

- 1 **Myocardial contusion:** This is associated, in blunt chest trauma, with fractures of the sternum or ribs. The diagnosis is supported by abnormalities on ECG and elevation of serial cardiac enzymes (if available). Cardiac contusion can simulate a myocardial infarction. The patient must be closely observed, with cardiac monitoring (if available). This type of injury is more common than is often realised, and may be a cause of sudden death some time after the accident.

- 2 **Pericardial tamponade:** Penetrating cardiac injuries are a leading cause of death in young men in some notorious urban areas, but rare in other settings. It is rare to have pericardial tamponade with blunt trauma. Pericardiocentesis must be undertaken early if this injury is considered likely (see Section 8.4.B for method). Look for pericardial tamponade in patients with:

- shock
- distended neck veins
- no pneumothorax
- muffled heart sounds.

- 3 **Thoracic great vessel injuries:** Injury to the pulmonary veins and arteries is often fatal, and is one of the major causes of on-site death.

- 4 **Rupture of the trachea or major bronchi:** This is a serious injury with an overall estimated mortality of at least 50%. The majority (80%) of the ruptures of bronchi are within 2.5 cm of the carina.

The usual signs of tracheobronchial disruption are:

- haemoptysis
- dyspnoea
- subcutaneous and mediastinal emphysema
- occasionally cyanosis.

### **Trauma to the oesophagus**

This is rare in patients with blunt trauma, and more frequent in association with penetrating injury. It is lethal if unrecognised, because of mediastinitis. Patients often complain of sudden sharp pain in the epigastrium and chest, with radiation to the back. Dyspnoea, cyanosis and shock occur, but these may be late features. Urgent IV broad-spectrum antibiotics covering both aerobic and anaerobic organisms, as well as nil-by-mouth nursing, are required.

### **Diaphragmatic injuries**

These may occur in association with either blunt or penetrating chest trauma, paralleling the rise in frequency of road traffic accidents. The diagnosis is often missed.

Diaphragmatic injuries should be suspected in any penetrating thoracic wound which is:

- below the fourth intercostal space anteriorly
- below the sixth interspace laterally
- below the eighth interspace posteriorly.

These injuries are more commonly seen on the left side.

### **Thoracic aorta rupture**

This occurs in patients who are exposed to severe decelerating forces, such as high-speed car accidents or a fall from a great height. It has a very high mortality due to rapid exsanguination; the total adult blood volume of 5 litres may be lost in the first minute following injury.

### **Abdominal trauma**

Abdominal injuries are common and, if unrecognised, may prove fatal. Any patient involved in any serious accident should be considered to have an abdominal injury until it has been ruled out.

Severe visceral injuries occur more frequently in children than in adults especially to the liver because of its relative size and lack of protection by the ribs in the young child.

Unexplained blood loss evident during the primary assessment may be due to intra-abdominal haemorrhage.

**The abdomen is a classical silent area after trauma. It has to be actively cleared of injury rather than simply noted to be soft and non-tender, especially in the face of altered consciousness.**

Cardiovascular decompensation may occur late and precipitously.

The organ most commonly injured in penetrating trauma is the liver, and in blunt trauma the spleen is often torn and ruptured. This is especially the case in children, in whom these organs are poorly protected by ribs and muscles, and especially where chronic illness may cause enlargement and fragility of the liver and spleen.

Thorough history taking and a careful examination of the abdomen may give clues to the origin of bleeding or perforation.

Gastric distension may cause respiratory embarrassment, and a gastric tube should be placed.

In order to gain the cooperation of a frightened child, place the examiner's hand over the mother's hand to undertake palpation.

There are two basic categories of abdominal trauma:

- 1 **Penetrating trauma**, where the need for surgical consultation is urgent. For example:
  - gunshot
  - stabbing.
- 2 **Non-penetrating trauma**. For example:
  - compression injuries
  - crushing injuries
  - seat-belt injuries
  - acceleration/deceleration injuries.

About 20% of trauma patients with acute haemoperitoneum have no signs of peritoneal irritation at the first examination, and **repeated primary assessment** must be undertaken.

Blunt trauma can be very difficult to evaluate, especially in the unconscious patient. These patients may need a peritoneal lavage although where ultrasound and/or abdominal CT is available, peritoneal lavage has been superseded. However, an exploratory laparotomy may be the best definitive procedure if abdominal injury needs to be excluded.

Complete physical examination of the abdomen includes rectal examination (although this should be avoided in children as a routine, and only performed if clinically indicated), assessing:

- sphincter tone
- integrity of the rectal wall
- blood in the rectum
- prostate position in adults.

Remember to check for blood at the external urethral meatus.

Women and girls of childbearing age should be considered pregnant until pregnancy has been excluded. The fetus may be salvageable, and the best treatment of the fetus is resuscitation of the mother. A pregnant mother at term, however, can usually be resuscitated properly only after delivery of the baby. This difficult situation must be assessed at the time (see Section 1.13).

The diagnostic peritoneal lavage (DPL) may be helpful for determining the presence of blood or enteric fluid due to intra-abdominal injury. The results can be highly suggestive,

but it is overstated as an important diagnostic tool. If there is any doubt, a laparotomy is still the gold standard.

The indications for DPL include:

- unexplained abdominal pain
- trauma of the lower part of the chest
- hypotension, and a fall in haematocrit with no obvious explanation
- any patient with abdominal trauma who has an altered mental state
- any patient with abdominal trauma and spinal cord injuries
- pelvic fractures.

The relative contraindications to DPL are:

- pregnancy
- previous abdominal surgery
- operator inexperience
- if the result would not change your management (e.g. if laparotomy is planned).

### **Other specific issues with regard to abdominal trauma**

- **Pelvic fractures** are often complicated by massive haemorrhage and urological injury.
- It is important to examine the rectum for the presence of blood and for evidence of rectal or perineal laceration (see above for the approach in children).
- X-ray of the pelvis may be valuable, if clinical diagnosis is difficult.

The management of pelvic fractures includes:

- resuscitation (ABC)
- transfusion
- immobilisation and assessment for surgery
- analgesia.

In a severely injured child, a urinary catheter should be inserted. This may be omitted in small babies and in less severely injured children. Small boys are particularly prone to urethral stricture after catheterisation. If the mechanism of injury is of concern, it is important to exclude renal tract injury by examining the first urine for red blood cells.

## **Management of severe abdominal injury**

Abdominal ultrasound (and CT scanning, if available) have become invaluable adjuncts to the secondary assessment, not only for diagnosing intra-abdominal injury, but also for monitoring progress when a defined injury is being managed conservatively.

Bleeding from solid organs may not show up immediately in the resuscitation room, and evidence of hollow-organ rupture may take 24 hours or more to show as free fluid on ultrasound. This commits the trauma team to a high index of suspicion well beyond the classical 'golden hour'. This phrase indicates the importance of prompt identification and resuscitation of Airway, Breathing or Circulation problems that, without intervention, would lead to further damage from hypoxia and hypovolaemia being suffered by the injured patient.

**Patients with refractory shock, penetrating injuries or signs of perforation require laparotomy.**

Other injuries may be managed conservatively. After

initial fluid transfusion, an experienced surgeon may decide that bleeding from an injured spleen, liver or kidney does not require immediate operative intervention. **CT scanning (if available) is an invaluable aid to decision making.**

**Splenic injury** is relatively common, and can occur after relatively minor trauma, especially if the spleen is enlarged following an inflammatory process or infection, notably malaria. Signs include left upper quadrant pain and tenderness, with referred pain to the shoulder tip. Non-operative management is used frequently in many centres, but long-term problems of splenectomy are insignificant by comparison with the potential consequences of inadequate supervision of conservative management which requires careful monitoring and fluid management with on-site, round-the-clock theatre, anaesthetic and surgical availability: all of which are difficult to provide in a low resource setting.

Increasingly, **liver injuries** are also being managed conservatively. Unlike the relatively straightforward operation of splenectomy, operative liver repair or resection is hazardous, and packing plays a major role in the operative management of uncontrolled hepatic bleeding.

**Injuries to the retroperitoneal organs**, such as the kidneys or pancreas, may present with vague or atypical signs, again requiring a high index of suspicion. A significant kidney injury does not always cause demonstrable haematuria.

Ultrasound studies and dynamic contrast CT scans (if available) may provide valuable information on renal structure and function, but false-negative results commonly occur. Intravenous urography remains useful for demonstrating the details of renal and ureteric injury, especially in centres without a CT scanner. Pancreatic injury may occur with a normal amylase level, and the amylase level may be raised in the absence of pancreatic damage.

### Spinal trauma (see Section 4.2.D)

Management of spinal cord injuries is particularly difficult in resource-limited settings, where spinal surgery may not be available within the country. Usually patients in these settings have not been handled carefully during transport from the site of injury to the hospital. Decisions have to be made as to whether or not cervical spinal immobilisation is appropriate, especially if it could interfere with airway resuscitation.

Spinal injury should be ruled out in any patient who has been subject to a mechanism of injury capable of damaging the spine. This seemingly obvious statement highlights the fact that it is often surprisingly difficult to ascertain whether there has been an injury to the spine or not, particularly in the face of a concomitant head injury, or in a child who is too young to communicate.

Even in an alert older child, distracting pain from a limb injury may lead the patient to ignore and deny neck pain, even when a spinal fracture exists. Radiological clearance in children is further complicated by the difficulty of interpreting X-rays of immature bones (see Section 7.3.B), and by the relative laxity of ligaments, which gives rise to pseudo-subluxation.

**Be aware of the significant incidence of spinal cord injury without radiological abnormality (SCIWORA) in children.**

Spinal injury is less common in children than in adults, partly because of the elasticity of the bones and ligaments. This same elasticity contributes to the different patterns of spinal injury that are seen. In the cervical spine, for example,

injuries tend to occur at a higher level than in adults, and often span several segments rather than dissipating energy in fracturing a single vertebra.

Examination of potentially spine-injured patients must be carried out with the patient in the neutral position (i.e. without flexion, extension or rotation), and without any movement of the spine.

The patient should be:

- log-rolled
- properly immobilised (using in-line immobilisation, a stiff neck cervical collar or sandbags)
- transported in the neutral position.

With vertebral injury (which may overlie spinal cord injury), look for:

- local tenderness
- deformities, as well as (for a posterior spinal cord injury) oedema.

Clinical findings pointing to injury of the cervical spine include:

- difficulties in respiration (diaphragmatic breathing; check for paradoxical breathing)
- flaccidity, with no reflexes (check the rectal sphincter)
- hypotension with bradycardia (without hypovolaemia).

The entire spine should be palpated during a log-roll, when the patient is turned on to their side in a controlled way, keeping the spine in line. The presence of palpable steps, boggy tenderness or tenderness should be noted. The limbs should be examined for sensory and motor signs of focal or segmental deficit.

### Neurological assessment

Assessment of the level of injury must be undertaken. If the patient is conscious, ask him/her questions relevant to their sensation, and ask them to try to make minor movements, to enable you to assess motor function of the upper and lower extremities.

Key reflex assessment to determine the level of the lesion is summarised below.

#### Motor response

- |                          |            |
|--------------------------|------------|
| ● Diaphragm intact level | C3, C4, C5 |
| ● Shoulder shrug         | C4         |
| ● Elbow flexion (biceps) | C5         |
| ● Wrist extension        | C6         |
| ● Elbow extension        | C7         |
| ● Wrist flexion          | C7         |
| ● Abduction of fingers   | C8         |
| ● Active chest expansion | T1-T12     |
| ● Hip flexion            | L2         |
| ● Knee extension         | L3-L4      |
| ● Ankle dorsiflexion     | L5-S1      |
| ● Ankle plantarflexion   | S1-S2      |

#### Sensory response

- |                                    |       |
|------------------------------------|-------|
| ● Anterior thigh                   | L2    |
| ● Anterior knee                    | L3    |
| ● Anterolateral ankle              | L4    |
| ● Dorsum great and 2nd toe         | L5    |
| ● Lateral side of foot             | S1    |
| ● Posterior calf                   | S2    |
| ● Peri-anal and perineal sensation | S2-S5 |

**If no sensory or motor function is exhibited, with a complete spinal cord lesion, the chance of recovery is small.**

A diaphragmatic breathing pattern, bradycardia, hypotension, peripheral vasodilatation and priapism suggest spinal cord injury.

Throughout the primary and secondary assessments, precautions for spinal protection should ideally be maintained, using a hard collar and side-supports (blocks and straps or sandbags and tape), except for airway procedures and local examination, when manual in-line immobilisation is reinstated.

If the patient is alert, able to communicate clearly and has no distracting pain from another injury, the spine can be cleared clinically without resorting to X-rays. Otherwise, ideally spinal precautions are maintained until radiological clearance is achieved and the patient is re-examined.

If possible, three X-rays of the cervical spine should be taken: cross-table lateral view with arm traction to reveal the C7-T1 interface; antero-posterior view and transoral odontoid peg view. These must be assessed by an experienced professional (if available), paying particular attention to the soft tissues as well as the bony structures (see Section 7.3.B).

If the mechanism of injury warrants it, thoracic and lumbar views are also required.

If the lower cervical spine is not adequately visualised on the lateral view, oblique views are requested. If the X-rays are inadequate or show suspicious areas, CT scanning (if available) is recommended to confirm or exclude a fracture. The MRI scan provides a better examination of neural, ligamentous and other soft tissues, although its sensitivity reveals minor as well as major tissue injury, making interpretation more difficult. It remains expensive and is not universally available. The MRI scanner is a frightening environment for an unsedated child, and the powerful magnetic field creates challenging logistical problems for the monitoring equipment applied to the patient.

Other neurological injuries include damaged nerves to fingers and the brachial plexus.

## Pelvic trauma

Pelvic injury remains a potentially life-threatening injury, especially if it is associated with a large retroperitoneal haematoma, or if the fracture site communicates with the rectum. External fixation of the pelvis may be valuable in controlling major venous haemorrhage.

Arterial bleeding may be controlled by embolisation (if available). The suitability of these techniques depends on the particular configuration of the fracture. It may be difficult to distinguish retroperitoneal haemorrhage from intraperitoneal haemorrhage, the latter requiring laparotomy.

In the absence of suitable equipment, tight compressive binding of the pelvis may help bleeding vessels to clot, although this is not practical in the presence of advanced pregnancy.

The purpose of pelvic binding is to reduce the volume of the pelvis thus tamponading any haemorrhage, as well as providing biomechanical stabilisation. This can be achieved by wrapping a folded sheet around the pelvis. The sheet should centre on the greater trochanters and extend to the iliac crests. Taping the thighs or the feet together also helps maintain the anatomical position of the pelvis.

Not all pelvic trauma is serious. Some pubic rami

fractures are minor injuries, with little intervention required. Nevertheless, the pelvis is a ring structure that tends to break in two places. On inspecting the pelvic X-ray, careful attention should be paid to the sacro-iliac joints and sacral foramina, to seek subtle evidence of a second break in the ring.

## Limb trauma

In general, limb fractures in children are more likely to be managed conservatively than those in adults, reflecting the child's capacity to heal, and the risk of interfering with growth plates. An understanding of the Salter–Harris classification of epiphyseal fractures is essential, and access to a radiological atlas of developmental stages is helpful (see Section 7.2).

**Examination** must include:

- skin colour and temperature
- distal pulse assessment
- grazes and bleeding sites
- limb's alignment and deformities
- active and passive movements
- unusual movements and crepitation
- the severity of pain caused by injury.

## Management of extremity injuries

Aim to:

- keep blood flowing to peripheral tissues
- prevent infection and skin necrosis
- prevent damage to peripheral nerves.

## Special issues relating to limb trauma

Stop active bleeding by applying direct pressure, rather than by using a tourniquet, as the latter can be left on by mistake, and this can result in ischaemic damage.

## Open fractures

Any wound situated in the vicinity of a fracture must be regarded as a communicating one.

Principles of the treatment are to:

- stop external bleeding
- immobilise, and relieve pain.

**Amputated parts of extremities** (such as fingers) should be covered with sterile gauze towels which are moistened and put into a sterile plastic bag. A non-cooled amputated part may be used within 6 hours after the injury, and a cooled one as late as 18–20 hours after it. This practice is only worthwhile if facilities for reimplantation are available.

## Early fasciotomy

Compartment syndrome is fairly common, and often underestimated. This condition is caused by an increase in the internal pressure of fascial compartments, which may result from crush injuries, fractures, intramuscular haematomas or amputations. This causes compression of vessels, with resultant hypoperfusion and hypoxia of tissues, including peripheral nerves.

Compartment syndrome is recognised by the following signs in a fractured or otherwise injured limb:

- pain, accentuated by passive stretching of the involved muscles
- decreased sensation
- swelling

- limb pallor
- limb paralysis
- absence of limb pulse.

The final result of this compartment syndrome is ischaemic (or even necrotic) muscles with restricted function.

Fasciotomy involves cutting the fascial bands around the affected muscle to release the pressure within the compartment, allowing the tissues to re-perfuse. The procedure requires a good knowledge of the relevant anatomy, and is usually performed by an orthopaedic surgeon.

### Special issues with regard to major trauma in pregnancy

Road traffic accidents are the most common cause of major trauma in pregnancy. Intimate partner violence starts or increases during pregnancy, and 40% of women who are murdered are killed by a current or former partner.

### Anatomical and physiological changes of pregnancy and the management of trauma

The anatomical and physiological changes that occur in pregnancy are extremely important in the assessment and resuscitation of the pregnant trauma patient.

#### Anatomical changes

- As the uterus increases in size during pregnancy, it becomes more vulnerable to damage by both blunt and penetrating injury. Before 12 weeks of gestation it is protected by the bony pelvis, but thereafter it is an abdominal organ. The uterine fundus reaches the umbilicus at 20 weeks, and the xiphisternum at 36 weeks.
- In the first trimester, the fetus is well protected by the thick-walled uterus and relatively large amounts of amniotic fluid. As the pregnancy progresses, the uterine wall becomes thinner, providing less protection for the fetus.
- In late pregnancy, the uterus and its contents shield the maternal abdominal contents, providing a degree of protection for the maternal viscera, at the expense of fetal well-being.

#### Physiological changes in pregnancy

These include the following:

- increased tidal volume
- blood volume increases by 40% to 100 mL/kg
- basal heart rate increases to 85–90 bpm
- 30% increased cardiac output
- a fall in blood pressure of 5–15 mmHg
- aortocaval compression as the uterus increases in size from 20 weeks' gestation, with the potential for reduced cardiac output
- upward displacement of the diaphragm as the uterus increases in size, with an impact on lung volume, and predisposing to gastro-oesophageal reflux.

### Special issues in the traumatised pregnant woman or girl

Blunt trauma may lead to:

- haemorrhage from abdominal organs, notably the spleen and liver
- uterine irritability and premature labour
- partial or complete uterine rupture

- partial or complete placental separation (up to 48 hours after trauma)
- fetal death
- fetal distress.

Pelvic fractures may be associated with severe blood loss.

### What are the priorities?

- Assessment and resuscitation according to the ABC and neurological failure structured approach.
- Resuscitation in the left lateral position after 20 weeks' gestation, to avoid aortocaval compression: remember the **left lateral tilt**.
- Assessment of fundal height and tenderness, and fetal heart rate monitoring as appropriate.
- Vaginal examination or speculum examination to assess vaginal bleeding, cervical dilatation and rupture of membranes.

If placenta praevia is known or suspected, digital vaginal examination should **not** be performed, as major haemorrhage may occur. Careful speculum examination is acceptable.

It is important to be alert to signs of hypovolaemia, which are delayed in pregnancy as the mother has a higher circulating volume. Hypovolaemia may compromise the fetus before the mother's vital signs become abnormal. A fall in maternal blood pressure is a late and ominous sign.

Resuscitation of the mother may save the baby as well. There are times when the mother's life is at risk and the fetus may need to be delivered in order to save the mother.

### Action plan

- 1 Call for the most senior help available.
- 2 Perform standard primary assessment and resuscitation.
- 3 In addition:
  - Assess fetal well-being. Use ultrasound examination to detect the fetal heart rate and to identify any retroplacental or intra-abdominal bleeding. Ultrasound is also useful for ascertaining the presentation of the fetus; transverse lie may suggest rupture of the uterus.
  - Consider whether Caesarean section is indicated for maternal or fetal reasons.

### Indications for Caesarean section (if facilities are available to perform it safely)

These include the following:

- cardiac arrest
- uterine rupture
- inadequate exposure during laparotomy for other abdominal trauma
- placental abruption
- an unstable pelvic or lumbo-sacral fracture with the patient in labour
- fetal distress with a viable fetus.

### Peri-mortem Caesarean section

This should be undertaken when maternal cardiac output has not been restored by initial cardiopulmonary resuscitation (CPR). Delivery should ideally be accomplished within 5 minutes of cardiac arrest.

The rationale behind peri-mortem Caesarean section is as follows:

- improvement in maternal cardiac output due to relief of aortocaval compression
- improvement in maternal oxygenation
- greater efficacy of CPR due to better access
- better chance of fetal survival if in third trimester.

Peri-mortem Caesarean section should be undertaken with a left lateral tilt of 15–30 degrees, or preferably with manual displacement of the uterus. CPR should continue throughout, until cardiac output is restored. The operation should take place at the scene of cardiac arrest, rather than after moving the patient to the operating theatre, which wastes precious time. Blood loss is minimal until cardiac output resumes. The woman can be moved to the operating theatre once cardiac output is restored. The fetus may survive, but this is a secondary consideration. The aim of peri-mortem Caesarean section is to save the mother's life, as resuscitation is more likely to be effective if the gravid uterus is emptied.

**Secondary assessment**

Left lateral tilt should be maintained throughout the assessment, in order to minimise aortocaval compression. If spinal injury is suspected, manual displacement of the uterus should be undertaken instead.

**Specific types of trauma**

**Blunt trauma**

The three commonest causes are road traffic accidents, falls and intimate partner violence.

Uterine rupture due to blunt trauma is relatively rare.

Blunt trauma to the abdomen may cause placental abruption. Kleihauer testing, if available, is useful for detecting fetomaternal haemorrhage as an indicator of placental damage. Detection of intra-abdominal haemorrhage may be difficult in pregnancy, so laparotomy should be considered. Remember that the mother may lose a third of her blood volume before the vital signs become abnormal.

**Penetrating abdominal wounds**

Knife and gunshot wounds are the most common. Penetrating injuries can cause uterine injury at any stage of pregnancy. The uterus, fetus and amniotic fluid reduce injury to the mother by absorbing energy and displacing bowel upwards and to the side. Penetrating injuries above the uterus may cause extensive gastrointestinal and vascular damage. Exploratory laparotomy is usually required in the management of penetrating abdominal wounds, in pregnancy as in the non-pregnant patient.

**Thoracic trauma**

Injury to major thoracic structures is particularly dangerous in pregnancy, due to the combination of pre-existing relative aortocaval compression, reduced respiratory excursion and

**Pathway of care: trauma in pregnancy.**

<b>Primary assessment and resuscitation</b>	<b>Airway:</b> increased risk of aspiration – early gastric tube
	<b>Breathing:</b> if chest drain is needed, place at higher level (3rd or 4th intercostal space)
	<b>Circulation:</b> left lateral tilt Abnormalities in pulse rate, blood pressure and capillary refill are late because of hypervolaemia of pregnancy 'Targeted resuscitation' with IV crystalloids, colloid or blood
	<b>Neurological failure:</b> convulsions may be due to eclampsia as well as head injury

<b>Secondary assessment and emergency treatment:</b>
Assess for:
<ul style="list-style-type: none"> <li>● Ruptured uterus and placental abruption after blunt trauma to abdomen (including seat-belt injury). Uterine tenderness, vaginal bleeding, shock all occur. They may be indistinguishable clinically. Scan may show fetal death or intra-abdominal fluid (blood)</li> <li>● Rupture of membranes (by speculum)</li> <li>● Fetal distress</li> </ul>
Evidence of intra-abdominal bleeding or injury to abdominal organs
Consider bowel injury (compressed by uterus and therefore more vulnerable to blunt trauma or penetrating injuries)

Ensure anti-tetanus measures
X-rays as needed
On discharge from hospital, patient to report abdominal pain, decreased fetal movements, vaginal bleeding or fluid leakage

increased oxygen requirement. However, most injuries can be identified by careful assessment, and managed with simple measures, including left lateral tilt and facial oxygen.

**Special issues with regard to major trauma in children**

Trauma is a leading cause of death for all children, with a higher incidence in boys. The survival of children who sustain major trauma depends on the severity of the trauma, effective pre-hospital care and early resuscitation.

The initial assessment of the paediatric trauma patient is identical to that of the adult. The first priority is the Airway, Breathing and Circulation, then early neurological assessment, and finally exposing the child for full examination, without loss of heat.

**TABLE 7.3.A.5 Paediatric 'normal' values are helpful as follows:**

Variable	< 1 year	1–2 years	2–5 years	5–12 years	> 12 years
Respiratory rate (breaths/minute)	30–40	25–35	25–30	20–25	15–20
Heart rate (beats/minute)	110–160	100–150	95–140	80–120	60–100
Systolic blood pressure (mmHg) 50th centile	80–90	85–95	85–100	90–110	100–120

### Specific resuscitation and intubation issues in children

- The head, tongue and nasal airway are relatively large.
- The angle of the jaw is greater, the larynx is higher and the epiglottis is proportionally larger and more 'U' shaped.
- The cricoid is the narrowest part of the larynx, which limits the size of the endotracheal tube. By adulthood, the larynx has grown and the narrowest part is at the cords.
- Obligatory nose breathing occurs in small babies.
- The trachea in the full-term newborn is about 4 cm long, and will admit a 2.5 or 3.5 mm diameter endotracheal tube. (The adult trachea is about 12 cm long.)
- Gastric distension is common following resuscitation, and a nasogastric tube is useful for decompressing the stomach.

If tracheal intubation is required, avoid using cuffed tubes in children under 10 years of age, so as to minimise subglottic swelling and ulceration. Oral intubation is easier than nasal intubation for infants and young children.

### Shock in the paediatric patient

The femoral artery in the groin and the brachial artery in the antecubital fossa are the best sites at which to palpate pulses in the child. If the child is pulseless, cardiopulmonary resuscitation should be commenced.

Signs of shock in paediatric patients include:

- tachycardia
- weak or absent peripheral pulses
- capillary refill time > 3 seconds
- tachypnoea
- agitation
- drowsiness
- poor urine output.

Hypotension is a late sign, even in the presence of severe shock.

A normal urine output is 1–2 mL/kg/hour for the infant and 0.5–1 mL/kg/hour in the older child.

Hypothermia is a major problem in children because of their relatively large surface area. They lose proportionally more heat through the head. All fluids should be warmed. Exposure of the child is necessary for assessment, but cover them as soon as possible.

### Continuing care for patients who have suffered major trauma

#### Tetanus prophylaxis

This is often forgotten in the management of severe trauma. In the fully immunised patient, an additional booster will depend on a clinical decision as to the possibility of exposure to contamination, the severity of injury and the timing of the last tetanus immunisation. In an unimmunised or incompletely immunised patient, tetanus immunoglobulin should be given and a full course of or a completing course of tetanus toxoid started (using a different limb to the one receiving the immunoglobulin).

#### Guidance on tetanus-prone wounds

These include the following:

- compound fractures
- deep penetrating wounds
- wounds containing foreign bodies (especially wood splinters)
- wounds complicated by pyogenic infections
- wounds with extensive tissue damage (e.g. crush injuries, contusions or burns)
- any wound that is obviously contaminated with soil, dust or horse manure (especially if topical disinfection is delayed for more than 4 hours).

TABLE 7.3.A.6 Guidance on the use of tetanus immunoglobulin and tetanus toxoid

History of tetanus vaccination		Type of wound	Tetanus vaccine booster (see below)	Tetanus immunoglobulin
≥ 3 doses	< 5 years since last dose	All wounds	No	No
	5–10 years since last dose	Clean minor wounds	No	No
		All other wounds	Yes	No
	> 10 years since last dose	All wounds	Yes	No
< 3 doses or uncertain		Clean minor wounds	Yes	No
		All other wounds	Yes	Yes

### Transfer

Not every hospital has the resources and expertise to safely care for injured pregnant women or girls and children. Ideally, children with serious injuries should be transported directly from the scene of the accident to a centre with such capability (if one exists in the country). Even then, geographical constraints may render transfer unsafe.

**Patients should be transported only if they are going to a facility that can provide a higher level of care.**

Even when the transfer is urgent, it is essential to achieve physiological stability before embarking on a hazardous journey in the isolated environment of the ambulance. There is always physiological deterioration during transfer. Thorough assessment should take place prior to transfer,

to exclude coexisting life-threatening conditions which may be amenable to treatment on site. For example, a child with a head injury should not be transferred in a hypotensive condition caused by unrecognised and untreated intra-abdominal bleeding.

It is essential that there is effective communication with:

- the receiving centre
- the transport service
- escorting personnel
- the patient and their relatives.

Communication between the referring and admitting clinicians is necessary, not only to agree that transfer is indicated, but also to establish guidelines for care in

transit, and to warn the receiving centre when the patient is expected to arrive.

Effective stabilisation necessitates:

- prompt effective initial resuscitation
- control of haemorrhage and maintenance of the circulation
- immobilisation of fractures
- analgesia.

**If the patient deteriorates, re-evaluate them by using the primary assessment, checking and treating life-threatening conditions, and then make a careful assessment focusing on the injuries area.**

Inter-hospital transfer requires careful planning, to provide:

- trained medical and nursing escorts
- simple compact robust equipment
- drugs for resuscitation, sedation, pain relief and muscle relaxation
- fluids and blood products if indicated
- a suitable vehicle and ambulance staff.

In trauma care, some transfers are time-limited (e.g. to evacuate an extradural haematoma). In such cases, the extra time taken for a retrieval team to reach the referring hospital may offset the benefit of their specialised skills.

### Peri-operative care in major trauma

In the operating theatre, definitive anatomical reduction, repair or resection of individual injuries takes place. While the surgical team focuses on anatomical correction, the anaesthetic team maintains physiological system control. The impetus and sense of urgency evident in the Emergency Department should be maintained, without losing the thoroughness necessary to manage all aspects of care.

If the patient has a significant head injury, the anaesthetic

agents should be chosen to avoid increasing intracranial pressure or cerebral blood flow. In general, this means avoiding high doses of volatile agents such as halothane or isoflurane. Ketamine has long been considered to be contraindicated in head injury, although there is recent evidence that challenges this view. It may be the only anaesthetic available.

**If the child is undergoing lengthy extracranial surgery in the face of a severe head injury, it is wise to observe the pupils at frequent intervals.**

Maintaining the child's core temperature is a key aim during prolonged surgery. Hypothermia impairs platelet function and increases the risk of infection, although it has been claimed to help to preserve brain function in severe head injury.

### High-dependency care

In the immediate management of the injured patient, the focus was on physiological assessment and intervention using an ABC structured approach, followed by anatomical assessment and definitive care.

When high-dependency care is instituted, physiological stabilisation again becomes the main concern, although it is important to remain alert to the possibility of any further injuries that were not evident in the secondary assessment. Detailed physiological control is facilitated by monitoring and good nursing.

See Section 1.14 for further information.

### Step-down care and rehabilitation

High-dependency care, acute ward care and rehabilitation serve to minimise disability, rather than influence mortality, which is already largely determined by this time. The emphasis shifts towards integration back into normal life, physically and psychologically, although the course may be interrupted by further reconstructive surgery.

## 7.3.B Emergency trauma radiology

### Introduction

Essential initial trauma films to screen for major injuries include the following.

- lateral cervical spine radiograph
- chest X-ray
- pelvic X-ray.

These should only be taken after immediately life-threatening injuries have been identified and treated (resuscitation).

The ABCD approach to X-ray interpretation is as follows:

- **A**dequacy, **A**lignment and **A**pparatus.
- **B**ones.
- **C**artilage and soft tissues.
- **D**isc spaces (in the spine), **D**iaphragm (in the chest).

First, all X-ray films should be checked for **adequacy**. Do they include all of the part that needs imaging? Is the film a proper antero-posterior view or is it at an angle? If the film is not of reasonable quality, interpretation is difficult and may be faulty.

### Cervical spine

The cervical spine should be immobilised (see Section 7.3.A) before any radiology. The standard film is a lateral radiograph, which may be supplemented by an AP (lower cervical spine and odontoid peg views) if appropriate.

Bony injury is not the primary focus in spinal injury. The main concern is to delineate actual or potential injury to the cord, as any unstable fracture, if inadequately immobilised, may lead to progressive cord damage.

A normal lateral cervical X-ray film may be falsely reassuring. The plain film only shows the position of the bones at the time when the film was taken, and gives no idea of the magnitude of flexion and extension forces applied to the spine at the time of injury. **The cord may be injured even in a child without any apparent radiographic abnormality.** This phenomenon is known as SCIWORA (see below).

Unlike adult spine injuries, most paediatric cervical spine injuries occur either through the discs and ligaments, at the cranio-vertebral junction (C1, C2 and C3), or at C7/T1. The relatively large head of the child, moving on a flexible neck

with weaker muscles, leads to injury in the higher cervical vertebrae.

Children show three patterns of spinal injury:

- 1 subluxation or dislocation without fracture
- 2 fracture with or without subluxation or dislocation
- 3 spinal cord injury without radiographic abnormality (SCIWORA).

The last of these, SCIWORA, is said to have occurred when radiographic films are completely normal in the presence of significant cord injury. **If the film is normal in a conscious child with clinical symptoms (such as pain, loss of function or paraesthesia in a limb), neck protection measures should be continued.** In an unconscious child at high risk, a cord injury cannot be excluded until the patient is awake and has been assessed clinically, even in the presence of a normal cervical spine film. Adequate spinal precautions should be continued until the child is well enough to be assessed clinically.

The most common site of a 'missed' spinal injury is where a flexible part of the spine meets the fixed part. In the neck these are the cervico-cranial junction and the cervico-thoracic junction.

The whole spine should be viewed from the lower clivus down to the upper body of T1 vertebra.

**Alignment**

When studying a cervical spine X-ray, look for the four lines shown in Figure 7.3.B.1. These lines should be uninterrupted. If there is a 'step' in any line, the spinal cord is at

Cervical spine review alignment:  
the cord lies between **2** and **4**

**FIGURE 7.3.B.1** Lines to examine on X-ray of the lateral cervical spine.

risk. The cervical immobilisation must be continued and an orthopaedic opinion sought.

The four lines are as follows:

- 1 anterior vertebral line
- 2 posterior vertebral line (anterior wall of the spinal canal)
- 3 facet line
- 4 spino-laminar line (posterior wall of the spinal canal).

Figure 7.3.B.2 shows an actual cervical spine X-ray with three of the lines delineated and the odontoid, a facet joint, a spinous process and a lamina identified. The gaps between the adjacent spinous processes and between each facet joint should be similar. Again, any discrepancy is suggestive of a potentially unstable spine.

**FIGURE 7.3.B.2** X-ray of the lateral cervical spine, showing three of the lines that are indicated in Figure 7.3.B.1. Od, odontoid; F, facet joint; L, lamina; SP, spinous process spaces.

The spinal cord lies in the canal between the posterior vertebral line (2) and the spino-laminar (4) line.

**Bones**

The outline of each vertebra should be reviewed in turn. Fracture lines going through the cortex, vertebral bodies, laminae or spinous processes should be sought.

The spaces between the facet joints and the gaps between adjacent spinous processes should be similar. The joint between the odontoid peg and the anterior arch of the atlas should be 1–4 mm in a child (see Figure 7.3.B.3).

**FIGURE 7.3.B.3** C1/C2 anatomy in the older child.

The orientation of the odontoid peg should always be perpendicular to the body of C2.

### Cartilage and soft tissues

Abnormal widening of the pre-vertebral soft tissues may indicate a haematoma due to cervical spine injury. However, there may be a significant spinal injury with normal soft tissues. Thus the absence of soft-tissue swelling does not exclude major bony or ligamentous injury. When a child is intubated, it is difficult to assess pre-vertebral soft-tissue swelling. Small children have large adenoids, which are seen as well-demarcated soft tissue swelling at the base of the clivus.

Acceptable soft-tissue thicknesses are as follows:

- above the larynx: less than one-third of the vertebral body width
- below the larynx: not more than one vertebral body width.

Below the level of the larynx, the pre-vertebral soft tissues become progressively **narrower** towards the cervico-thoracic junction (see Figure 7.3.B.4). If the pre-vertebral soft tissues are wider at C7 than at the C5 level, this suggests trauma at the C7/T1 level.

**FIGURE 7.3.B.4** Lateral cervical spine showing soft tissues.

Any soft-tissue swelling outside these limits should be regarded as abnormal, and neck protection measures maintained until a further clinical opinion can be obtained. In small children the soft tissues may appear abnormally wide if the film is taken with the infant lying in flexion. If in doubt, maintain the neck protection and ask for advice.

### Discs

The height of the vertebral disc should be compared from C2/C3 to C7/T1. The discs should all be of similar height, as shown earlier in Figure 7.3.B.1. Any significant discrepancy suggests a crush fracture of the vertebrae (usually caused by a fall from a height).

**Flexion and extension cervical spine films should never be performed in the acute trauma situation.**

## Chest X-ray

### Adequacy and alignment

**Adequacy** can be assessed by evaluating both radiographic penetration and the depth of the patient's inspiration. The film should just show the disc spaces of the lower thoracic vertebrae through the heart shadow. At least five anterior rib ends should be seen above the diaphragm on the right

side. If the film is taken in expiration, it may mimic a chest infection. Films are difficult to take in young children, as they are unable to 'hold their breath' on command, so the radiographer has to try to take the picture at the moment of full inspiration.

**Alignment** can be assessed by ensuring that the medial ends of both clavicles are equally spaced about the spinous processes of the upper thoracic vertebrae. Abnormal rotation may create an apparent mediastinal shift. The trachea should be equally spaced between the clavicles.

### Apparatus

Check the position of any apparatus, including the following:

- tracheal tube
- central venous lines
- chest drains.

Misplacement of the endotracheal tube (ETT) into a bronchus should be evident clinically, but may be seen on a chest film if you look for it. Do this first when reviewing any chest X-ray on an intubated patient. Ventilation of only one lung will lead to hypoxia in a compromised patient.

The ideal position for an ETT is below the clavicles and at least 1 cm above the carina. To find the carina, identify the slope of the right and left main bronchi. The carina is where the two lines meet in the midline.

### Bones

Look at each rib in detail. This can be done by tracing out the upper and lower borders of the ribs from the posterior costochondral joint to the point where they join the anterior costal cartilage at the mid-clavicular line. The individual internal bone patterns can then be assessed.

The ribs in children are soft and pliable, and only break when subjected to considerable force. Even greater force is required to fracture the first rib or to break multiple ribs. Consequently, the presence of these fractures should stimulate you to look for other sites of injury both inside and outside the chest. Fractures in children's rib bones are hard to see while fresh unless there is displacement. Diagnosis is often made a week or so later if an X-ray is taken then, when the calcifying new callus is seen.

Finish assessing the bones by inspecting the visible vertebrae and the clavicles, scapulae and proximal humeri.

Thoracic spine injuries may be overlooked on a chest radiograph. Abnormal flattening of the vertebral bodies,

**FIGURE 7.3.B.5** Vertical fracture of the thoracic spine.

widening of the disc spaces, or gaps between the spinous processes or pedicles may be seen. On the antero-posterior views, increased vertical or horizontal distances between the pedicles or spinous processes indicate an unstable fracture, as shown in Figure 7.3.B.5.

If there are rib fractures in the first three ribs, these may be associated with major spinal trauma and great vessel injury.

### Cartilage and soft tissues

#### Lungs

In a well-centred film, the lungs should appear equally black on both sides. Compare the left and right lungs in the upper third, middle third and lower third of the chest.

Check that the lungs go all the way out to the rib cage (i.e. that there is no pleural effusion or pneumothorax). A lung that is black on one side may be due to a pneumothorax or air trapping. A lung that is white on one side may be due to collapse, pulmonary haemorrhage, contusion or effusion (including haemothorax).

On the supine film, blood or fluid lies posteriorly, giving a generalised greyness to the lung, rather than the typical meniscus sign seen on the erect film. At the apex of each lung, an effusion displacing the lung downward may indicate spinal injury or major vessel damage.

A suspected tension pneumothorax should be treated clinically in the emergency situation, without confirmatory X-ray.

On a supine film, the air in a simple pneumothorax rises anteriorly and may only be evident from an abnormal blackness or 'sharpness' of the diaphragm or cardiac border. The standard appearances of a pneumothorax, where there is a sharp lung edge and the vessels fail to extend to the rib cage and the lung edges, may not occur in the supine film.

#### The heart

The cardiac outline should lie one-third to the right of the midline and two-thirds to the left of the midline. If the film is not rotated, which should be checked, mediastinal shift is due to the heart being either pushed from one side or pulled from the other. For example, mediastinal shift to the left may be due to a pneumothorax, air trapping or effusion on the right side, or collapse of the left lung.

All emergency major trauma X-rays are taken in the supine position because of the seriousness of the patient's condition, often using portable X-ray machines. The X-ray tube is near to the patient and the heart is anterior with the film posterior. The heart in this situation appears abnormally magnified (widened), and the cardiothoracic ratio is difficult to assess on supine AP films.

The mediastinal cardiac outline should be clear on both sides. Any loss of definition suggests consolidation (de-aeration) of adjacent lungs. A 'globular' shape to the heart may suggest a pericardial effusion. Tamponade is managed clinically. A cardiac ultrasound scan is useful in equivocal cases.

#### The upper mediastinum

In the teenager the mediastinum should appear as narrow as in an adult. In children under the age of 18 months, the normal thymus is large, causing a confusing and often 'sail-shaped' upper mediastinal shadow. A normal thymus may touch the right chest wall, left chest wall, left diaphragm or right diaphragm, making it very difficult to

exclude mediastinal pathology. Fortunately, mediastinal widening due to aortic dissection or spinal trauma is very rare in small children.

In the older child involved in trauma, mediastinal widening may mean aortic dissection, or major vessel or spinal injury. Ultrasound scanning will be helpful (if available).

#### Diaphragms

The cardiophrenic and costophrenic angles should be clear on both sides. The diaphragms should be clearly defined on both sides, and the left diaphragm should be clearly visible behind the heart. Loss of definition of the left diaphragm behind the heart suggests left lower lobe collapse, an abnormal hump suggests diaphragmatic rupture, and an elevated diaphragm suggests effusion, lung collapse or nerve palsy.

At the end of the systematic ABCD review of the X-ray, check again in the key areas shown in the following list:

- Behind the heart: left lower lobe consolidation or collapse.
- Apices: for effusions, pneumothorax, rib fractures and collapse or consolidation.
- Costophrenic and cardiophrenic angles: fluid or pneumothorax.
- Horizontal fissure: fluid or elevation (upper lobe collapse).
- Trachea for foreign body (and ETT).

#### Pelvic X-ray

A single, antero-posterior pelvic view is sufficient.

#### Adequacy and alignment

It is very important to have the pelvic film positioned as a true antero-posterior (AP) view, as rotation causes interpretation problems. In a true AP film the tip of the sacrum will be aligned with the symphysis pubis.

The whole of the pelvis from the top of the iliac crests to the ischial tuberosities and both hip joints should be seen. The femoral necks shown to the level of the trochanters should be included.

#### Bones

The pelvis is composed of the sacrum, innominate bones (iliac wings), ischium and pubic bones. These come together to form a Y-shaped cartilage in the floor of the acetabulum. In young children, the joint between the ischium and the pubis (ischiopubic synchondrosis) is commonly seen and may simulate a fracture.

FIGURE 7.3.B.6 Normal pelvis in a young child.

**FIGURE 7.3.B.7** Multiple pelvic fractures.

The pelvis is reviewed as a number of rings on the two-dimensional film. These include the pelvic brim, the two obturator rings and both acetabular fossae. The rings should appear smooth and symmetrical in a well-centred

film (see Figure 7.3.B.6, which shows a normal child pelvis). The femoral necks must be checked for fracture. Figure 7.3.B.7 shows a pelvis with multiple fractures, at major risk of serious pelvic bleeding as large vessels are torn with the force shown by the widespread fractures.

### Cartilage and soft tissues

Minor rotation, hip flexion or rotation will distort the fat plane and make assessment of soft-tissue displacement difficult. Abnormal widening of the obturator fat pad may indicate a pelvic side wall haematoma.

The paediatric pelvis is held together by cartilage. Separation through the cartilage of the sacro-iliac joint, the symphysis pubis or the 'Y' cartilage of the acetabular floor may occur without apparent bony injury. Comparison of both hips and sacro-iliac joints on a well-centred film may show this. On a well-centred film the distance between the femoral head and the floor of the acetabulum 'crescent' should be symmetrical – it is abnormal in effusion or dislocation of the hip joint.

## 7.3.C The child with a head injury

### BOX 7.3.C.1 Minimum standards

- ABC and neurology and maintenance of oxygenation and blood pressure with control of environmental temperature while exposing and examining the whole patient.
- Emergency burr-hole by an experienced operator if available.
- Parenteral antibiotics.
- Mannitol or hypertonic saline (2.7% or 3%).
- Anticonvulsants.

### Introduction

The primary aim of the management of traumatic brain injury is to prevent secondary brain injury, which results from failure to maintain adequate oxygenation and optimal blood pressure in the head-injured child, in addition to the brain swelling which is the usual response of the child's brain to injury. This aim is made more difficult by the presence of other injuries which may be reducing oxygenation and causing shock. Severity of brain injury in toddlers and children can be measured by using the Glasgow Coma Scale (GCS). The GCS score ranges from 3 to 15. A GCS score of 14–15 is categorised as minor brain injury, a score of 9–13 as moderate brain injury, and a score of 3–8 as severe brain injury.

The GCS is based on eye opening (E), best motor response (M) and verbal response (V).

#### Scores for best eye response (4)

- 1 None
- 2 Eye opening to pain
- 3 Eye opening to verbal command
- 4 Eyes open spontaneously

#### Scores for best verbal response (5)

- 1 None

- 2 Incomprehensible sounds
- 3 Inappropriate words
- 4 Confused conversation
- 5 Orientated

#### Scores for best motor response (6)

- 1 None
- 2 Extension to pain (decerebrate)
- 3 Flexion to pain (decorticate)
- 4 Withdrawal from pain
- 5 Localises pain
- 6 Obeys commands

### Children's Coma Scale

#### Scores for best eye response (4)

- 1 None
- 2 Eye opening to pain
- 3 Eye opening to verbal command
- 4 Eyes open spontaneously

#### Scores for best verbal response (5)

- 1 Alert, babbles, usual words
- 2 Less than usual words spontaneous irritable cry
- 3 Cries only to pain
- 4 Moans to pain
- 5 No response to pain

#### Scores for best motor response (6)

- 1 Spontaneous or obeys verbal command
- 2 Localises to pain or withdraws to touch
- 3 Withdraws from pain
- 4 Abnormal flexion to pain (decorticate)
- 5 Abnormal extension to pain (decerebrate)
- 6 No response to pain

Another factor that must be documented is pupillary size

and reaction to light. This helps when localising brain injury and its progress.

### Major diffuse brain injury

Cerebral oedema is the most likely pathological process following serious head injury in children. Intracranial haematomas are quite uncommon in childhood: they are more likely to be found in an adult patient. Even the presence of unequal pupils in a seriously head injured child may be a false localising sign, and does not have the same significance that this sign has in the adult head-injured patient.

The only measures that are of proven value are maintenance of adequate oxygenation and perfusion and the avoidance of adverse effects (see below). Removal of intracranial haematomas, if identified, is very helpful, but this pathology is much less frequently found in the paediatric population, where cerebral oedema predominates. A CT scan (if available) will identify any haematoma. **Artificial ventilation, tracheostomy and more sophisticated medical measures designed to control raised intracranial pressure may be of value, but require evacuation to a fully equipped and staffed children's neurointensive care unit.**

In the absence of such a facility, the best strategy is to concentrate on optimising the care of the unconscious patient with attention to:

- preservation of the airway
- maintenance of adequate ventilation
- avoidance of hypotension by maintaining the circulating volume with normal Ringer-lactate or Hartmann's solution
- the maintenance of appropriate fluid and electrolyte balance, avoiding hypotonic IV fluids, hyponatraemia and hypoglycaemia
- avoidance of fever > 38°C. Use rectal paracetamol: child 1–5 years 125–250 mg/dose up to 4 doses in 24 hours; 5–12 years 250–500 mg/dose maximum 4 doses; 12 years–adult 500 mg/dose maximum 4 doses
- maintaining the patient in a 20-degree head-up position with no neck flexion and with the head in the midline
- if there is deterioration of the GCS score, giving an IV infusion of mannitol 0.25–0.5 g/kg
- mannitol can be repeated later but there is a decreasing response to this treatment. Alternatively, hypertonic saline can be used (2.7% or 3% at a dose of 3 mL/kg). This may not be associated with a 'rebound' brain swelling as occurs with mannitol and does not induce a diuresis like mannitol but rather augments plasma volume
- care of the skin, bladder and bowel.

Fluid restriction is not indicated, but fluid overload should be avoided.

If transfer or evacuation is required within the first 48 hours after injury, endotracheal intubation and mechanical ventilation are desirable. Steroids are of no value and increase the risk of intercurrent infection. Antibiotics are reserved for patients with evidence of sepsis. Anticonvulsant drugs are only given if there are seizures.

### Intracranial haematomas

Only 6 in 1000 patients will develop a significant intracranial haematoma following a non-missile head injury. **The most useful guide to the development of an intracranial haematoma is deterioration in the level of consciousness.** The presence of inequality of the pupils will help to identify the lesion. **The ideal investigation is CT (if available).** If CT is not readily available, burr-hole exploration on the same side as the injury as the dilated pupil and the opposite side to any motor weakness is justified in the hope of finding an extradural or subdural clot. **However, burr-holes must only be made by a skilled surgeon using appropriate equipment.**

Emergency temporary reduction of raised intracranial pressure can be achieved by one or more of the following medical measures:

- mannitol 20% by IV infusion over 20 minutes (0.25–0.5 g/kg). This can be repeated as required but response becomes progressively lessened
- Alternatively, hypertonic saline can be used (2.7% or 3% at a dose of 3 mL/kg). This may not be associated with a 'rebound' brain swelling as occurs with mannitol and does not induce a diuresis like mannitol but rather augments plasma volume
- intubation and artificial ventilation to keep PaCO<sub>2</sub> around 4 kPa.

An extradural clot will always be beneath the site of trauma. The place to make the burr-hole is therefore at the site of any external site of injury. This may be known from the history, or may be found by shaving the entire scalp in search of bruises, grazes, lacerations or soft-tissue swelling. A plain skull radiograph (if available) may show a fracture, and if so the burr-hole should be made at the site of the fracture. If there are none of the above-mentioned clues, then 'blind' burr-hole exploration will be required. This should commence on the side of the dilated pupil, or on the side of the pupil that dilated first.

Three standard burr-holes can be made: subtemporal, frontal and parietal. It is crucial to make the sub-temporal burr-hole low enough in the middle cranial fossa. The correct position is immediately above the zygoma at the midpoint between the outer canthus of the eye and the external auditory meatus. If an extradural clot is found, the burr-hole must be extended as either a craniectomy or a craniotomy. The margins should extend sufficiently far to uncover the entire clot, which can then be evacuated by suction. Bleeding meningeal arteries can be controlled with diathermy or by under-running with a suture. Bleeding from major venous sinuses can be controlled by haemostatic gauze and by hitching the adjacent dura to the surrounding pericranium with sutures. Diffuse meningeal oozing will stop spontaneously if it is not tampered with; the application of hydrogen peroxide or warm saline packs may help. When the clot has been evacuated and the bleeding has stopped, it is essential to hitch the dura around the perimeter of the bone opening to the adjacent pericranium in order to prevent recurrence. In very young children, it may be better to pass sutures through small drill holes in the surrounding bone. If a craniotomy has been made, the bone flap is replaced.

If no extradural haematoma is found at any of the burr-hole sites, the dura should be opened cautiously. If there is a subdural clot, a craniotomy is necessary. It is safer to make multiple short dural incisions rather than a wide dural

opening. It is difficult to be certain whether a tense dura is due to subdural clot or brain swelling. Most acute subdural clots are associated with quite severe brain injury, and a wide dural opening is very likely to be followed by massive uncontrollable extrusion of the brain material.

Post-operatively, anaesthesia can be reversed unless the patient is to be evacuated to another facility. If a significant clot has been found, there should be a prompt improvement in the level of consciousness.

In a baby with severe signs of rapidly progressive raised intracranial pressure following a closed head injury, it is reasonable to search for an acute subdural haematoma by passing an adult (18-gauge) lumbar puncture needle into the subdural space through the anterior fontanelle or through a diastased coronal suture. The baby is wrapped in a sheet and held supine by an assistant so as to secure the head, the arms and the trunk. The entry point is either at the most lateral extremity of the anterior fontanelle or at a point in line with the pupil, whichever is the furthest from the midline. **In a conscious child, local anaesthesia must first be applied.** The needle is passed at a shallow angle, in an anterior direction, through the skin and then through the relatively resistant dura. The trocar is removed from the needle and any subdural fluid allowed to drain spontaneously. The needle is then withdrawn and the puncture hole in the skin closed with a suture.

### Skull fractures

Most skull fractures heal without treatment, but they should be observed for 24 hours in case an intracranial haematoma occurs unless a CT scan has shown no intracranial bleeding. Fractures which are compound, either externally (i.e. the overlying scalp is broken) or internally (i.e. there is a fracture into a paranasal sinus or into the middle ear) require attention.

### Externally compound fractures

- Like all wounds, these should be explored to remove all dead tissue and foreign material. This is the most effective means of preventing infection. Operation should be performed as soon as possible. Simple wounds can be explored under local anaesthetic, but more complex wounds will require general anaesthesia.
- Depressed fractures may require elevation to ensure that the full extent of the wound, including the brain substance, has been cleaned and that the dura is repaired if it has been torn. If the wound is less than 24 hours old and not heavily contaminated, the bone fragments can be replaced. If the wound is older than 24 hours or is heavily contaminated, it is safer to discard the bone fragments.
- Antibiotics are not generally required, as it is the mechanical debridement of the wound that is the crucial step. However, compound depressed skull fractures that have occurred in any setting, especially an agricultural or rural one, may be contaminated with *Clostridium tetani* and are best covered with 5 days of IV benzylpenicillin (for children aged 1 month to 12 years, 50 mg/kg every 6 hours by slow injection, and for those over 12 years, 2.4 grams every 6 hours) with anti-tetanus active immunisation and toxoid as appropriate (see Section 7.3.A). Animal bites, especially from dogs, will be contaminated with *Pasteurella multocida* and should be covered with ampicillin IV (40 mg/kg 8-hourly up to a

maximum of 4 grams/day). If surgery is delayed for more than 24 hours, antibiotics should be given.

The scalp has excellent vascularity and every effort should be made to preserve scalp. Once significant areas are lost, complex skin flaps will be required. Split-skin grafts will not take on bare calvarial bone. If substantial areas of full-thickness scalp are lost, as in burns or attacks by large animals, a useful technique is to make multiple burr-holes, leaving the dura intact. Over the course of a few weeks the florid granulation tissue that grows out of the burr-holes will form a satisfactory base to accept split-skin grafts.

### Internally compound fractures

- These carry the risk of CSF fistula and meningitis.
- Prophylactic antibiotics are not indicated.
- Most CSF rhinorrhoea or otorrhoea will resolve spontaneously, but cases persisting for longer than 2 weeks will require formal repair. This will involve referral to a higher centre with facilities for CT scanning and neurosurgical expertise.
- Meningitis complicating traumatic CSF rhinorrhoea or otorrhoea is usually caused by *Streptococcus pneumoniae*, and should be treated for 2 weeks with IV benzylpenicillin (at the dose stated above) or IV cefotaxime (for children under 12 years, 50 mg/kg every 6 hours and for those over 12 years 1–3 g every 6 hours). It is an absolute indication for surgical repair to prevent further episodes.

### Penetrating injuries

Children are especially prone to suffering penetrating injuries because of the thin nature of the immature skull, especially around the orbit. **Such wounds require exploration through their full extent to prevent brain abscess.**

Missile injuries require removal of all foreign material wherever feasible. High-velocity penetrating brain injuries from modern military weapons are invariably fatal because of the extreme forces involved, and these patients, along with those who are in deep coma following even low-velocity gunshot wounds, will not make a useful recovery, so **only palliative care is appropriate.**

### Early traumatic epilepsy

Epileptic seizures in the first 48 hours after injury are common in children. Except in infants they do not, in isolation, indicate the presence of an intracranial haematoma. Most seizures are self-limiting and simply require airway protection. An anti-epileptic drug should be given to prevent further fits. It is important to remember that the child with an acutely injured brain will be exquisitely sensitive to the respiratory depressant effects of diazepam or lorazepam. These are best avoided unless there is no alternative, when they must be used to stop the convulsion, which will worsen the effects of the head injury.

When using either diazepam or lorazepam, always have a functioning bag-mask resuscitator immediately available. The main side effect of these drugs is apnoea or hypoventilation, but it is short-lived, and a few minutes of bagging with the bag-mask will result in spontaneous respiration restarting. The safest drug is paraldehyde administered per rectum (0.4 mL/kg up to 1 year of age, then one mL per year of age up to a maximum of 10 mL). Unfortunately, it is becoming increasingly difficult to obtain as it is not

manufactured widely. Paraldehyde can be diluted with an equal volume of olive oil. It can be given using a plastic syringe if given immediately, otherwise by glass syringe. Do not use paraldehyde if it has a brown colour or smells of acetic acid.

A longer-acting drug must also be given at the same time and maintained. The most appropriate are **phenobarbitone** for children aged less than 5 years (load 15 mg/kg slowly IV, then a total of 5 mg/kg/day starting dose up to a

maximum of 6 mg/kg/day IV, or orally in two divided doses 12 hours apart) and **phenytoin** for those aged over 5 years, administered IV initially (load 15 mg/kg IV over 20 minutes, followed by a further 10 mg/kg IV over a further 20 minutes if the first dose is unsuccessful). Then give 2.5 mg/kg every 12 hours IV over 20 minutes initially, increasing up to a maximum of 7.5 mg/kg every 12 hours (with each dose given over 20 minutes if IV). Phenytoin can also be given orally.

### 7.3.D Electrical injury

#### BOX 7.3.D.1 Minimum standards

- ABC.
- ECG monitoring.
- Sodium bicarbonate.

#### Introduction

Electrical injuries usually occur in the home, and involve relatively low currents and voltage. The mortality from electrical injuries from high-power external sources such as electrified railways is high, and death is immediate.

Other injuries may occur during the event. For example, the patient may fall or be thrown. Therefore a full trauma assessment must be undertaken.

#### Pathophysiology

Alternating current (AC) produces cardiac arrest at lower voltages than does direct current (DC). Regardless of whether the electrocution is caused by AC or DC, the risk of cardiac arrest is related to the size of the current and the duration of exposure. The current is highest when the resistance is low and the voltage is high.

#### Current

The typical **effects of an increase in current** are as follows:

- **Above 10 mA:** Tetanic contraction of muscles may make it impossible for the patient to let go of the electrical source.
- **Above 50 mA:** Tetanic contraction of the diaphragm and intercostal muscles leads to respiratory arrest, which continues until the current is disconnected. If hypoxia is prolonged, secondary cardiac arrest will occur.
- **From 100 mA to 50 A:** Primary cardiac arrest may be induced. (The defibrillators that are used in resuscitation deliver around 10 A.)
- **From 50 A to several 100 A:** Massive shocks cause prolonged respiratory and cardiac arrest and more severe burns. A lightning strike is a massive direct current of very short duration which can depolarise the myocardium and cause an immediate asystole.

#### Resistance

The resistance of the tissues determines the path that the current will follow. Generally, the current will follow the path of least resistance from the point of contact to earth. The relative resistance of the body tissues is, in increasing order, as follows: tissue fluid, blood, muscle, nerve, fat, skin, bone. Electrocution generates heat, which causes a

variable degree of tissue damage. Nerves, blood vessels, the skin and muscles are damaged most. Swelling of damaged tissues, particularly muscle, can lead to a crush or compartment syndrome that requires fasciotomy. Water decreases the resistance of the skin and will increase the amount of current that flows through the body.

#### Voltage

High-voltage sources such as lightning or high-tension cables cause extremely high currents and severe tissue damage. However, very high voltages can cause severe superficial burns without damaging deeper structures (flash burns and arcing).

#### Primary assessment and resuscitation

Call for help and disconnect the electricity **in a safe manner**.

Be aware that high-voltage sources can discharge through several centimetres of air.

#### Airway

The upper airway should be opened and secured, especially if this is compromised by facial or other injuries. The cervical spine should be immobilised if there is a strong possibility of an unstable fracture.

#### Breathing

If the patient is not breathing, give rescue breaths using a mouth-to-mouth technique if no equipment is available (e.g. in the home) and, if available, a bag and mask with high-flow oxygen through an attached reservoir. If the patient is breathing but cyanosed, or low oxygen saturation is present, give inspired oxygen to maintain SaO<sub>2</sub> (if a pulse oximeter is available) in the range 94–98%.

#### Circulation

If the patient appears lifeless despite the rescue breaths, commence chest compressions and continue cardiopulmonary resuscitation (CPR) as described in Section 1.12 until help arrives. In the resuscitated or non-arrested patient who has been brought to hospital, after ABC assessment and management, the entry and exit point of the current should be sought in order to gain a picture of the sort of possible internal injuries that could have occurred. Children with significant internal injuries have a greater fluid requirement than one would suspect on the basis of the area of the external electric burn.

## Secondary assessment and emergency treatment

Other injuries should be treated in an appropriate and structured manner (see Section 7.3.A).

Associated injuries are common in electrocution. Almost all possible injuries can occur as a result of falls or being thrown from the source. Burns are particularly common, and are caused either by the current itself or by burning clothing. Tetanic contraction of muscles can cause fractures, subluxations or muscle tearing.

### Other problems

Burns cause oedema and fluid loss. Myoglobinuria occurs

after significant muscle damage, and acute renal failure is a possibility. In this case, it is important to maintain a urine output of more than 2 mL/kg/hour in a child or 60 mL/kg/hour in a pregnant woman or girl with the judicious use of diuretics such as mannitol and appropriate fluid loading. Alkalinisation of the urine with sodium bicarbonate, 1 mmol/kg in a child (1 mL/kg of 8.4% solution or 2 mL/kg of 4.2% solution) or 50 mmol in pregnancy increases the excretion of myoglobin.

Arrhythmias can occur up to a considerable time after the electrocution, and continuous ECG monitoring is helpful (if available).

## 7.3.E Drowning

### BOX 7.3.E.1 Minimum standards

- ABCD and **early** basic life support.
- Early management of hypothermia: radiant heat/hot-water bottles.
- Low-reading thermometer.
- Orogastric or nasogastric tube.
- High-dependency care (if available).

### Introduction

#### Definition

**‘Drowning’ is defined as ‘a process resulting in primary respiratory impairment from submersion/immersion in a liquid medium’.**

According to WHO data, in 2004 there were 388 000 known deaths as a result of drowning worldwide, although the WHO considers this to be a massive underestimate. For children under the age of 15 years, drowning is the leading cause of accidental death worldwide. The low- and middle-income countries account for 96% of unintentional drowning deaths, and over 60% of the world’s drowning events occur in the Western Pacific Region and South-East Asia, although the above figures do not include the massive loss of life from floods and tsunamis and from water transport accidents.

#### Pathophysiology

Bradycardia and apnoea occur shortly after submersion as a result of the diving reflex. As apnoea continues, hypoxia and acidosis cause tachycardia and a rise in blood pressure. Between 20 seconds and 5 minutes later, a breakpoint is reached, and breathing occurs. Fluid is inhaled and on touching the glottis causes immediate laryngeal spasm. After a variable but short period of time the laryngospasm subsides and fluid is aspirated into the lungs, resulting in alveolitis and pulmonary oedema. Hypoxia is by this time severe and the patient will have lost consciousness. Bradycardia and other dysrhythmias can also occur and may be fatal (ventricular fibrillation is rare).

Hypoxia is thus the key pathological process that ultimately leads to death, and needs to be corrected as quickly as possible.

Children who survive because of interruption of this

chain of events not only require therapy for drowning, but also assessment and treatment of concomitant hypothermia, hypovolaemia and injury (particularly spinal). Major electrolyte abnormalities due to the amount of water swallowed seldom occur.

The type of water is associated with infections with unusual organisms, and aspiration of water contaminated with petroleum products can lead to a severe respiratory distress syndrome.

Submersion injuries are generally associated with hypothermia. The large body surface area to weight ratio in infants and children puts them at particular risk. Hypothermia may have a protective effect against the neurological sequelae following hypoxia and ischaemia, but is also associated with life-threatening dysrhythmias, coagulation disorders and susceptibility to infections.

The initial approach to the drowning patient focuses on the correction of hypoxia and hypothermia, and the treatment of associated injuries, which are common in older children and often overlooked. Cervical spine injury should always be suspected in drowning victims for whom the mechanism of injury is unclear, although these are rare (0.5% overall, and much rarer in children under 5 years).

#### Remember:

- Small children can drown in small volumes of water (e.g. in a bucket or shallow pool).
- Not all drowning is accidental (consider the possibility of abuse or neglect).
- Other injuries may be present.
- Other illnesses may have resulted in the drowning (e.g. epilepsy).
- Consider the possibility of drug or alcohol abuse.

#### Properties of water

- Water can be fresh (hypotonic) or salty (hypertonic).
- Water can conceal hidden dangers, such as trauma, entrapment, tide and flow, and contamination.
- Water can act as a solid at high-impact velocity.
- Water may be only one of several problems affecting the child (consider alcohol, drugs, child abuse, epilepsy, trauma, etc.).

#### Problems that may be present at drowning

- Hypothermia.

- Hypoxia.
- Pulmonary oedema.
- Hypotension.
- Ventricular arrhythmias and cardiac arrest.
- Cerebral depression, coma and hypoxic–ischaemic brain injury.
- Other injuries, especially spinal and head injuries.
- Electrolyte disturbances.
- Ingestion of alcohol, anticonvulsant drugs, etc.
- Pre-existing epilepsy.

### Primary assessment and resuscitation

Call for help and move the victim from the water as quickly as possible without risk to the rescuer, in order to allow CPR and ABC to proceed.

Rescue of the victim in a vertical position may lead to cardiovascular collapse due to venous pooling. However, horizontal rescue in the water must not be allowed to delay the rescue.

The initiation of **early and effective basic life support is vital**. ABC reduces the mortality drastically and is the most important factor for survival. Five rescue breaths must be given as early as possible even in shallow water, if this can be done without risk to the rescuer. Mouth-to-nose ventilation may be easier in this situation. Basic life support (see Section 1.12) then proceeds according to the standard paediatric or maternal algorithm, even in hypothermia. The presence of cardiac arrest can be difficult to diagnose, as pulses are difficult to feel. If there are no signs of life, chest compressions should be started and continued with a rate of 15 compressions to two breaths.

**Airway** and manual in-line cervical spine control (if there is a major suspicion of unstable neck injury) are the first steps. Following submersion, the stomach is usually full of swallowed water. The risk of aspiration is therefore increased, and the airway must be secured as soon as possible on arrival at a healthcare facility. The best airway protection is usually provided by endotracheal intubation using a rapid sequence induction, once in a hospital setting. Following this, an oro- or nasogastric tube should be inserted.

**Breathing:** commence and continue mouth to mouth or mouth to mouth and nose ventilation.

**Circulation:** commence and continue chest compressions in the ratio 15 compressions to 2 ventilations until a satisfactory output is achieved, confirmed by palpation of a pulse or signs of life (i.e. breathing, movement or gagging).

Keep the victim as warm as possible. Remove wet clothing and wrap in dry garments/towels if this can be done by bystanders without interrupting CPR.

If in a hospital setting or professional help has arrived, advanced life support protocols can be followed if necessary (see Section 1.13).

Respiratory deterioration can be delayed for 4–6 hours after submersion, and even children who have initially apparently recovered should be observed for at least 8 hours. Keep the oxygen saturation in the range 94% or higher. Once the circulation is restored, take blood for haemoglobin, electrolytes (if available) and cross-matching. If the patient is in shock, give 10 mL/kg of Ringer-lactate or Hartmann's solution. Reassess and repeat if required. Give fluids warmed to body temperature if possible.

**Disability** and neurological examination (AVPU scale).

**Exposure** and temperature control: the core temperature measurement is best taken with a low-reading thermometer.

### Secondary assessment and emergency treatment

Ensure that there are no other injuries requiring treatment. Examine the patient from head to toe. Any injury may have occurred during the incident that preceded immersion, including spinal injuries (see Sections 4.2.D and 7.3.A). Older children or pregnant women may have ingested alcohol and/or drugs.

### Hypothermia

A core temperature reading should be obtained as soon as possible, and further cooling prevented. Hypothermia is common following drowning, and adversely affects resuscitation attempts unless it is treated.

The advantages of endotracheal intubation in hypothermia (if a skilled person is available) outweigh the small risk of precipitating arrhythmias. Not only are arrhythmias more common, but some, such as ventricular fibrillation, may be refractory to treatment at temperatures below 30°C, when defibrillation should be limited to three shocks (see Section 1.13) and inotropic or anti-arrhythmic drugs should **not** be given.

If defibrillation is unsuccessful, the patient should be warmed to above 30°C as quickly as possible, when further defibrillation may be attempted. The dose interval for resuscitation drugs is doubled between 30°C and 35°C. Resuscitation should be continued until the core temperature is at least 32°C or cannot be raised despite active measures.

Once above 32°C the temperature should ideally rise by 0.25–0.5°C per hour to reduce haemodynamic instability. Most hypothermic patients are hypovolaemic. During rewarming, vasodilatation occurs, resulting in hypotension which requires warmed IV fluids, but it is important not to give too much and risk circulatory overload and pulmonary oedema. Continuous monitoring of the pulse rate, respiratory rate and liver size, and auscultation of the lungs looking for crepitations that might suggest pulmonary oedema, are essential. Therapeutic hypothermia (32–34°C) for at least 24 hours has been shown to improve the neurological outcome in some patients, and may be of benefit in children who remain comatose, but requires high-level intensive care facilities.

### Rewarming strategies

#### External rewarming

- Remove cold wet clothing.
- Supply warmed dry blankets.
- If these are not immediately available, place the child in skin-to-skin contact with an adult (kangaroo-type care).
- Warm air system (fan heaters).
- Heating blanket.

#### Core rewarming

- Warm IV fluids to 39°C to prevent further heat loss.
- Beware rewarming shock. Do not allow the temperature to rise > 37°C.

#### Monitoring

- Core temperature.

- Vital signs: heart rate, respiratory rate, blood pressure, capillary refill time and pulse volume.
- ECG tracing (if available).
- Glucose, electrolytes, and **blood gases (if available)**.
- Basic blood clotting tests.
- Chest X-ray.
- Urine output and urinalysis.
- Blood culture.

Prophylactic antibiotics are often given after immersion in severely contaminated water. Fever is common during the first 24 hours, but is not necessarily a sign of infection. Gram-negative organisms, especially *Pseudomonas aeruginosa*, are common, and *Aspergillus* species have been reported. If an infection is suspected, broad-spectrum IV antibiotic therapy (e.g. cefotaxime) should be started after blood and sputum cultures (if available).

Keeping the patient normoglycaemic is important for the neurological outcome.

### Prognosis

The outcome is determined by the duration of hypoxic-ischaemic injury and the adequacy of initial resuscitation. It is assumed that hypoxic brain damage is reduced when the brain cools before the heart stops. No single factor can predict good or poor outcome in drowning reliably. However, the following factors may give an indication of outcome.

### Immersion time

Most children who have been submerged for more than 10 minutes have a very small chance of intact neurological recovery or survival.

### Time to basic life support

Starting basic life support at the scene greatly reduces mortality, whereas a delay of more than 10 minutes is associated with a poor prognosis.

### Time to first respiratory effort

If this occurs within 3 minutes after the start of basic cardiopulmonary support, the prognosis is good. If there has been no respiratory effort after 40 minutes of full cardiopulmonary resuscitation, there is little or no chance of survival

unless the child's respiration has been depressed (e.g. by hypothermia, medication or alcohol).

### Core temperature

Pre-existing hypothermia and rapid cooling after submersion also seem to protect vital organs and can improve the prognosis. A core temperature of less than 33°C on arrival and a water temperature of less than 10°C have been associated with increased survival. This effect is pronounced in small children because of their large surface area to weight ratio.

### Persistent coma

A persistent GCS score of less than 5, or a score of U on the AVPU scale, indicates a poor prognosis.

### Type of water

Whether the patient was in salt or fresh water has no bearing on the prognosis.

### When to stop resuscitation

- Immersion time: most children who do not recover have been submerged for more than 10 minutes.
- If the first gasp occurs between 1 and 3 minutes after cardiopulmonary resuscitation, the prognosis is good.
- Intact survival has been reported after cold submersion for 1 hour.
- Survival has been reported after 6.5 hours of cardiopulmonary resuscitation.
- A child has been revived from a body temperature of 15°C **but** cool-water drowning does not have the protection offered by ice-cold water.
- Failure to restore a perfusing rhythm within approximately 30 minutes of rewarming to 32–35°C makes further efforts unlikely to be successful.
- **Resuscitation should not be discontinued until the core temperature is at least 32°C or cannot be raised.**

Resuscitation should only be discontinued out of hospital if there is clear evidence of futility, such as massive trauma or rigor mortis.

## 7.3.F Heat stroke and hypothermia

### BOX 7.3.F.1 Minimum standards

#### Heat stroke

- ABC.
- Shock treatment.
- Ice packs.
- Fans.

#### Hypothermia

- Skin-to-skin contact with carer.
- Warm blankets and clothing.
- Heated blanket.
- Infra-red warming lamp

### Heat stroke

#### Clinical signs

- Confusion.
- Tachycardia.
- Fever (> 40°C)
- Hot dry skin.
- Tachypnoea.
- Hypotonia.

#### Pathophysiology

- Neurological impairment.
- Renal insufficiency.
- Disseminated intravascular coagulation.
- Acute respiratory failure.

- May have underlying infection predisposing to heat stroke.

#### Treatment

- **Urgent cooling:** Aim to cool the patient within 30 minutes. Remove clothes, spray with cool water, use a fan if available, and apply ice packs to the neck, axillae and groin. **It is especially important to cool the head.**
- Provide system support as necessary.
- Give fluids intravenously, especially if there is respiratory failure.
- Give oxygen.
- In hot climates, each hospital should have a cool room (ice or air-conditioned) for emergency treatment.

#### Hypothermia: prevention and treatment

Hypothermia occurs in association with drowning, and it may also occur during sepsis, especially in the very young child. Malnourished children in particular have a low metabolic rate. The thermoneutral temperature is 28–32°C. At 24°C they can become hypothermic. Those with infection or extensive skin lesions are at particular risk. A hypothermic malnourished child should always be assumed to have septicaemia.

#### Signs

The signs of hypothermia are a core temperature (oral)

< 35.5°C (with low reading thermometer). If axillary temperature is < 35°C or does not register, assume hypothermia.

#### Routine prevention

- Cover all sick children with clothes and blankets unless they are febrile.
- Keep the ward doors and windows closed to avoid draughts.
- Avoid wet nappies, clothes or bedding.
- Do not wash very ill children. Others can be washed quickly, ideally with warm water, and dried immediately.
- Avoid making a sick or injured child cold when undertaking medical examinations.

#### Emergency treatment of hypothermia

- Immediately place the child on the carer's bare chest or abdomen (skin to skin) and cover both of them. Give the mother a hot drink to increase her skin blood flow.
- If no adult is available, clothe the child very well (including the head) and put them near a lamp or radiant heater, or use a warming blanket if one is available.
- Immediately treat for hypoglycaemia (see Section 5.8.B), and then start normal feeds if appropriate to the child.
- Consider sepsis, and give condition- and age-appropriate antibiotics.
- Monitor the temperature every 60 minutes until the temperature is normal (> 36.5°C).

### 7.3.G Landmine injuries

#### BOX 7.3.G.1 Minimum standards

- ABC resuscitation.
- Shock management.
- Analgesia.
- Anti-tetanus immunisation and immunoglobulin.
- Prostheses that are changed as the child grows.

#### Patterns of injury

- **Injuries caused by stepping on to a buried blast mine or improvised explosive device (IED):** traumatic amputation of the detonating limb, with fragment and minor blast damage to the other leg (most common injury).
- **Injuries caused by fragmentation landmine or IED:** widespread fragment injury to the limbs and trunk.
- **Injuries caused by close-proximity detonation of a landmine or IED in the hand or close to the face:** amputation of the hand or arm, plus damage to the face, eyes and head. Usually occurs in mine clearers or in those handling weapons.

Some mines are scattered from aircraft or by shells to lie on the surface of the ground. These weapons are unstable and likely to explode when handled. Unexploded ordnance, such as grenades, can also explode if handled, resulting in the same pattern of injury. Recently IEDs have been placed next to roads and pathways, causing similar injuries.

#### Specific problems in children

- Children sustain a higher level of injury per gram of explosive than adults, because of their smaller body mass. A small antipersonnel mine of approximately 30 grams, which would normally require a below-knee amputation in an adult, may result in an above-knee amputation in a child.
- Children are susceptible to close-proximity detonation injuries, because of their tendency to pick up and play with objects that they find.

#### Treatment

- Initial surgical management follows the basic principles of resuscitation (see Section 7.3.A).
- In injury caused by stepping on a buried blast mine or IED, airway maintenance is not usually a problem, as the child is frequently conscious.
- As with all injured children, fear and bewilderment due to pain and the unfamiliar surroundings can be distressing for all involved.
- In close-proximity detonation injury, airway maintenance can be a problem. The patient is often unconscious and there may be damage to the upper airway from the blast. A tracheostomy may be required.
- Benzylpenicillin and anti-tetanus toxoid should be administered in all cases.
- Anaesthesia can be achieved using a ketamine infusion (see Section 1.15 for pain relief).

### Injury from stepping on to a buried blast mine or IED: technique of amputation

- On the operating table, a thorough wash with warm clean water and a scrubbing brush will get rid of the gross contamination and general soiling of the limbs prior to formal skin preparation.
- **Always use an above-knee orthopaedic tourniquet to minimise peri-operative blood loss**, which is proportionally greater in children than in adults.
- Perform a standard amputation according to International Committee of the Red Cross surgical guidelines. Remember the following points:
  - The muscles are usually contused more proximally by blast damage than may be initially apparent.
  - Dirt and contamination can be propelled up tissue planes by the blast. An amputation through the blast damage can leave contamination in the wound.
  - Make a bulky myoplasty to cover the bone end using the medial gastrocnemius below the knee, or the medial vastus above the knee. Leave generous skin flaps, as the muscle in the stump will swell considerably post-operatively.
- Make an anterior bevel to the bone when dividing it, and file the edges down.
- Let the tourniquet down when the amputation is completed, to check haemostasis before applying the dressing.
- Perform thorough wound toilet of the injuries to the other leg. Explore all wounds and excise contaminated tissue. Leave these wounds open to be closed or skin grafted at 5 days post-operatively.
- **Never close the amputation stump primarily.** Lightly pack the open stump with gauze and apply a bulky dressing. Write on the dressing the date for wound inspection (usually at 5 days post-operatively).
- Do not take the dressing down on the ward unless the patient manifests signs of systemic toxicity (i.e. fever, tachycardia, foul-smelling dressing).
- Give blood only if the haemoglobin level falls to less than 8 grams/dL.
- Give IV benzylpenicillin for 48 hours (50 mg/kg 6-hourly), then orally for a further 3 days (12.5 mg/kg four times daily).
- Give appropriate tetanus prophylaxis (see Section 7.1).
- Inspect the wound at 5 days. If the tissue is healthy and not infected, close with interrupted non-absorbable sutures over a drain. Leave the sutures in for 3 weeks.
- Early physiotherapy is crucial to success, especially to eliminate flexion contracture of the below-knee amputation.
- Refer early to a prosthetic workshop for casting. Children will need several sets of prostheses as they grow.

## 7.3.H Gunshot wounds

### BOX 7.3.H.1 Minimum standards

- ABC resuscitation.
- Shock.
- Analgesia.
- Anti-tetanus immunisation and immunoglobulin.
- Penicillin.
- X-rays and ultrasound.
- High dependency care.

### Introduction

Although the end of the Cold War led to a reduction in the risk of conflict in Europe, numerous conflicts continue to rage in the developing world. Many of these conflicts are between ill-disciplined or irregular armies who often specifically target civilian populations in defiance of the Geneva Conventions. In this process, children are inevitably susceptible to sustaining gunshot wounds.

The International Committee of the Red Cross has drawn attention to the global proliferation of weapons. For example, there are estimated to be as many as 125 million AK47 assault rifles in circulation worldwide. As conflicts resolve, these weapons become marketable commodities and spread to neighbouring states, where they become the criminal's weapon of choice. The net result of this is injury to the civilian population, including children.

### Ballistics

The science of ballistics addresses aspects of missile and

bullet flight and relates these to the potential for injury. The following issues are relevant to the mechanism of wounding:

- When a bullet impacts on tissue it will impart some of its kinetic energy to that tissue.
- This will cause the tissue to accelerate away from the track of the projectile, resulting in a **temporary cavity**.
- Once the bullet has passed, the inherent elasticity of the tissues will cause the temporary cavity to collapse, leaving some degree of **permanent cavity** along the track.

The extent to which cavitation occurs is governed by the amount of kinetic energy imparted to the tissues by the projectile. The equation governing this is as follows:

$$\text{kinetic energy} = \frac{1}{2} m (V_1^2 - V_2^2)$$

where  $m$  is the mass of the projectile,  $V_1$  is the velocity on entering the tissues and  $V_2$  is the velocity on exiting. The degree to which the projectile's velocity is attenuated while transiting the tissues is dependent upon the diameter of the bullet, its orientation and flight characteristics on impact, and the nature of the tissue itself.

### Categories of gunshot wounds

In practice, the masses of most commonly used bullets are similar, and thus the velocity of the projectile largely defines the injury potential. In this regard, gunshot wounds can largely be divided into three categories depending on the nature of the weapon used.

### Handguns

- The commonest types of handgun feature a bullet with a diameter of 9 mm and a muzzle velocity of around 1000 feet/second.
- Only a small temporary cavity is formed, and the injury is essentially confined to the bullet track.
- Provided that the bullet has not transected any major structures, the degree of injury may only be slight.
- Some of the bullets for these types of weapon are designed to deform on impact. These are the hollow or soft- (lead-) tipped bullets. On impact they tend to flatten, presenting a greater surface area to the direction of travel, thus resulting in an increased transfer of energy and greater wounding effect.

### Shotguns

- The cartridge contains multiple pellets of a specified diameter.
- This diameter can range from 1 mm ('birdshot') to 10 mm ('buckshot').
- Once fired, the pellets disperse in a cone-shaped pattern.
- The degree and rapidity of dispersion are proportional to the size and number of pellets as well as the diameter of the shotgun barrel at the muzzle.
- Due to their aerodynamics, the velocity of individual pellets will attenuate over short distances, even in air. Furthermore, the conical dispersion leads to a rapid decline in the number of pellets that will hit a particular target as the range increases.
- The above factors lead to this weapon being virtually ineffective at ranges over 50 metres.
- A severe pattern of injury is seen at close range. Although each pellet may only be travelling at low ballistic velocity, the combined effect of multiple pellets is a formidable destructive force, shredding the tissues and causing massive disruption.

### Military assault rifles

- These weapons typically have a bullet 7.62 mm in diameter that leaves the weapon at a speed of around 3000 feet/second.
- Rifling of the barrel sets the bullet spinning, which, combined with the increased velocity, leads to greater accuracy at long range.
- Rather than following a uniform flight path, the bullet has a periodic motion, oscillating around its flight axis with the movements of precession, nutation and yaw.
- The very much greater kinetic energy of these bullets leads to a much larger temporary cavity than is seen in low-velocity munitions.
- The sub-atmospheric pressure in the cavity will tend to suck in clothing and other debris from outside the wound, causing contamination.
- The shock front of accelerating tissue, propagating away from the point of impact, causes stretching and tearing of the tissues, cellular disruption and microvascular injury.
- The margin of tissue around the cavity, termed the **zone of extravasation**, is full of haemorrhage, has little tendency to further bleeding and, if muscle, shows no tendency to contract when stimulated. This tissue is non-viable and will become a culture medium for infection if left *in situ*.

- The shock wave itself can cause fracture of bone and intimal disruption of major vessels.
- The oscillating nature of the bullet trajectory can cause it to 'tumble' on impacting with the tissues. When this occurs, due to the non-uniform motion, even greater proportions of the kinetic energy are transmitted. The resulting tissue acceleration can lead to the exit wound made by such a bullet being very much larger than the entry wound.
- The nature of the tissue being transited has a great impact on the extent of damage occurring. Relatively elastic, compressible tissue such as lung propagates the shock wave to a much lesser extent than dense, fluid-filled tissue such as liver. Therefore a high-velocity bullet may transit lung causing only contusion, whereas transiting solid organs causes gross disruption.

### Treatment

Although it is clearly impossible to cover the treatment of gunshot wounds to every possible anatomical structure in the body, there are some themes common to all such injuries. Most of the wounds encountered will be to the limbs, as gunshot wounds to the head, chest and abdomen have a high rate of on-scene mortality.

Protocols for treating gunshot wounds have been adopted and publicised by the International Committee of the Red Cross (ICRC), who have extensive experience of treating such injuries as part of their war surgery programmes.

### Initial measures

The initial measures in the treatment of gunshot wounds are similar to those for any severe injury.

- General assessment and resuscitation of the patient, addressing potentially life-threatening conditions according to ABC priorities (compressing exsanguinating haemorrhage, airway, breathing, circulation), is the priority (see Section 7.3.A).
- The degree to which fluid resuscitation should be carried out has been controversial. An initial bolus of 10 mL/kg in a child or 500 mL in pregnancy of Ringer-lactate or Hartmann's should be given and the response to this initial fluid challenge assessed. The concern is to avoid restarting massive bleeding again from disrupting a just-clotting wound by increasing peripheral perfusion. So until the patient can be in a position to have any torn vessels managed, i.e. be in an operating theatre with competent staff, and receive a blood transfusion, crystalloid fluid management remains the minimum that keeps vital organs perfused.
- Give analgesia as required (usually IV morphine) (see Section 1.15).
- Apply dressings to the open wounds.
- Undertake emergency splintage of fractures.
- Antibiotics: the ICRC recommend IV benzylpenicillin at a dose appropriate to the size of the child (usually 50 mg/kg IV 6-hourly) and in pregnancy 600–1200 mg IV 6-hourly.
- Give tetanus toxoid and antitetanus serum.
- Appropriate radiographs of the injured areas should be taken.

**Wound assessment**

Before proceeding to surgical treatment, the following aspects of the wound need to be assessed:

- From the history, the nature of the weapon used (if known).
- The site of the entrance wound (and exit wound, if present).
- The sizes of the entrance and exit wounds.
- Cavity formation.
- The anatomical structures that may have been transited.
- Distal perfusion.
- Presence of fractures.
- Degree of contamination.

**Wound debridement and management**

This involves removal from the wound of any dead and contaminated tissue which if left would become a medium for infection. It is most relevant to high-energy-transfer (high-velocity) wounds, which feature large cavities and considerable amounts of dead tissue and contamination.

- Wound debridement should be a planned procedure with prior consideration given to the position of the patient and the type of anaesthesia required.
- For limb wounds, a pneumatic tourniquet should be used where possible to reduce blood loss.
- Skin incision decompresses the wound and allows swelling of the tissues without constriction.
- Where possible, the incisions should be longitudinal and not cross joints.
- Skin is a resilient tissue, so only minimal excision is usually necessary.
- Dead and contaminated tissue should be excised.
- Dead muscle is dusky in colour, shows little tendency to bleed, and does not contract to forceps pressure.
- Foreign material should be excised from the wound. However, the obsessive pursuit of small metallic debris, such as that from a disintegrating bullet or shotgun pellets, is not worthwhile.
- Bone fragments denuded of soft-tissue attachment (muscle or periosteum) should be removed as, if left in the wound, they will become infected and form osteomyelitic sequestrae.
- There should be no primary repair of nerve or tendon. Where obviously divided, these structures should be marked (with suture) for later repair.
- At the end of the procedure, the debrided wound should be washed with copious quantities of saline and then a dry bulky sterile dressing applied.
- Some low-energy-transfer (low-velocity) wounds, such as those from most handguns, because of the minimal cavitation and zone of extravasation, do not need the extensive debridement and excision outlined above. These wounds can, in certain circumstances, be managed without surgery.

**Delayed primary closure**

Once wound debridement has been undertaken, the patient can be returned to the ward and the following regime followed:

- Continued analgesia.
- Benzylpenicillin; IV 50 mg/kg every 4 hours for the first 24 hours and then orally for a further 4 days (12.5 mg/kg four times daily).
- Monitoring of the patient for signs of sepsis; check their tetanus status.
- The dressing should be left in place on the ward and only removed when the patient returns to theatre after an interval period for **delayed primary closure**.
- The ICRC recommend an interval period of 5 days, but most recent practice tends towards shorter periods of 48–72 hours.
- The only indication for return to theatre and dressing removal before this interval period has elapsed is an offensive dressing combined with signs of patient sepsis. The most common cause of this situation is an inadequate initial wound excision.

In the process of delayed primary closure:

- The dressing should be removed in theatre under appropriate anaesthesia.
- If clean, the wound can be closed, or if skin cover is deficient, split-skin grafted.
- If there is evidence of infection, further debridement/excision can be undertaken and the process repeated, aiming for delayed closure after a further 5 days.
- Following closure, rehabilitation of the injured part can commence.

**Specific features relating to certain anatomical sites**

- Wounds of the head and neck, by virtue of the enhanced vascular supply to these areas, can safely be closed or reconstructed at the initial operation.
- Wounds to major vessels need to be reconstructed primarily.
- Breaches of the dura, pleura and peritoneum should, where possible, be closed at initial surgery.
- Most gunshot wounds to the chest can be treated with tube thoracostomy alone.
- Penetration within 5 cm of the midline of the thorax or abdomen is associated with a risk of injury to the great vessels or heart.
- Gunshot wounds to the head that transit the cranial cavity carry a very poor prognosis, especially if from a high-energy-transfer weapon.
- Penetrating gunshot wounds of the abdomen are associated with a more than 85% chance of bowel or major organ transit. Exploratory laparotomy is therefore virtually mandatory.

**Conclusion**

Gunshot wounds from any type of weapon represent a severe injury. Some understanding of ballistics can help in the assessment of these injuries. Treatment according to basic principles, such as those recommended by the International Committee of the Red Cross, can lead to a satisfactory outcome even with limited clinical resources.

### 7.3.1.a Ingestion burns

#### BOX 7.3.1.A Minimum standards

ABCD management.

- IV steroids.
- Stomal feeding.
- Oesophageal dilation/stenting.
- Oesophageal reconstruction.

#### Introduction

Oral and oesophageal burns occur in three groups of patients: unintentional ingestion of hot or caustic liquids by young children, or by people of any age with delayed development (poor supervision plays an important part in each of these two groups), and ingestion to cause intentional self-harm.

#### Types of ingestion burns

##### Hot fluids

- Burns from drinking hot fluids are relatively rare in developmentally normal children, but can occur in those with learning difficulties.
- Normally only the mouth is burned.
- Swelling and blistering can be very rapid, and require an oral or nasal (preferred) airway.
- Swelling usually goes down within 48 hours, and the need for further treatment is unusual.

##### Caustic fluids

- Burns from drinking caustic fluids are much more severe.
- In general, caustic alkali solutions are more damaging to tissues than acids.

##### Immediate treatment

- In the home or at the place where ingestion occurred, the **immediate** drinking of a small amount of milk (this is futile after 30 minutes) may have some beneficial effect in the case of ingestion of solid or granular alkalis, but not for liquid alkalis or for acids.

##### Hospital treatment

- Assess Airway, Breathing and Circulation. If there are signs of respiratory distress with stridor, the airway must be urgently secured. Intubation is difficult and may cause perforation, so a cricothyroidotomy followed by a tracheostomy may be needed.
- **Do not make the child vomit**, as burning fluid causes further damage when passing up the oesophagus.

### 7.3.1.b Burns in children and in pregnancy

#### BOX 7.3.1.B Minimum standards

- ABC management.
- Analgesia.
- Antiseptic dressings.
- Anti-tetanus immunisation.
- Antibiotics.

- **Do not pass a tube into the stomach**, as this may perforate the oesophagus. A gastrostomy will usually be needed
- **Do not attempt to neutralise the chemical** (e.g. by giving acid for alkali ingestion, or alkali for acid ingestion), as this will cause a high-temperature reaction that will further damage the tissues.
- **Do not give more milk or give water**: it is too late and may precipitate vomiting and more damage to the oesophagus.

#### Definitive treatment

The only way to assess the oesophageal damage is by **flexible oesophagoscopy**. If there are significant signs of inflammation, steroids are often used, and there is some evidence that they can reduce the severity of any developing stricture. The route will have to be parenteral (hydrocortisone 4 mg/kg every 6 hours, maximum dose for children under 2 years is 25 mg, for those under 5 years is 50 mg, and for those over 5 years is 100 mg per dose). The length of treatment is not identified, but should be short (3–4 days) in view of the effect of steroids on healing and immunity.

Significant stricture formation will **need reconstructive surgery** or a gastrostomy (see below).

#### Complications

- Serious burning, particularly of the oesophagus, can lead to perforation, and in the later stages to strictures.
- Acute perforation of the oesophagus is frequently fatal; treat by drip and suction and then thoracotomy if severe.
- Late stricture during and after the healing phase is a very common problem after ingestion of caustic fluids.
- Mild cases can be treated by later dilatation of the oesophagus.
- **More severe cases may require an oesophagectomy, followed by a stomach pull-up or small bowel replacement.**
- However, if the stricture reduces the ability of the child to eat, a feeding gastrostomy tube passed through the abdominal wall directly into the stomach may be needed to provide nutrition.

#### Prevention

- Parents and teachers must be informed about the need to keep dangerous fluids out of the reach of children.
- Never put chemicals in the wrong bottles or containers.

#### Summary of actions (more information on each action below)

- Primary assessment and resuscitation according to ABC. If there are signs of developing or actual airway obstruction, call for an anaesthetist, open the airway and consider early intubation before swelling and total respiratory obstruction occur. Observe closely for shock.

- Take a very brief history, and consider whether there could be other injuries or medical conditions.
- Make a rapid assessment of the burn area, take care with clothing removal.
- If there are clearly more than 10% burns, establish an IV cannula and give IV analgesia (morphine according to age and weight see Section 1.15).
- Commence either Ringer-lactate or Hartmann's solution IV in the following volumes in mL:

burn (%) × weight (kg) × 4 per day for a child

burn (%) × weight (kg) × 2 to 4 per day in pregnancy

- Fluid is given over the first 24 hours, backdated to the time of the burn. Half of the fluid should be given (in hourly divided doses) during the first 8 hours, and the second half in the next 16 hours, again in hourly doses. This is **in addition to** maintenance fluids which can be given later and orally if the child is able to take these (see below). Any fluid boluses given IV to treat shock should be **included** in the additional fluid for the burn and subtracted from that calculated as described above.
- Normal (0.9%) saline can be used if Ringer-lactate or Hartmann's solution are unavailable, but be aware that, especially in larger volumes, normal saline causes a hyperchloraemic acidosis which is detrimental to sick or injured patients.
- Even if there are less than 10% burns, consider IV opiate analgesia if the patient is clearly distressed by pain.
- Do not give oral fluids immediately.
- Make an accurate assessment of the area of the burn and draw its position on a chart (see Table 7.3.1.B.1 and Figure 7.3.1.B.1).
- Estimate the depth of the burn.
- Establish, and if necessary update, the anti-tetanus status of the patient.
- Consider and decide whether an escharotomy is necessary for circumferential burns on a limb or the chest that may cause tissue necrosis from compression by swelling tissues or restriction of ventilation.
- Dress the burned areas, or treat any area that is going to be kept exposed.
- Consider and decide whether the patient needs admission (for a child, with their parent).
- Commence oral fluids if the patient can drink. If not, add the maintenance fluids to those given for the burn as calculated above. In burns over 8% divide the calculated daily maintenance requirement by 24 and give it on an hourly basis either orally or IV.
- Decide whether the patient requires urinary catheterisation (over 30% burns, or burns with complications).

## Introduction

The skin is a barrier to infection and evaporative fluid loss. It is a sensory organ and it regulates temperature through sweating.

- The severity of a burn depends both on the area of the body involved and on the depth of the burn.
- The majority of burns in children occur in those under 2 years of age and are caused by hot fluids or flames.
- Other causes include electricity, chemicals, radiation and frostbite.

Burns are more common where there is poverty from overcrowding and unsafe heating and cooking practices.

## Definition of terms

**Erythema or first-degree burn:** This causes an increase in skin capillary blood flow. In pigmented skin it is often difficult to recognise, but is characterised by pain, and a slight thickening and change in texture of the surface of the skin with later partial or complete desquamation occurring some days afterwards. **The important feature is that blistering does not occur, and fluid is not lost from the circulation. Intravenous fluids are therefore not needed for the burn.** It heals without scarring within 2–10 days.

**Superficial partial-thickness burn:** This is skin in which there is early (within 1 hour) blistering following the injury, associated with pain. If the blisters are removed (**do not remove them**), the exposed surface is shiny, loses pigmentation in pigmented races, and is extremely painful. Pressure on the surface causes blanching, which on release of the pressure instantly becomes red again. It heals within 7–14 days with mild pigmentation change or scarring.

**Deep dermal burn:** Red blood cells leave the capillaries and become fixed in the dermis. In non-pigmented skin, therefore, the redness does not blanch on pressure. This is much more difficult to diagnose in pigmented skin, but the skin becomes thicker and harder in the area. Blistering occurs later, or may not occur at all. If the burn is in the deeper part of the dermis, the heat breaks down the red cells and the area becomes white with no blanching present. Removal of the blistering, if it has occurred, leaves a bed that is wet and shiny, but has only mild discomfort as the nerve endings have been damaged. It heals within 14–21 days with scarring which is often hypertrophic. Grafting will usually be required.

**Both of the last two categories may be called a second-degree burn, but as the treatment may be different, the type that is present should be accurately diagnosed.**

**Deep burn:** All elements of the skin and the skin hair follicles, sweat glands, etc. are destroyed. The skin is either white or charred brown. No blistering occurs. **It is painless on examination.** Severe scarring occurs and grafting will always be required. **This may be called a third degree burn.** A burn involving tissue damage occurs at temperatures above 48°C and after only 1 second at 70°C.

Capillary permeability is increased for up to 48 hours, and is maximal at 8 hours. With large burns there is increased blood viscosity, haemoglobinuria may occur, and there is a loss of protein, which needs to be corrected by adequate nutrition.

## First aid

Cold water rapidly applied is the best first aid. The quicker this is done, the better. The longer the skin is in contact with the flame or hot fluid, the greater is the extent and depth of burning. The best first aid in all situations, except those involving electricity, is cold water or other cold fluid (e.g. milk) applied as soon as possible. It is less important whether the water is sterile or not, and it should be applied before the clothes are removed, as removal can often take some time. Cold water reduces the severity of the burn as it removes thermal energy, and also reduces pain. It should ideally be applied for approximately 10 minutes,

but no longer. Following this, the burn should be covered with clean sheets or towels or 'clingfilm' plastic wrapping.

If the cause of the burn is electricity, it is important that the patient is isolated from the electricity supply or that it is turned off before cold water is applied, otherwise greater damage may be caused.

Following the period of cooling with water, **the patient needs to be kept warm**, otherwise **hypothermia can result**, particularly in young babies.

### Primary assessment

- Assessment of a burn must be carried out in the same way as assessment of any other injury.
- It is quite possible that the burn is not the major injury or problem when the patient is seen. For instance, it may have been an epileptic attack that caused the burn, or the patient may have fallen or jumped from a burning house, or been involved in a road traffic accident and therefore has multiple fractures and/or a head injury.
- **Special issues regarding burns in pregnancy.** Any burn affecting more than 20% total body surface area (TBSA) is a serious risk to the mother and fetus. In a mother with a burn > 70–80% of the TBSA mortality is 50–90%. If the burn affects < 30% TBSA the prognosis is good for both fetus and mother and depends on the management of complications such as hypoxia, hypotension and sepsis.

## ABC

### Airway and Breathing

- If either of these is compromised, call for an anaesthetist and open the airway. Early endotracheal intubation may be required.
- If flame inhalation has occurred (see below for more information on inhalation burns), the airway tends to close very rapidly, making intubation very difficult. Apart from the history, the signs to observe are altered voice or presence of stridor, singeing of the nasal hairs, and deposition of soot in the throat or nose.
- Remove any constricting clothing and place the patient in dry and clean sheets or towels.
- Give additional inspired oxygen if SaO<sub>2</sub> is < 94% or the patient is cyanosed.
- If breathing is inadequate, use a bag-valve-mask and consider intubation if the airway is compromised or may imminently become so.
- Chemical damage may occur from highly irritant gases, which can lead to progressive respiratory failure.
- Many plastics and modern materials give off cyanide, which may be absorbed into the blood stream.
- Carbon monoxide is the most common poison produced in fires.

### Circulation

- Fluid is lost through the capillaries following a burn. Shock takes time to develop. In minor burns this is a local phenomenon, but **in severe burns all of the vascular bed becomes leaky**. Assess the total body surface area (TBSA) affected (see below).
- A patient with a burn of less than 10% of the total body surface area can normally cope by having their oral intake increased. However, this is not an absolute figure, and in particular if the patient is vomiting, IV fluid

may be necessary for a smaller burn. Similarly, if safe IV fluid is not available, a burn of up to 25% may have to be managed with increased oral fluids alone. When oral fluids are being used, either in combination with IV therapy or alone, only small regular doses of fluid should be given by mouth.

- For burns that are 5% or larger, oral fluids should be an electrolyte solution (ORS).
- Fluid loss is greatest in the first 12 hours, causing disturbances in fluid and electrolyte composition.
- For burns of 10% or more, secure IV access and replace fluids with warmed Ringer-lactate or Hartmann's each containing 5 or 10% glucose (see below for calculating TBSA and the Appendix for how to make up solutions containing glucose).

### Management of the circulation in pregnancy

A pregnant woman requires 2 to 4 mL per kg per 1% of body surface area burnt to be given over the first 24 hours in addition to baseline maintenance fluids. Half of this volume is given in the first 8 hours, half in the next 16 hours. *The quantity of fluid given in the first 8 hours must include any fluids given as a resuscitation bolus for shock.*

- Monitor urinary output (should be > 30 mL per hour).
- *Assess the need to deliver the fetus.* Fetal survival is poor in burns affecting > 50% TBSA. In view of the high mortality in mothers with such extensive burns, those in the second or third trimester should be delivered as soon as possible after admission as fetal survival is not improved by waiting and the presence of the fetus increases the risk to the mother. Abortion is common in patients with burns > 33% TBSA, especially during the second trimester. Fetal loss during the third trimester can be expected with extensive burns unless delivery occurs. Dexamethasone to reduce respiratory distress syndrome in a preterm infant (Section 3.1) is not contraindicated in the presence of extensive burns.

### Management of the circulation in childhood

Children usually require 4 mL per kg per 1% body surface area burnt (TBSA) to be given over the first 24 hours in addition to baseline maintenance fluids. Half of this volume is given in the first 8 hours, half in the next 16 hours. *To avoid circulatory overload, the quantity of fluid given in the first 8 hours must include any fluids given as a resuscitation bolus for shock.*

For example, if there is a 20% burn × 15 kg child × 4 = 1200 mL of Ringer-lactate or Hartmann's solution. Give 600 mL in the first 8 hours from the time of the burn.

### Intravenous fluid management

- IV Ringer-lactate or Hartmann's solution or 0.9% saline (if the former two are not available) is necessary in large burns because of the loss of the intravascular component of extracellular fluid. **Glucose 5% alone and glucose in 0.18% saline are dangerous and can lead to hyponatraemia and water overload.** However, especially in young children, watch for hypoglycaemia, which can be prevented by adding glucose to any crystalloid solution (e.g. 50 mL of 50% glucose in a 500-mL bag of crystalloid will give a 5% solution).
- Ideally, give IV fluids by peripheral or external jugular vein; in an emergency, in shock or where rapid sequence induction for intubation is needed, intra-osseous or

central venous lines may be needed, but the latter can increase the risk of infection.

- If the patient is in shock, in a child give 10 mL/kg as an IV bolus as rapidly as possible and in pregnancy give a 500 mL IV bolus and then reassess and repeat if they are still shocked, up to a maximum of three boluses.
- Wherever possible, long IV lines should not be used, as this increases the risk of septicaemia.
- Both natural colloids (i.e. albumin solution and plasma) and artificial colloids (e.g. Haemaccel, and various starch derivatives) are available. The former have risks of transmitting infection and are expensive, and the latter have not been well studied for resuscitation of burns, but are cheaper.
- Blood transfusion may be needed if anaemia develops.
- It is essential that not too much IV fluid is given, as it may lead to pulmonary and/or cerebral oedema, together with an excessive extravascular deposition of fluid. Crystalloid resuscitation can also lead to 'compartment syndrome' because of the increasing pressure within the muscular compartments and it is important to observe for pain, particularly in the lower legs.
- The amount of fluid loss from burns decreases over the first 48–72 hours after the injury. The amount of fluid to be given initially therefore depends on how long before admission the burn occurred. Following this, the assessment of the resuscitation can be made by a combination of the clinical picture, i.e. degree of dehydration, the blood haematocrit and the urine output aim for 2 mL/kg/hour of urine in a child and 30 mL/hour in pregnancy.
- It is essential that accurate and updated fluid input and output charts are kept throughout. For major burns (over 30%), hourly haematocrit (or haemoglobin) and urine outputs are helpful in the first 24 hours, decreasing in frequency thereafter. For burns between 10% and 30%, 4-hourly tests are normally sufficient.
- In larger burns (greater than 30%), burns involving the genitals, and burns in young normally incontinent female children, a urinary catheter is essential. In males, a urinary bag can be used. A catheter may also be necessary

if fluid resuscitation is not proceeding well to give an accurate picture of the urine volume produced hourly. Catheters can lead to infection and should be removed as soon as possible.

#### Enteral fluid management

- Start oral or nasogastric feeding as soon as possible after admission. If a child is being breastfed, this should continue.
- Although thirst is common, giving too much free fluid orally may induce vomiting.
- For burns between 5% and 10% the daily requirement of the patient's oral intake should be increased by 50% to allow for the burn (given on an hourly basis).
- The normal oral requirement of a child can be calculated as 100 mL/kg for the first 10 kg, 50 mL/kg for the next 10 kg, and 25 mL/kg for any weight up to the total weight of the child. The normal daily fluid requirement in pregnancy is 1500–2500 mL.
- This may need to be increased by 10% or 20% in hot climates.
- The oral fluid given should ideally be ORS. If this is not available, diluted milk is acceptable.
- If all is well after 24 hours, free fluids can be given, but careful input and output charting will continue to be required.

**Maintenance of body temperature:** burnt children can lose heat rapidly.

#### Feeding

- Early feeding (especially breastfeeding) reduces the risk of gastric stress ulcer formation and of stasis. It is recommended therefore that small quantities of food are given either orally or with a thin-bore nasogastric tube. The latter can be used to give milk or other similar high-protein foodstuffs.
- Parenteral nutrition is strongly contraindicated, as this leads to a high risk of septicaemia in burns patients.

### Burn area and depth

TABLE 7.3.I.B.1 Body proportions at different ages for burns assessment (%)

Percentage surface area at:					
Area on diagram	0	1 year	5 years	10 years	15 years
A	9.5	8.5	6.5	5.5	4.5
B	2.75	3.25	4.0	4.5	4.5
C	2.5	2.5	2.75	3.0	3.25

#### Area of burn

Estimation of the area of a burn is based on either Wallace's rule of nines, or on charts (see Table 7.3.I.B.1 and Figures 7.3.I.B.1 and 7.3.I.B.2). In addition, the area of the patient's open palm is approximately 1% of the total body surface area. Wallace's rule of nines is applicable to children over 14 years of age and to adults. For newborn babies it can be modified by adding 9% to the area of the head and subtracting 9% from the area of the legs. For every additional year of age, 1% is subtracted from the head and added to the legs until, at the age of 10 years, approximately adult proportions has been reached.

In pregnancy the abdomen represents a larger proportion of the TBSA.

The area of the patient's hand can be used for estimating the size of small burns, but can also be used to estimate the areas that are unburned in extensive burns, and this can then be extracted from the rule of nines figures (e.g. if 2% of an arm is unburned, the area of burn on that arm will be 7%).

- It is very common for inexperienced people to overestimate the size of a burn.
- **Erythema must not be included**, as fluid is not lost.
- The decision as to whether or not to start IV fluids is

**FIGURE 7.3.I.B.1** Wallace's 'rule of nines' for burns assessment in children over 14 years of age and adults.

dependent on this initial assessment, and on whether there are other injuries or medical conditions.

- An overestimate may mean that far too much fluid is given.

#### Depth of the burn

The depth of the burn is based on history, appearance and examination.

- Flame or hot fat burns are almost always deep.
- Hot water burns (scalds) may be superficial or deep dermal.
- The appearance can be altered if more than a few hours old, or by the application of various first-aid treatments.
- First assess capillary return. Prompt capillary return means a superficial burn.
- Then test sensation. Is it increased (in a superficial partial thickness burn), reduced (in a deep dermal burn) or absent (in a full-thickness burn)?
- The test is done by using a sterile hypodermic needle. In older children, and in pregnancy, it is possible to ask whether they can tell the difference between the sharp and the blunt ends when these are lightly applied to

**FIGURE 7.3.I.B.2** Body proportions at different ages for burns assessment.

the burn. In younger children the best way of doing the test is to wait until the child is sleeping or has their eyes closed, and then very gently touch what appears to be the deepest part of the burn. If there is a sudden startle reflex, it is probably a superficial partial-thickness burn. A slow awakening indicates a deep dermal burn, and if it is possible to put the needle into the burn without any response it is likely to be a deep burn.

- In full thickness burns the area is insensitive to pain and may appear dirty or white (the eschar).
- A simple test to distinguish between partial and full thickness burns is to pull a hair out: if it comes out easily the burn is full thickness.

Many superficial burns become deeper during the first 48 hours after their occurrence, and need to be reassessed at 48 hours.

#### Inhalational injury

This includes:

- thermal damage
- asphyxiation
- pulmonary irritation.

#### Thermal damage

- This is usually limited to the oropharyngeal area.
- The exceptions are injuries caused by steam, volatile gases, explosive gases or aspiration of hot liquids.

#### Asphyxiation

Combustion utilises oxygen in the burning environment, leading to hypoxia. The **production of carbon monoxide** within the burning environment causes further tissue hypoxia by:

- decreasing the oxygen-carrying capacity of the blood
- shifting the oxyhaemoglobin saturation dissociation curve towards the left
- decreasing myocardial contractility.

The highest possible concentration of oxygen should be given.

**Cyanide** gas can be released during the combustion of plastics, polyurethane, wool, silk, nylon, nitrites, rubber and paper products. It is 20 times more toxic than carbon monoxide, and can cause immediate respiratory arrest.

**Methaemoglobinaemia** occurs due to heat denaturation of haemoglobin, oxides produced in fire, and methaemoglobin-forming materials such as nitrites. Rarer than cyanide and carbon monoxide toxicity, this decreases the oxygen-carrying capacity of the blood and causes a shift of the oxyhaemoglobin dissociation curve to the left, similarly to carboxyhaemoglobin (HbCO). Again treat with high concentrations of oxygen.

#### Pulmonary irritation

- Direct tissue injury.
- Acute bronchospasm.
- Activation of the body's inflammatory response system.

#### Evidence of inhalational injury

- Burns around the mouth.
- Soot in the mouth or nostrils.
- Carbonaceous sputum.
- Singed facial or nasal hairs.
- Facial burns.
- Oropharyngeal oedema.
- Changes in the voice (hoarseness), and stridor.
- Altered mental status.
- History suggesting confinement in a smoke-filled environment.

**Symptoms may be delayed until 24–36 hours after injury. Secure the airway by endotracheal intubation before dangerous obstruction develops.**

Deliver high-flow supplemental oxygen. Inhalation of hot gas normally does not injure distal airways, as the heat-exchange capacity of the upper airway is excellent. Distal airway injury is more likely to be due to the direct effects of the products of combustion on the mucosa and alveoli.

### Treatment of skin surface burns

#### Analgesia

In all cases of shock, or potential shock, IV opiate analgesia should be given (see Section 1.15).

Oral analgesia is ineffective, and **IM analgesia can be very dangerous** because when the circulatory volume is re-established and muscle blood flow recommences, the child can become overdosed. Opiate overdose can be reversed with naloxone given intravenously (see Section 1.15).

### Treatment of the burn itself

#### Minor burns

The best definition of a minor burn is one that can be treated as an outpatient.

#### Hospital admission

A child with a burn should be admitted unless it is completely safe for them to be treated as an outpatient. If possible, isolate the child in a warm clean room.

The following patients require admission:

- all airway burns or patients with a history of smoke inhalation
- burns of more than 5% TBSA in children and in pregnancy
- deep burns more than 5 cm in diameter
- moderate burns of the face, hands or perineum
- circumferential burns of the thorax or extremities\*
- electrical burns (see Section 7.3.D)
- where there is inadequate social support in the home
- where there is any suspicion of non-accidental injury.

**\*If circumferential full-thickness burns involving the extremities or the chest are present, escharotomy may be necessary.**

#### Dressings

Because a burn is normally caused by hot fluids or flame, the burn wound is initially sterile.

**Hands should be washed and sterile gloves should be worn by all members of the team whenever the patient is being touched.**

Ideally plastic aprons should also be used to prevent cross-infection during dressings, etc.

The purposes of a dressing are:

- to maintain sterility
- to relieve pain
- to absorb fluid produced by the burn wound
- to aid healing.

#### Placement of the dressing

- The layer of the dressing closest to the wound should be **non-adherent** (e.g. paraffin gauze) and may contain an antiseptic, such as silver sulphadiazine, although the evidence that antiseptics are useful to prevent infection and promote healing is ambiguous.
- On top of this dressing should be placed a layer of gauze and then sterile cotton wool to absorb fluid.
- The whole dressing should be held in place by a bandage.

#### Dressing changes

- Every time a dressing is changed, there will be pain, and the delicate reforming epithelium will be injured.
- **Therefore dressings should not be changed on a daily basis**, particularly in a superficial partial-thickness wound. The initial change should be at approximately 48 hours after the burn, when dressings come off easily, the maximum amount of fluid has been discharged from the wound, and it is possible to reassess the wound for area and depth.
- **Effective pain relief is vital at dressing changes or the child will come to dread the procedure.** Providing an anaesthetist is present, ketamine provides excellent brief anaesthesia of up to 15 minutes with an IV injection (over 1 minute) of 250–500 microgram/kg ketamine. For longer anaesthesia, an infusion will be needed. A safer alternative, especially in pregnancy, is oral morphine (see Section 1.15 for doses) given about 30 minutes before the anticipated dressing change.
- If at the first dressing change the wound is still a superficial partial-thickness burn, the second dressing is left for a further 8 days, by which stage healing should have occurred.
- If the wound is deeper, a decision as to whether to

- operate must be made (see below), but the second dressing can still be left for at least a week.
- If surgery is not possible or appropriate, dressings can be done initially on a weekly basis but increased to two or three times a week as greater infection and discharge develops.
  - Take a sample for microbiology (if available).

### Tetanus

Anti-tetanus prophylaxis should be given at the earliest possible time.

**TABLE 7.3.I.B.2 Guide to tetanus immunoglobulin and tetanus toxoid use in wounds**

History of tetanus vaccination		Type of wound	Tetanus vaccine booster (see below)	Tetanus immunoglobulin
≥ 3 doses	< 5 years since last dose	All wounds	No	No
	5–10 years since last dose	Clean minor wounds	No	No
		All other wounds	Yes	No
	> 10 years since last dose	All wounds	Yes	No
< 3 doses or uncertain	Clean minor wounds	Yes	No	
	All other wounds	Yes	Yes	

In pregnancy, if the woman has not previously been vaccinated, give two doses of TT/Td one month apart.

### Antibiotics

- Haemolytic *Streptococcus pyogenes* and *Pseudomonas aeruginosa* are the most common serious infections.
- In most burns, *Staphylococcus aureus* is also present, but does not need treatment unless it is invasive. If it is, flucloxacillin or cloxacillin is more appropriate than penicillin.
- Antibiotics should only be given when there are signs of infection.
- *Streptococcus pyogenes* should be treated with benzyl penicillin and flucloxacillin if found on a swab or suspected clinically (e.g. lymphangitis).
- *Pseudomonas aeruginosa* can be treated with ceftazidime, piperacillin, aztreonam, gentamicin or tobramycin.

### Surgery

The surgical treatment of burns can be divided into four time zones:

- Immediate: within hours.
- Early: within days.
- Medium term: within weeks.
- Long term: within years.

### Immediate surgery

There are two operations which may need to be done within hours of the burn:

- Tracheostomy:
  - Whenever possible this operation should be avoided, as an endotracheal tube usually gives better results and less mortality (depending on available intensive care).
  - An emergency tracheostomy for a severely swollen oral, pharyngeal or laryngeal airway is a very high-risk operation if the airway has not already been secured. It is better to use a mini-tracheostomy through the cricothyroid membrane.
  - Tracheostomy has a high mortality because of infection, displacement, lung-volume loss and tube blockage.
- Escharotomy:
  - A deep circumferential full-thickness burn of the limb,

or even occasionally the trunk, can act as a tourniquet to that area.

- Very early release (i.e. within 2 hours) is necessary to prevent severe and irrecoverable muscle and nerve damage. This can be done without any anaesthetic because the deep burn has no sensation.
- The incisions should not overlie superficial bone or tendons, but need to go down to the fascia.
- For more severe burns, and in particular high-voltage electrical burns, appropriate incisions are needed to decompress the deep compartments as well.
- Urgent decompression of deep compartments may be required in severe high-voltage electrical burns, which can damage the underlying muscle with no skin damage visible except at the entry and exit points.

### Early surgery

- Early surgery for deep dermal and deep burns has been shown to give better functional and cosmetic results with less risk of infection than allowing the natural processes of the body to remove the dead tissue.
- However, it is a technique that is difficult to learn from books, and often requires blood transfusion. Therefore if tangential excision is to be used without previous experience, only a small area should be attempted.
- Blood loss can be very rapid.
- An experienced anaesthetist is important.

### Medium-term surgery

When wounds are granulating, thin split-skin grafts (ideally perforated or meshed) can be taken to cover the granulating areas.

### Late surgery

Reconstruction to release contractures, and to improve both function and appearance, is best carried out, where possible, in a specialist centre.

### Facilities and personnel

- All serious burn patients are best cared for in specialist burns units with a trained team of personnel. This includes all widespread second or third degree burns and burns significantly involving the face, hands and genitals.

- For larger burns, ideally single rooms are most appropriate, and these should be kept warm at all times. It is extremely important that they are clean and that insects, etc. are controlled.
- One of the most serious problems is cross-infection between patients, and adequate plastic aprons, gloves and hand-washing facilities must be available for all staff and relatives.
- In the early stages of burn resuscitation, and after surgery, nursing should be on a one-to-one basis (if available).

### Psychology

- There are frequently major psychological consequences to major burns. First, there is a long and often painful stay in hospital. Secondly, there is the loss of function and appearance that can result from the burn injury.
- There are often psychological consequences for the parents of a burnt child, both as a result of the guilt about allowing the accident to happen, and from having to come to terms with the often major alterations in appearance and function of their child.

### Prevention

- The best solution to the problem of the burn injury is prevention.
- Use antenatal classes, posters in village halls and talks in school.

- The causes of burns in children will vary in different communities, and prevention should be directed at local causes.
- If possible:
  - limit the temperature of water coming from domestic taps
  - do not cook on the floor
  - keep children away from boiling water, coffee, tea, etc. In many communities these are the commonest causes of scalds.

### Features of burns that suggest child abuse

Burns are a common feature of child abuse and the clinician should have a high degree of awareness both of the physical appearance of inflicted burns and also of the developmental stage of the child to see if the injury is compatible with that stage.

Burns are sometimes used as a punishment in child rearing practices. Children with developmental delay are at particular risk of burns, both accidental and intentional.

Physical signs:

- Pattern burns that suggest contact with an object of a specific shape, such as an iron.
- Cigarette burns.
- Stocking, glove or circumferential burns.
- Burns to the genitals or perineum.

## 7.4

## Poisoning

### BOX 7.4.1 Minimum standards

- ABC, oxygen and glucose.
- Naloxone.
- Activated charcoal.
- Paediatric ipecacuanha.
- Wide-bore gastric tubes.
- Desferrioxamine.
- N-acetylcysteine.
- Sodium bicarbonate.
- Vitamin K.
- Exchange transfusion.
- Atropine.
- Pralidoxime.
- d-Penicillamine.
- EDTA.

### Introduction

The World Health Organization (WHO) definition of poisoning is the injury or destruction of cells by the inhalation, ingestion or absorption of a toxic substance. Key factors that predict the severity and outcome of poisoning are the nature, dose formulation and route of exposure of the poison, co-exposure to other poisons, the state of nutrition

of the child or their fasting status, age, and pre-existing health conditions.

**Mortality:** Low- and middle-income countries have 91% of the world mortality from poisoning as reported by WHO in 2004.

**Accidental poisoning** is most common in the 12–36 months age group.

**Intentional overdose** may be a cry for help, rather than a serious attempt at suicide. However, all children and young people who take intentional overdoses should have a full psychiatric and social assessment and always be admitted to hospital if facilities are available.

**Drug abuse** may be misuse of alcohol or abuse of volatile substances or more potent recreational drugs, such as ecstasy, LSD or opiates.

**Deliberate poisoning** of children by adults is rare. It may be associated with depressive illness or may be part of a spectrum of abuse inflicted on the child (see Section 7.6).

### Clinical diagnosis and management

#### Symptoms and signs of poisoning

These can include:

- respiratory distress

- acidotic breathing
  - tachycardia or flushing
  - cardiac arrhythmias
  - hypotension
  - diarrhoea
  - vomiting
  - drowsiness or coma
  - convulsions
  - ataxia
  - pupillary abnormalities
  - hypoglycaemia
  - acidosis.

The presentation may be more general, such as sudden unexplained illness in a previously healthy child, or unusual behaviour. Remember that there may not be a history of poisoning, so when taking a history ask specifically about access to prescribed drugs, local medicines, household substances, berries and plants.

## Management of poisoning

### First aid

- Remove the patient from the source of the poison. This mainly applies to fumes (e.g. in a house fire).
- Wash contaminated skin and eyes with water.
- **Never** try to induce vomiting with salt or by inserting an object into the pharynx.

### Primary assessment and resuscitation

Identify life-threatening emergencies and the early signs of a seriously ill child using the structured ABC approach (see Section 1.11).

The whole assessment should take less than a minute. Treat any problems with the ABC approach as they are found.

An alternative approach to emergencies such as this is the Emergency Triage and Treatment (ETAT) approach, if it is practised at your hospital.

Once Airway, Breathing and Circulation are recognised as being stable, or have been stabilised, definitive management of specific conditions can proceed. During definitive management, **reassessment of ABCD at frequent intervals will be necessary to assess progress and detect deterioration.**

### Secondary assessment and emergency treatment

Identify the substance ingested or inhaled, if at all possible. Ask the following questions:

- What medicines, domestic products, berries and plants has the child had access to?
- How much has been taken?
- When did the child have access to these substances?
- Is the container or a sample available? This will be helpful at the hospital.
- Are other children involved?
- What symptoms has the child had?

Use National Poisons Information Centres or Internet references, if these services are available, to obtain information on the side effects, toxicity and treatment needed.

**Hypoglycaemia:** Test blood glucose levels for all patients, and if hypoglycaemia is present, treat with a

sugar drink orally if the patient is conscious. If they are unconscious give by IV or intraosseous routes 2 to 5 mL/kg 10% glucose over 3 minutes then 5 mL/kg/hour to keep blood glucose at 5–8 mmol/litre. In pregnancy, dilute 50 mL of 50% glucose with 50 mL of Ringer-lactate, Hartmann's or 0.9% saline and give IV over 5 minutes followed by an IV infusion containing 5% glucose (see Appendix). If blood glucose testing is not available, then treat for hypoglycaemia if this diagnosis is possible (especially in infants and young children).

**Convulsions:** Treat convulsions in children with diazepam 300–400 micrograms/kg IV or IO slowly or 500 micrograms/kg per rectum.

In pregnancy the loading dose of diazepam is 2 mg increments IV every 2 minutes up to 10 mg. The maintenance dose is diazepam 40 mg in 500 mL of Ringer-lactate or Hartmann's solution, titrated to keep the mother sedated but able to be woken and without hypoventilation. Maternal respiratory depression may occur when the dose exceeds 30 mg in 1 hour. Alternatively, in pregnancy the loading dose diazepam is 20 mg in a 10-mL syringe. Remove the needle, lubricate the barrel and insert the syringe into the rectum to half its length. Discharge the contents and leave the syringe in place, holding the buttocks together for 10 minutes to prevent expulsion of the drug. Alternatively, the drug may be instilled in the rectum through a catheter.

Ensure close observation after treatment with diazepam at any age, and make sure that a bag-valve-mask of suitable size is available and the staff giving the diazepam know how to use it.

**Opiate or methadone overdose:** If an opiate or methadone overdose is suspected, give naloxone.

- IV dose for children aged 1 month to 12 years: 10 micrograms/kg; if there is no response, give 100 micrograms/kg (review the diagnosis if there is still no response).
- Give patients over 12 years of age and in pregnancy 400 microgram–2.0 mg; if there is no response, repeat every 2–3 minutes up to a maximum of 10 mg (then review the diagnosis).

Remember that naloxone has a short half-life and further boluses or an infusion of and further boluses or an infusion of 10–20 micrograms/kg/hour or more may be required. Give this treatment even if poisoning is only suspected (because of the presence of such drugs in the home) because breathing is shallow or the patient has stopped breathing. If the patient is hypoventilating or has stopped breathing, ventilate with bag-valve-mask before giving the naloxone as hypercapnia with naloxone can cause arrhythmias, acute pulmonary oedema, seizures or asystole.

### Minimising the effects of the ingested substance as quickly as possible

If the substance is **non-toxic** give oral fluids liberally.

If the substance is **corrosive**, there may be serious injury to the mouth, throat, airway, oesophagus or stomach (see also Section 7.3.1.a). The most dangerous substances are sodium or potassium hydroxide cleaning fluids (e.g. toilet cleaners). Others include bleach and other disinfectants. Serious oesophageal injury can result in perforations and mediastinitis, later leading to oesophageal strictures. The presence of burns within the mouth is of concern, and suggests that oesophageal injury is possible. Stridor suggests laryngeal damage. **No emetic should be given.** Milk or water

given as soon as possible may be of benefit, especially with solid caustics such as sodium hydroxide crystals. If there is a severe stricture it may be necessary to bypass the oesophagus with a gastrostomy tube. Ideally, flexible endoscopy should be performed to identify injury, but this may not be available. A perforated oesophagus will lead to mediastinitis and should be treated with gastrostomy and prophylactic antibiotics (cefuroxime and metronidazole).

In a few instances, specific **antidotes** are advised. These should only be given when full information on the poison is available from a Poisons Centre. **Never give salt to induce vomiting.**

**For all other poisons except heavy metals, iron, alcohol and domestic products** give activated charcoal if this is available (1 gram/kg suspended in water for a child and 50 gram in pregnancy). The sooner it is given the better (preferably within 1 hour of ingestion of the poison). Repeat after 4 hours if a sustained-release drug has been taken. If charcoal is not available and a potentially life-threatening dose of poison has been taken (particularly of iron), give paediatric ipecacuanha (10 mL for those aged 6 months to 2 years, and 15 mL for those aged over 2 years, plus a glass of water) to induce vomiting. **Do not give ipecacuanha if the child has a decreasing level of, or impaired, consciousness. Do NOT give if corrosive solutions have been ingested or if kerosene, turpentine or petrol have been ingested, as they could be inhaled following vomiting, resulting in lipid pneumonia.**

**Gastric lavage** with a wide-bore orogastric tube should be used only if a potentially life-threatening dose has been taken, and provided that the airway is protected. It should not be used if there is a decreasing level of, or impaired, consciousness without airway protection. **It should not be used for poisons containing hydrocarbons or corrosives.** Lavage cycles of 15 mL/kg are usually appropriate. Gastric lavage is not an effective way of removing most poisons, and may wash tablets into the duodenum. In a small child the size of nasogastric tube that can be inserted will almost certainly be too small to allow tablets to be drawn through it. Liquid preparations may be evacuated in this way, but in most cases they will have left the stomach within an hour, which is likely to sooner than the child reaches hospital.

#### **Treat symptoms as they arise.**

**Child abuse:** Always remember that an older child or adult may have given the child drugs intentionally. This is child abuse, and if there is the slightest suspicion of this, the appropriate child protection procedures should be instituted if they are available. The child should be admitted (see Section 7.6).

**Admit** all patients with symptoms or signs attributable to poisons, all patients who have ingested iron, pesticides, corrosives, paracetamol (unless blood testing shows a low level of drug), salicylate, narcotic drugs or tricyclic antidepressant drugs, all who allege deliberate ingestion, and any cases in which child abuse is suspected.

## **Commonly ingested drugs**

### **Local medicines**

- These are often prescribed for diarrhoea and vomiting. They may cause profound acidosis and respiratory distress. They can also cause paralytic ileus.
- Treat the metabolic disturbance.
- Consider using a nasogastric tube.

### **Iron**

- Poisoning is usually the result of taking iron tablets prescribed for another family member. Even two or three adults' tablets can cause serious symptoms in a small child.
- Iron poisoning causes severe gastrointestinal effects, with vomiting, diarrhoea, gastrointestinal bleeding and metabolic acidosis. Subsequently after 12–24 hours there is encephalopathy, liver damage and circulatory collapse.
- Late effects include scarring of the stomach, which may produce pyloric stenosis.
- **If available, a serum iron level at 4 hours of more than 300 micrograms/dL indicates significant poisoning.**
- X-ray may show the number of tablets. **In a child aim to remove as much as possible by induced vomiting with ipecacuanha.**
- Gastric lavage with a wide-bore orogastric tube may also remove significant amounts of iron if it is still in the stomach, but there is also a risk that the lavage may wash the tablets through into the bowel. Do not use gastric lavage in pregnancy.
- Desferrioxamine should be given by deep IM injection, 1 gram for children under 12 years and 2 grams for those over 12 years and in pregnancy. IM doses of desferrioxamine of desferrioxamine of 1–2 g should be repeated every 12 hours until serum iron is normal (serum iron less than iron binding capacity). If the patient is very ill, give an IV infusion of desferrioxamine 15 mg/kg/hour up to a maximum dose of 80 mg/kg in 24 hours. Usually reduce the rate after 6 hours.

### **Paracetamol**

- Paracetamol poisoning can lead to liver and renal failure (see Section 5.6.C and Section 5.7.B).
- Induce vomiting and, if possible, measure the paracetamol level.
- Give N-acetylcysteine or methionine as soon as possible, ideally within 8 hours of ingestion. If the patient is conscious and tolerating oral fluids, and within 8 hours of ingestion, give methionine orally (for children under 6 years, give 1 gram every 4 hours for four doses; for those aged 6 years or over and in pregnancy, give 2.5 g every 4 hours for four doses).
- If the patient presents more than 8 hours after ingestion or cannot be given an oral preparation, give IV N-acetylcysteine (initially as a loading dose of 150 mg/kg over 15 minutes, then as an IV infusion of 50 mg/kg over 4 hours, and finally as 100 mg/kg IV over 16 hours). An oral form of N-acetylcysteine is available (give a loading dose of 140 mg/kg, and then 70 mg/kg every 4 hours for 16 doses).

### **Salicylates**

- Salicylate poisoning produces acidotic-like breathing, vomiting and tinnitus.
- Hyperventilation is due to direct stimulation of the respiratory centre and produces respiratory alkalosis, but also there is a metabolic acidosis from ketosis. Consequently, the hyperventilation is extreme.
- A fever may occur.
- There is peripheral vasodilatation.
- Moderate hyperglycaemia develops.

There is delayed gastric emptying, so give activated charcoal if available (1 gram/kg in a child and 50 gram in pregnancy and repeat after 4 hours) even if more than 4 hours after ingestion. If charcoal is not available, induce vomiting.

Give sodium bicarbonate 1 mmol/kg IV as 4.2% over 4 hours to correct acidosis and aid excretion of salicylate.

Give sufficient IV fluids to compensate for hyperventilation, and give sufficient glucose to minimise ketosis, but regularly monitor blood glucose levels.

Monitor electrolytes carefully and avoid hypokalaemia and hypernatraemia.

In very severe cases, **peritoneal haemodialysis (if available) is ideal**. In its absence, exchange transfusion may help.

### Benzodiazepines

Flumazenil is a specific antagonist. The initial dose is slow IV 10 micrograms/kg; repeat at 1-minute intervals up to a maximum of 40 micrograms/kg (2 mg maximum dose). If necessary this can be followed by an infusion of 2–10 micrograms/kg/hour (not recommended in children who have received long-term benzodiazepine treatment for epilepsy). In pregnancy give 200 micrograms IV then 100 micrograms per minute IV up to a maximum total of 1 mg until reversal has occurred.

### Tricyclic antidepressants

- In overdose these cause drowsiness, ataxia, dilated pupils and tachycardia.
- Severe poisoning results in cardiac arrhythmias (particularly ventricular tachycardia) and severe hypotension and convulsions.

In children induce vomiting, perform gastric lavage and administer charcoal as described above, **but first protect the airway if the patient is drowsy. In pregnancy only administer charcoal**.

Treat convulsions as for any status epilepticus (see Section 5.16.E).

Monitor the ECG (if available) continuously.

Arrhythmias can be reduced by using IV phenytoin which must be diluted only in 0.9% saline. Phenytoin is given as a loading dose of 15–20 mg/kg over 30–45 minutes (maximum dose 2 grams) and then 2.5–7.5 mg/kg 12 hourly. The maximum infusion rate is 1 mg/kg/minute (maximum 50 mg/minute). A lidocaine infusion (10–50 micrograms/kg/minute) is an alternative to phenytoin.

Alkalinisation of the intravascular compartment has been shown to reduce the toxic effects on the heart. Give sodium bicarbonate 1–2 mmol/kg slowly. This can be repeated if necessary.

The aim is to increase the arterial pH to 7.45–7.5.

Where there is severe cardiac toxicity, prolonged external cardiac massage may keep the patient, especially a child, alive long enough for the effects of the drug to wear off.

### Poisonous household and natural products *Petroleum compounds such as kerosene, turpentine and petrol*

**Do not induce vomiting.**

- If inhaled these may cause hydrocarbon (lipoid) pneumonia, leading to a cough, and respiratory distress

with hypoxaemia due to pulmonary oedema and lipoid pneumonia. A chest X-ray is essential in all cases.

- If large amounts are ingested they may cause encephalopathy.
- Additional inspired oxygen may be required.
- An antibiotic may be needed, but only for secondary chest infections.
- Dexamethasone may help in lipoid pneumonia.

### *Organophosphorus compounds and carbamates*

- Insecticides such as malathion, chlordion, parathion, TEPP and phosdrin can be absorbed through the skin, lungs or gastrointestinal tract.
- Symptoms are due to excessive parasympathetic effects caused by inhibition of cholinesterase, and include excessive secretions of mucus in the lungs (bronchorrhoea) with ensuing respiratory distress and sometimes wheezing, salivation, lacrimation, bradycardia, sweating, gastrointestinal cramps, vomiting, diarrhoea, convulsions, blurred vision and small pupils, muscle weakness and twitching, progressing to paralysis, and loss of reflexes and sphincter control.

Treatment aims to remove poison from:

- the eyes: use copious irrigation
- the skin: remove contaminated clothing and wash the skin
- the gastrointestinal tract: give activated charcoal 1 gram/kg and repeat after 4 hours.

Admit all cases, as some effects do not appear until a late stage.

In severe cases, particularly where there is bronchorrhoea, give **atropine in a child** 20 micrograms/kg IV or IM every 5–10 minutes until the skin becomes flushed and dry, the pupils dilate and tachycardia develops (that is atropinisation has occurred: maximum dose 2 mg). In pregnancy give 600 micrograms and repeat in doses of 300 micrograms as needed.

- A specific cholinesterase reactivator can also be given as follows, and ideally within 12 hours of ingestion (it is ineffective after 24 hours).
  - **Pralidoxime** 30 mg/kg diluted with 10–15 mL of water by IV infusion at a rate not exceeding 5 mg/minute. It should produce an improved muscle power in 30 minutes. It can be repeated once or twice as required and as is shown to be effective, or an infusion of 8 mg/kg/hour can be used. Maximum dose is 12 gram in 24 hours.
- **Assisted ventilation** may be required (if available).

### *Bleach (3–6% sodium hypochlorite)*

**Do not induce vomiting.**

- Symptoms: burning sensation, vomiting and abdominal discomfort.
- Treatment: liberal fluids and milk.

### *Corrosive agents*

**Do not induce vomiting.**

- Oven cleaners (30% caustic soda).
- Kettle descalers (concentrated formic acid).
- Dishwashing powders (silicates and metasilicates).
- Drain cleaners (sodium hydroxide).

- Car battery acid (concentrated sulphuric acid).

Symptoms: considerable tissue damage to the skin, mouth, oesophagus or stomach; late strictures may occur. Treatment consists of washing the skin and mouth to dilute the corrosive fluid (see Section 7.3.1.a).

### Lead poisoning

This is usually a chronic form of poisoning. The lead can come from paint, lead piping or car batteries. In some cultures, lead-containing substances may be applied to the skin for cosmetic purposes (e.g. Surma in India).

- Early signs are non-specific (e.g. vomiting, abdominal pain, anorexia).
- Anaemia is usually present.
- Prior to encephalopathy with raised intracranial pressure, there may be headaches and insomnia.
- Peripheral neuropathy may be present.
- X-rays may show bands of increased density at the metaphyses.
- Harmful effects on the kidneys result in hypertension, aminoaciduria and glycosuria.
- There is a microcytic hypochromic anaemia with punctate basophilia.
- The diagnosis is made by showing a marked increase in urinary lead levels after d-penicillamine, and elevated blood lead levels.

### Treatment

- Treat by first removing the source of ingested lead.
- A diet rich in calcium, phosphate and vitamin D (plenty of milk) should be given if possible.
- In cases of lead encephalopathy, give an IV infusion of edetate calcium (EDTA) in 5% glucose or normal saline, 20 mg/kg every 6 hours for 5–7 days at a concentration of no more than 30 mg/mL. Give over an hour.
- Boluses of mannitol 250–500 mg/kg IV over 30–60 minutes may also be required for raised intracranial pressure while the above is given.

### Poisonous plants

- Usually only small quantities are ingested.
- Recent reports describe nicotine poisoning by absorption through the skin in children who are tobacco pickers.

**Treatment:** For ingested poisonous plants this consists of activated charcoal and supportive therapy.

### Carbon monoxide poisoning

- Toxic effects are due to hypoxia.

**Treatment:** Move the patient from the source and give them 100% oxygen as soon as possible (the half-life of carbon monoxide is 5 hours in room air, but only 1.5 hours in 100% oxygen). The patient may look pink but is hypoxaemic, so base the duration of oxygen treatment on other clinical signs of hypoxia rather than on cyanosis, which will be masked. For similar reasons, pulse oximeters will give falsely high readings. ABCD management according to APLS may be required.

- Cerebral oedema may develop.
- **Hyperbaric oxygen treatment may be helpful (if available).**

### Volatile substance abuse ('sniffing')

This mainly occurs in the age range 11–17 years and is a group activity. Substances that are sniffed or sprayed into the respiratory system are numerous. The commonest are solvent-based adhesives ('glue sniffing'), butane gas, cleaning fluids, aerosols and fire-extinguisher substances.

### Clinical features

- Sores around the mouth and nose.
- Smell of solvents on the clothes and breath.
- All of the features of ethyl alcohol intoxication, plus extreme disorientation, hallucinations and sudden 'unexplained' death
- Accidents can occur secondary to volatile substance abuse, for example falling from height, drowning, suffocation and inhalation of vomit.

### Management

- Remove the child from the atmosphere of solvent.
- Admit them to hospital.
- Treat symptomatically.
- Arrange expert psychological and emotional support.

### Laboratory investigations in poisoning

These are often expensive and/or very time consuming to perform. They should only be requested if the result will alter the management of the patient. Many hospitals in resource-limited countries will not have these facilities.

### Alcohol

- Blood alcohol estimations are useful if:
  - there is an indication that methyl alcohol has been ingested
  - the patient is very drowsy or comatose and there is doubt whether sufficient alcohol has been ingested to explain the symptoms.
- Blood glucose levels should be measured in all cases of alcohol ingestion in children.
  - Do a blood glucose stick test first, and if this is low, a quantitative glucose analysis should be requested.

**FIGURE 7.4.1** Graph for N-acetylcysteine use in paracetamol poisoning. This Crown copyright material is reproduced by permission of the Medicines and Healthcare Products Regulatory Agency under delegated authority from the Controller of HMSO.

- If in doubt, give glucose 2–5 mL/kg of 10% glucose IV if unable to drink or unconscious, otherwise give a sugary drink.

### Interpretation

Peak blood levels of alcohol occur 30–60 minutes after ingestion.

### Iron

Patients who have ingested iron should ideally have a plasma iron level estimated before desferrioxamine is given. Serum levels of over 300 micrograms/dL are associated with moderate toxicity, levels of over 500 micrograms/dL with serious toxicity, and levels over 1 mg/dL with death.

### Interpretation

Patients with acute iron poisoning have significant increase

in plasma iron levels within 2 hours of over-dosage. Initial serum levels of less than 90 micromol/litre are supportive but not absolute evidence of mild poisoning. Normal serum iron levels are in the region of 10–30 micromols/L (80–180 micrograms/dL).

### Paracetamol

Take blood samples at least 4 hours after ingestion of paracetamol.

### Interpretation

A plasma level that falls above the treatment line at different times indicated in the graph of paracetamol level against time (see Figure 7.4.1) indicates moderate to severe poisoning. Treat with N-acetylcysteine. Lower thresholds for treatment are indicated if the patient is on enzyme-inducing drugs or alcohol is taken habitually.

## 7.5 Envenomation

### BOX 7.5.1 Minimum standards

- Mono- and polyspecific antivenoms.
- Chlorphenamine.
- Anticholinesterase (only if appropriate for the region).
- Analgesia.
- Prazosin (only if appropriate for the region).
- Heart failure treatment.

### Introduction

Envenoming by snakes, scorpions, spiders or marine venomous animals is common in many areas of the tropics. Children are particularly at risk; they may be attracted to venomous creatures and do not recognise the danger that they represent. Envenoming is often more severe and more rapid in children because the ratio of the amount of venom to body weight is much higher.

A clear-cut history of envenoming is often not present. Some bites are not recognised at the time of the event; other children will be too young to explain what has happened. Envenoming should always be considered in any child with an unexplained illness, particularly if there is severe pain, swelling or blistering of a limb, or if the child is bleeding or shows signs of neurotoxicity.

### Prevention

Discourage children from handling snakes, scorpions or spiders or touching marine animals. They should be taught to avoid putting their hands down holes, and to carefully check their shoes and clothing before dressing. Keeping grass short around dwellings, use of sensible footwear, keeping dwellings insect-free, and taking care when swimming can all help to prevent injury by venomous animals.

### Snakebite

There are a large number of species of venomous snakes throughout the world. These can be divided into three main categories: **vipers**, **elapids** and **sea snakes**. The pattern of envenoming depends upon the biting species. Therefore clinicians need to know about the snakes present in the region in which they work. **Only 50–70% of patients who are bitten by venomous snakes develop signs of envenoming.**

Major clinical effects following snakebite can be categorised as follows:

- **Local effects:** pain, swelling or blistering of the bitten limb. Necrosis at the site of the wound may sometimes develop.
- **Systemic effects:**
  - Non-specific symptoms: vomiting, headache, collapse.
  - Painful regional lymph node enlargement indicating absorption of venom.
  - Specific signs: non-clotting of blood; bleeding from gums, old wounds and sores.
  - Neurotoxicity: ptosis, bulbar palsy and respiratory paralysis.
  - Shock: hypotension.
  - Rhabdomyolysis: muscle pains and black urine.

**Vipers** most commonly cause local swelling, shock, bleeding and non-clotting blood.

**Elapids** cause neurotoxicity and usually minimal signs at the bite site (with the exception of some cobras which also cause necrosis).

Sea snakes cause myotoxicity and subsequent paresis.

Exceptions to this general rule do occur. For example, some vipers cause neurotoxicity and some Australasian elapids also cause non-clotting blood and haemorrhage.

### First aid outside hospital

- Reassure the patient. Many symptoms following snake-bite are due to anxiety.
- Avoid harmful manoeuvres such as cutting, suction or the use of tourniquets.
- Immobilise and splint the limb. Moving the limb may increase systemic absorption of venom.
- Apply a pressure bandage if tissue necrosis is rare following snakebite in your region, particularly if rapid transport to hospital is not possible. This is especially important for snakes that cause neurotoxicity. Apply a crepe bandage over the bite site and wind it firmly up the limb. **This can only be recommended on a geographical basis, not a clinical one, as necrosis is not apparent initially.**
- Transport the patient to hospital as soon as possible.
- If the snake has been killed, take it with the patient to the hospital.

### Diagnosis and initial assessment

- Carefully examine the bitten limb for local signs.
- Measure the pulse, respiration rate, blood pressure and urine output. Blood pressure and other signs of shock (see Section 5.5) must be watched for if children are unwell, are bleeding or have significant swelling; shock is common in viper bites.
- Look for non-clotting blood. This may be the only sign of envenoming in some viper bites. The 20-minute whole-blood clotting test (WBCT20) is an extremely easy and useful test. It should be performed on admission and repeated 6 hours later.

#### WBCT20 test

- Place a few millilitres of freshly sampled blood in a new clean dry glass tube or bottle.
- Leave undisturbed for 20 minutes at ambient temperature.
- Tip the vessel once.
- If the blood is still liquid (i.e. unclotted) and runs out, the patient has hypofibrinogenaemia ('incoagulable blood') as a result of venom-induced consumption coagulopathy.

Look carefully for signs of bleeding which may be subtle (e.g. from gums, old wounds or sores). Bleeding internally (most often intracranial) may cause clinical signs.

- Look for early signs of neurotoxicity, such as ptosis (children may interpret this as feeling sleepy), limb weakness, or difficulties in talking, swallowing or breathing.
- Check for muscle tenderness and myoglobinuria in sea snake bites.
- Take blood for:
  - haemoglobin, white cell count and platelet count
  - prothrombin time, APTT and fibrinogen levels (if available)
  - serum urea and creatinine
  - creatine phosphokinase (CPK) (reflecting skeletal muscle damage) (if available).
- ECG (if available).

### Hospital or health centre management

#### General management

- Observe the patient in hospital for at least 24 hours, even if there are no signs of envenoming initially. Review regularly, as envenoming may develop quite rapidly.
- Nurse the patient on their side with a slight head-down tilt to prevent aspiration of blood or secretions.
- Avoid IM injections and invasive procedures in patients with incoagulable blood.
- Give tetanus prophylaxis. Routine antibiotic prophylaxis is not required unless necrosis is present.

#### Antivenom

Antivenom is indicated for signs of systemic envenoming. Evidence for its efficacy in severe local envenoming is poor, but it is usually indicated if swelling extends over more than half of the bitten limb. Monospecific (monovalent) antivenom may be used for a single species of snake, and polyspecific (polyvalent) antivenom for a number of different species. The dose of antivenom depends upon the manufacturer's recommendations and local experience.

Children require exactly the same dose as pregnant women (the dose is dependent upon the amount of venom injected, not body weight).

- Dilute the antivenom in two to three volumes of 5% glucose or Ringer-lactate or Hartmann's or 0.9% saline and infuse over 45 minutes to an hour. The infusion rate should be slow initially and gradually increased. Note that doses of antivenom vary considerably; always follow the instructions enclosed with the antivenom.
- Draw up adrenaline in a syringe ready for use.
- Observe the patient closely during antivenom administration. Common early signs of an antivenom reaction include urticaria and itching, restlessness, fever, cough or a feeling of constriction in the throat.
- Patients with anaphylaxis should be treated with adrenaline (epinephrine). In a child give 10 micrograms/kg IM (see Section 5.1.B) and in pregnancy give 1 mL of 1 in 1000 adrenaline (1 mg) (see Section 5.1.B). An antihistamine, such as chlorphenamine, 200 micrograms/kg IM or IV, should also be given.
- Unless life-threatening anaphylaxis has occurred, antivenom can cautiously be restarted after this treatment.
- Routine adrenaline prophylaxis may reduce the incidence of antivenom anaphylaxis, but should not generally be used.
- Monitor the response to antivenom. In the presence of coagulopathy, restoration of clotting depends upon hepatic resynthesis of clotting factors. Repeat WBCT20 and other clotting studies if available, 6 hours after antivenom. If the blood is still non-clotting, further antivenom is indicated. After restoration of normal clotting, measure clotting at 6- to 12-hour intervals, as a coagulopathy may recur due to late absorption of venom from the bite site.

The response of neurotoxicity to antivenom is less predictable. In species with predominantly postsynaptically acting toxins, antivenom may reverse neurotoxicity, and failure to do so is an indication for further doses. However, the response to antivenom is poor in species with presynaptically acting toxins.

### Other therapy

- Excise sloughs from necrotic wounds. Skin grafting may be necessary. Severe swelling may lead to suspicion of a compartment syndrome. Fasciotomy should **not** be performed unless there is definite evidence of raised intra-compartmental pressure (> 45mmHg) (if measurable), and any coagulopathy has been corrected. **Clinical assessment for compartment syndromes is often misleading following snakebite. Therefore objective criteria are helpful.**
- Blood products are not necessary to treat a coagulopathy if adequate antivenom has been given.
- Endotracheal intubation or even tracheostomy should be considered to prevent aspiration if bulbar palsy develops; this is often obvious when difficulty in swallowing leads to pooling of secretions.
- If there is uncontrolled bleeding in the absence of antivenom, give fresh blood, vitamin K in a child 300 micrograms/kg IV and in pregnancy vitamin K 10mg IV/IM and fresh-frozen plasma 10 grams/kg IV (if available).
- Paralysis of intercostal muscles and diaphragm requires artificial ventilation. This can be performed by manual bagging with a bag-valve mask and may need to be maintained for days, using relays of relatives if ventilators and skills are not available.
- Anticholinesterases may reverse neurotoxicity following envenoming by some species.
- Maintain careful fluid balance to treat shock and prevent renal failure.
- Some cobras spit venom into the eyes of their victim. Rapid irrigation with water will prevent severe inflammation, and 0.5% adrenaline (epinephrine) drops may help to reduce pain and inflammation.

### Scorpion stings

In some areas of the world, scorpion stings are more common than snakebites and cause significant mortality. The stinging scorpion is not often seen. A number of different species have broadly similar clinical effects. The major feature of envenoming is severe pain around the bite site, which may last for many hours or even days. Systemic envenoming is more common in children and may occur within minutes of a bite. The major clinical features are caused by activation of the autonomic nervous system (see Table 7.5.1).

Severe hypertension, myocardial failure and pulmonary oedema are particularly prominent in severe envenoming.

TABLE 7.5.1 Scorpion stings

Clinical features of scorpion stings	
Tachypnoea	Muscle twitching and spasms
Excess salivation	Hypertension
Nausea and vomiting	Pulmonary oedema
Lacrimation	Cardiac arrhythmias
Sweating	Hypotension
Abdominal pain	Respiratory failure

### Management

- Take the patient to hospital immediately; delay is a frequent cause of death.
- Control the pain with infiltration of 1% lignocaine around the wound or give systemic opiates (with care) (see Section 1.15).
- Scorpion antivenom is available for some species. Give intravenously in systemic envenoming, but IM injection has been used with good effect if there is no alternative.
- Prazosin is effective for treating hypertension and cardiac failure (orally 10–15 micrograms/kg two to four times a day increasing to control blood pressure to a maximum of 500 micrograms/kg/day for under 12 years and 20mg/day over 12 years). The patient should be lying down for the first 4–6 hours of treatment in case there is a sudden fall in blood pressure.
- Severe pulmonary oedema requires aggressive treatment with diuretics and vasodilators (see Section 5.4.B).

### Spider bites

Three main genera of spiders cause significant envenoming in the tropics. Each causes different clinical effects, but fatal envenoming is rare.

- **Widow spiders** (*Latrodectus* species) are found throughout the world. Severe pain at the bite site is common. Rare cases develop systemic envenoming with abdominal and generalised pain and other features due to transmitter release from autonomic nerves. Hypertension is characteristic of severe envenoming (see use of prazosin above). Antivenom is available in some regions, and is effective for relief of pain and systemic symptoms. Opiates are also useful for the treatment of pain (see Section 1.15).
- **Recluse spiders** (*Loxosceles* species) have a wide distribution and cause bites in which pain develops over a number of hours. A white ischaemic area gradually breaks down to form a black eschar over 7 days or so. Healing may be prolonged, and occasionally severe scarring occurs. The efficacy of antivenom and other advocated treatments (dapson, steroids and hyperbaric oxygen) remains uncertain.
- **Banana spiders** (*Phoneutria* species) occur only in South America. They usually cause severe burning pain at the site of the bite, but in severe cases may cause systemic envenoming with tachycardia, hypertension, sweating and priapism. Polyspecific antivenom is available.

### Marine envenoming

#### Venomous fish

Many different venomous fish may sting children if they stand on or touch the fish. Systemic envenoming is rare. Excruciating pain at the site of the sting is the major effect.

- Regional nerve blocks and local infiltration of 1% lignocaine may be effective (see Section 1.24).
- Most marine venoms are heat-labile. Immersing the stung part in hot water is extremely effective for relieving the pain. Care should be taken to avoid scalding, as the envenomed limb may have abnormal sensation. The clinician should check the water temperature with their own hand. Asking the patient to immerse their non-bitten limb may help to avoid scalding.

**Jellyfish**

Venomous jellyfish have large numbers of stinging capsules (nematocysts) on their tentacles which inject venom when the tentacles contact skin. Pain and wheals are the usual effects but, rarely, systemic envenoming can be life-threatening. Many of the nematocysts will remain undischarged on tentacles that adhere to the victim. Therefore rubbing the area of the sting will cause further discharge and worsen envenoming.

- In box jellyfish stings, pouring vinegar over the sting will prevent discharge of nematocysts. For most other jellyfish, seawater should be poured over the stings and the adherent tentacles gently removed. Ice is useful for pain relief.
- Box jellyfish stings may occasionally be rapidly

life-threatening. Antivenom is available and can be administered intramuscularly.

**7.6****The child who has been ill treated, abused or exploited****BOX 7.6.1 Minimum standards**

- Knowledge of the in-country legal framework for child protection.
- Understanding of cross-cultural child-rearing practices.
- Links between health services, police child protection teams and/or social services in place.
- Access to X-rays and blood clotting measurements.
- Access to forensic advice.
- Access to photography services, with secure storage of images.
- Healthcare workers trained to recognise signs of physical and sexual abuse.

**Children's rights**

Article 19 of the United Nations Convention on the Rights of the Child states that children (people less than 18 years of age) have a right to be protected from being hurt and maltreated physically and mentally. It goes on to state that governments should ensure that children are properly cared for and should protect them from violence, abuse and neglect by their parents or anyone who looks after them.

Child abuse results in actual or potential harm to the child's health, survival, development or dignity in the context of a relationship of responsibility, trust or power with the abuser.

Healthcare workers have a major responsibility in contributing to the prevention and recognition of childhood ill treatment. This poses particular challenges for healthcare workers when they work with children and families from different belief systems and cultural backgrounds. They may find that they have to care for street children, child soldiers, and children separated from their parents by civil strife and unrest, and find themselves making difficult judgements about how a child can be best protected when they have few if any points of reference, and only limited contact with other agencies.

The basic principles of the investigation of child maltreatment are that:

- the welfare of the child is paramount
- multi-agency/multi-sectored collaboration is needed
- agencies must work together within the legal framework of the country (where this is in place).

Child maltreatment or abuse involves acts of omission and commission which result in harm to a child. It can occur in the family, in the community or in institutions (e.g. schools, hospitals, churches, mosques, temples, clubs, orphanages or other institutions). It encompasses:

- exploitation through trafficking for sexual or other forms of slavery
- exploitation through enforced prostitution
- physical abuse
- emotional abuse
- neglect
- sexual abuse
- fabricated induced illness (FI)
- conscription as child soldiers.

**Features of presentation of a child to hospital which suggest possible ill treatment or abuse**

- Delay in seeking medical help for an injury or serious clinical symptoms or signs (e.g. bleeding).
- A history that is vague or rehearsed, with inconsistencies and significant changes on re-telling or following questioning.
- No explanation of the cause of the injury.
- Repeated attendance at healthcare facilities (this may suggest fabricated or induced illness, FI; see below).
- Parents or carers being evasive or hostile.
- A history of injury that is inconsistent with the child's age and/or developmental skills.

- A 'collusion of silence', or one parent implicating the other.
- Accusations that the child is a witch, or that witchcraft has been perpetrated by others.
- The presence of other injuries, or a previous history of unusual injury.
- Child appearing sad, withdrawn, anxious or frightened ('frozen watchfulness'), or over-compliant.
- Child may indicate the abuser.

Particular consideration needs to be given to children with disabilities who may be unable to communicate about their ill treatment, and where their presentation may be misattributed to their disability.

Children who suffer abuse are often threatened by being told that they will be to blame if the family is separated. Fear of what might happen to them may result in children between the ages of 4 and 10 years colluding with the abusive parent.

### Physical abuse/ill treatment (non-accidental injury)

Physical abuse can be defined as any act resulting in a non-accidental physical injury, including not only intentional assault, but also the results of excessive or violent punishment. Physical abuse occurs when a person deliberately injures a child or young person.

Around 25–50% of all children report being physically abused, according to the World Health Organization (WHO).

Physical abuse usually coexists with emotional abuse, and sometimes accompanies sexual abuse. However, in some settings, physical chastisement (especially of older children) continues to be considered part of 'good parenting' and important for instilling discipline in a community's children. In many countries, laws define which childhood punishments are considered excessive or abusive.

Some classifications define physical abuse as an injury that produces a mark. However, this does not take into consideration the emotional effects of physical abuse. The number and size of the bruises are helpful in distinguishing between mild and serious abuse. Any assault on a child is unacceptable and constitutes child abuse. A small bruise in a baby may predict future serious or fatal abuse.

Typical injuries include the following:

- lash marks, especially on the trunk, legs and hands
- bruises, especially on the face, scalp, and on or behind the ears and on the buttocks
- certain patterns of bruises, such as fingertip marks or bruises in the shape of the implement used, or multiple bruises of different ages. However, current scientific evidence concludes that we cannot accurately date a bruise from clinical assessment or from a photograph.
- Burns, including branding and scalds, especially when these are bilateral and/or symmetrical (e.g. buttocks or face held against a hot object such as a radiator, or both hands or feet or buttocks scalded as a result of the child being immersed deliberately in hot water). A pattern suggesting a cigarette burn or burns is also important, but be careful about the possibility of impetigo, which may mimic such burns (impetigo heals quickly and without scarring with antibiotic treatment, topical if a small area and systemic if widespread, whereas burns heal more slowly and may scar)

- injuries to the mouth (especially a torn frenulum)
- bleeding from the mouth or nose in an infant (indicating the possibility of intentional suffocation)
- adult bite marks
- bony injuries, especially in non-ambulant children; skull fractures, spiral fractures of the humerus, rib fractures in young children and multiple fractures of different ages, epiphyseal separation at the end of long bones, periosteal separation and haematomas
- inflicted head injury (especially in infants) involving tearing of the superficial veins over the brain and retina, causing subdural and retinal haemorrhages: this can be fatal, or may cause physical and mental impairment and visual loss.
- failure to thrive due to neglect (category 2) or deliberate starvation (category 3)
- induced illness, including suffocation or poisoning.

Figure 7.6.1 shows the common injury sites for both accidental and abusive injuries.

**FIGURE 7.6.1** Common sites for (a) non-accidental (abusive) injuries and (b) accidental injuries.

Particular care needs to be taken when interpreting skin marks in settings where traditional practitioners use cupping, coining, scarification or tattooing treatments.

Children are more likely to be killed or to experience violence in their own home than outside it. The triad of violence against a partner (usually the female partner), child abuse and substance misuse (drugs and/or alcohol) is a common association. There is a strong correlation between domestic violence and child abuse.

### Emotional and psychological abuse

This can occur as isolated incidents, as well as within a pattern of failure over time on the part of a parent or caregiver to provide a developmentally appropriate and supportive environment. This has a high probability of damaging the

child's physical or mental health, or their physical, mental, spiritual, moral or social development.

This category should be used where it is the main or only apparent form of abuse.

Emotional and psychological abuse includes the restriction of movement, patterns of belittling, blaming, threatening, frightening, name-calling, scapegoating, persistent criticism, discriminating against the child compared with their siblings, ridiculing them, and other non-physical forms of rejection or hostile treatment.

This type of abuse can be difficult to recognise. Concerns are frequently raised by a child's extended family, neighbours, or nursery or school staff. All abuse involves some emotional abuse, but emotional abuse may exist independently. Emotional abuse occurs when, for example, there is:

- emotional unavailability of the parent or carer (e.g. when they are preoccupied with their own needs because of mental health problems, substance abuse problems, or work commitments)
- failure to allow the child to interact normally socially with others.

The consequences of emotional abuse vary with age and with its duration, and may include the following:

- Impaired physical development: these children often fail to reach their optimum potential in terms of growth; this improves when the child is placed in a more nurturing environment.
- Impaired cognitive development, including speech and language delay, poor concentration and academic underachievement.
- Behavioural abnormalities, such as anxious attachment, lack of social responsiveness, expressionless face, fear of speaking, eagerness to please, attention seeking, overactivity or 'hyperactivity', no wariness with strangers, hunger for human contact, inability to form relationships, self-injurious or self-stimulating behaviours, hoarding and stealing of food, pica, enuresis and encopresis, and bizarre behavioural patterns (sometimes there is autistic-like behaviour).
- Impaired psychological development, especially with regard to speech and language: aggression, emotional unresponsiveness, emotional instability, impaired social development, low self-esteem, dependency and separation anxiety, serious social difficulties, underachievement, negative self-evaluation, poor concentration, and poor academic performance or school attendance.
- Psychiatric disorders: emotional maltreatment and abuse have been described in association with three psychiatric disorders of childhood:
  - depression
  - reactive attachment disorder of infancy
  - multiple personality disorder.
 In general, these children become sad, dejected and withdrawn.
- Medical problems include the following:
  - failure to thrive
  - recurrent and severe nappy rash
  - generally unkempt appearance, with poor hygiene
  - recurrent minor infections.

### Neglect

Neglect includes both isolated incidents and a pattern

of failure over time on the part of a parent or other family member to provide for the development and well-being of the child (where the parent is in a position to do so) in one or more of the following areas.

Neglect is persistent failure to meet a child's essential needs by inattention or omitting basic parenting tasks and responsibilities in all aspects of their needs (health, hygiene, clothing, education, and social, emotional, mental, spiritual and moral needs). It also includes failure to provide appropriate nutrition, shelter and safe living conditions.

Examples include lack of supervision, with failure to protect the child from dangers (e.g. cold temperatures, sunburn, drowning) due to poor supervision and attention to safety in the home (e.g. not providing stair gates or locks on windows), failure to thrive, and failure to meet the child's emotional needs for love, affection and stimulation.

Neglect is seen as the persistent failure of a parent or carer to meet a child's developmental, basic physical and/or psychological needs by omission of basic parenting. It results in serious impairment of the child's physical health, psychological well-being and development. It may coexist with other forms of ill treatment.

The parents' or carers' own problems (e.g. learning difficulties, mental and physical health problems, poverty, inappropriate housing) can all contribute to this. In unstable settings, such as armed conflict, there may be significant security issues that contribute to their inability to provide a safe environment for their children.

## Child sexual abuse (CSA)

### Introduction

This is the involvement of children in sexual activity to which they cannot consent. Another definition could be any activity in which an adult or older child uses a younger child in a sexual way.

In addition to direct sexual contact between adult and child (including intracural, oral, vaginal or anal sex and the masturbation of an adult), it includes the use of penetrative instrumentation, the production of pornographic imagery of children, exposing a child to indecent acts or pornography, and other voyeuristic practices. Very young children may also be trafficked for use in the sex industry, and older children may be groomed for prostitution.

Sexual abuse is a serious global problem that transcends economic or social barriers. Poverty, emotional deprivation and lack of education often mean that young people are powerless to avoid being trapped both in sexually abusive situations and in domestic violence. However, it is universally true that sexual abuse is most often suffered at the hands of a neighbour, family friend or a trusted person, including a parent. A significant power differential usually exists between victim and abuser. This fact is important when examining situations of sexual behaviour between children themselves.

In legal terms there are two types:

- 1 when a stranger or someone the child knows abuses the child
- 2 incest: when a relative by blood or by law abuses the child.

### Some facts about CSA

- Child sexual abuse is a problem in all socio-economic classes.

- Boys are also sexually abused.
- Abusers are usually people whom the child knows.
- It is **never** the child's fault if they are sexually abused.
- Women can also be abusers.
- Abusers cannot be recognised by their physical appearance.
- Sharing the experience of abuse with someone who is supportive and understanding helps the victim deal with it.
- Very young children can be abused in this way.
- A child who is abused at a very young age will also be affected by it, even if they forget the particular episode.
- CSA is rarely accompanied by violence and physical force.
- The main motive behind sexual abuse is not sexual frustration but to gain 'power' and 'control'.

Worldwide, 40–47% of sexual assaults are reported to involve girls under the age of 15 years. In Tanzania, almost 30% of adolescents undergoing abortions had been impregnated by men aged 45 years or older. In India, a study in 2007 reported that over 50% of children had been subjected to sexual abuse, and in 21% of cases this was of a severe nature. That study also reported that children living on the street or in institutional care were most vulnerable to sexual abuse.

Rape and impregnation as a weapon of war is now well recognised as a distressing and complex issue arising in countries where conflict is endemic.

### Physical symptoms of CSA

Sexual abuse may go undetected for years because the symptoms are vague and easily attributed to other factors, such as the arrival of a new sibling in the home or family breakdown. Abuse may come to light abruptly when a child says something inappropriate or makes a direct allegation (disclosure) when in a situation in which they feel safe, sometimes to a friend or teacher at school.

Physical symptoms are unusual and vague. Unexplained episodic dysuria and frequency or genital soreness are most often recalled in retrospect. Sexually transmitted disease and pregnancy may make the diagnosis irrefutable in some cases. Obvious pain, bleeding and signs of acute physical trauma to the genital and anal area are rarely presenting features, and usually accompany violent and reckless assaults, often by a stranger.

Other symptoms include difficulty in walking, gastrointestinal disturbances (including nausea), eating disorders, abdominal pain, and in the genital area pain, itching, visible injury, discharge, infection or difficulty urinating.

Bruises, cuts and other injuries on any part of the body for which the cause is not clear and the child cannot give a full explanation may be present. Sexually transmitted diseases may occur at the time of abuse or lie dormant for months or even years, only to flare up in adolescence or adulthood.

There may be a noticeable fear of a particular person or place, sudden bedwetting or soiling, preoccupation with sexual acts, and a change of language or re-enacting their experiences with other children. Nightmares, withdrawn behaviour, changes in appetite and a decline in school achievement are not uncommon.

Other behavioural effects include the following:

- persistent and inappropriate sexual play with peers, toys, animals or self
- sexual themes and fears in the child's artwork, stories and play
- sexual understanding or behaviour beyond that expected for the child's developmental stage
- self-harm or hurting others, including fire setting and cruelty to animals
- fear of being alone, of going home, or of particular places and people
- running away from home
- drug and/or alcohol use
- adolescent prostitution or sexual promiscuity
- suicidal feelings and attempts.

Parents should be concerned if a child appears to have unexplained expensive objects or financial resources. The grooming process often involves making a child feel cherished and creating dependency by offering them quality time, treats and gifts; in older children, the grooming process often includes encouragement to indulge in and provision of cigarettes and alcohol.

These effects may be symptoms of something other than CSA, but the possibility of CSA should always be explored.

Most of the symptoms relate to long-term psychological damage. Young adults find it difficult to make intimate relationships and to trust others. Alcohol and drug dependency, anxiety disorders, self-harming and suicidal ideation may be linked to sexual abuse, especially at the hands of a trusted adult such as a parent. The traumagenesis of sexual abuse has been extensively described by Finklehor. He proposed four dynamics; traumatic sexualisation, powerlessness, betrayal and stigmatisation.

### Clinical examination and physical signs

Clinical assessment of the sexually abused child should ideally be conducted by trained and experienced professionals, and preferably a specialist forensically trained doctor or nurse. The environs of the clinical space should be child friendly and the examination unhurried. All examinations should consider the global health needs of the child first; the needs of law enforcement should not be paramount.

Careful history taking is the first step, and if prosecution is being sought, the history should be obtained without risk of contamination, either directly from the child before a recording witness or in the child's absence from the adult who knows first-hand what the child has said. The history should be elicited with free recall and by posing indirect questions (e.g. 'Tell me why you are here' or 'Is there something that has upset you? Can you talk about it?').

Children will feel less threatened if other aspects of their health are also examined at the same time. The normal child health enquiry about growth, diet, systems enquiry and school function is important. Clinical examination of the child should also be holistic, and incidental findings should be relayed back to the parent and child appropriately. A whole body approach is more likely to promote a sense of healing than a prolonged focus on the genitals and anus.

Physical abuse and sexual abuse are seen together in around 15% of cases.

Physical signs of sexual abuse are uncommon even in long-standing, intrusive and painful abuse. Such subtle signs as may be present will be missed if the examiner does not encourage the child to be fully relaxed. The use of a high-quality lighting source is critical, as is the child's

posture. The gold standard is the use of photo-colposcopy, which provides magnification, light and a recording of the findings.

Small children are best examined in the frog-leg position, assisted by someone whom they trust. The knee–chest position may have to be used to define the hymenal free edge. Gentle anterior traction on the labia usually suffices to open or stretch the orifice. Older and pubertal girls may benefit from the use of stirrups and a damp swab to identify deep clefts. This should be done after appropriate specimens have been collected for forensic analysis.

Criminal prosecution from sexual abuse allegations and forensic evidence gathering is a demanding process that requires strong links between law enforcement agencies and forensic examiners. Doctors and nurses who expect to provide such a service require training from experts in the field.

Essential reading for forensic practitioners should include *The Physical Signs of Child Sexual Abuse*, produced by the Royal College of Paediatrics and Child Health in the UK in collaboration with the Royal College of Physicians of London and the Faculty of Forensic and Legal Medicine. This document presents a review of all the substantial research into individual physical signs. It also presents guidance on best practice relating to examinations and healthcare (see the Further reading list at the end of this section for details).

### Diagnosis of CSA

This is usually achieved following multi-agency assessment, the history and medical examination being only a part of the process.

**Acute sexual assault findings** (within hours or a few days):

- Bruising and swelling, abrasions and lacerations to the external genitals without a history of accidental trauma.
- Grip marks and bruising around the limbs.
- Cigarette or lighter burns around the breasts and pubic area.
- Bite marks, including suction bites around the breasts, abdomen and thighs.
- Petechiae around the eyes, tears to the oral frenulum, petechiae over the posterior fauces.
- Visible petechiae over the hymen, hymenal tears, haematomas and bleeding.
- Petechiae or bites over the glans penis and scrotum.
- Bruising, oedema and lacerations around the anal area (oedema usually resolves within 48 hours).
- Semen may be found in the vagina or rectum.
- Pregnancy is a major and not uncommon result.

**‘Chronic’ sexual abuse findings** (the most common presentation):

- Hymenal transections, deep clefts and notches in the posterior hymen, and loss or absence of posterior hymenal tissue are signs seen almost exclusively in the abused child.
- Significant tears can heal rapidly, but may leave mounds or adhesions on the hymen.
- The size of the hymenal orifice is too variable to be a guide to penetration, but a gaping orifice created by loss of the posterior hymen is significant.
- A mounded scar over the fourchette is evidence of

significant stretching trauma in the absence of a history of accidental straddle injury.

- Hymenal injuries are never acceptable from a history of a straddle or other fall unless there is convincing evidence of direct penetration by an object.
- Small superficial notches, bumps and labial adhesions are not uncommon in non-abused girls.
- Anal findings are uncommon. They include marked sustained laxity and gaping, deep and poorly healing fissures and venous congestion. Such signs may be seen in non-abused children, and must be considered in the context of the history given.

### Differential diagnoses

Several common naturally occurring conditions not due to abuse may give rise to a suspicion of sexual abuse but must be excluded.

**Non-specific vulvo-vaginitis** is the commonest. A frequent presentation in the pre-pubescent child, symptoms are of intermittent mild dysuria, redness and a sticky discharge. Symptoms are likely to relate to withdrawal of the maternal oestrogen effect, which makes some children intolerant of the use of strong detergents and poor hygiene practices. The use of loose-fitting underwear, gentle cleansing and the regular application of simple emollients usually provide relief of a condition that tends to recur until early puberty.

The presence of **pinworms** can cause genital symptoms, as can localised eczema in the napkin area. These require appropriate measures.

**Infective vulvo-vaginitis** presents with significant inflammation and pain, sometimes associated with upper airways infection, and often streptococcal in origin. If possible, bacterial cultures should be obtained before appropriate antibiotics are offered.

**Lichen sclerosus et atrophicus** is an uncommon skin disorder which may be associated with other autoimmune disease, including morphea in adults, but it tends to be a stand-alone diagnosis in children. It presents with fragility, haemorrhaging and bruising of the skin of the labia, dysuria and occasional urinary retention. Diagnosis is made easy by the classical picture of de-pigmentation in a figure-of-eight configuration associated with obvious skin fragility, and easy bleeding on stretching. Vigorous treatment with emollients is often adequate in mild cases, but topical steroids may be required to control severe signs and symptoms.

**Retained foreign bodies** can be the cause of intermittent bloodstaining and purulent or offensive discharge in very young children. It should be recognised that repeated insertion of foreign bodies into the vagina by a young child may be the presenting sign of learned or disturbed behaviour.

**Constipation** can give rise to intermittent anal bleeding and discomfort.

**Inflammatory bowel disease** may present with anal fissures, bleeding and discharge.

It is important to communicate to parents and other professionals that sexual abuse may not result in any physical findings, and that there are few signs which are absolutely

diagnostic. Nevertheless, a medical examination following an allegation of sexual abuse may provide valuable forensic information as well as an opportunity for reassurance, treatment of infection, and access to wider therapeutic support.

Difficult judgements about how to proceed may have to be made in settings where female genital cutting is practised, and where legislation and/or community action against this practice is weak.

### Fabricated and induced illness (FI)

This is the severe end of a spectrum of unusual or abnormal health-seeking behaviours in which significant harm is caused by a parent or carer (usually the mother), who deliberately fabricates signs or symptoms or induces illness in a child. Sometimes the abuse is the direct result of inappropriate and often invasive and unnecessary investigations or treatment by healthcare workers responding to the parent's fabricated accounts of non-existent illness. It is probably more common in developed than developing countries. The child is frequently brought for multiple medical assessments and investigations, the perpetrator (often the child's mother) denies knowledge of the causation of the illness, and the acute signs and symptoms cease when the child is separated from the perpetrator.

Healthcare workers in hospital are often the first professionals to suspect FI in a child on the basis of concerns about:

- being given erroneous or misleading information
- deliberate poisoning
- deliberate burns or damage to the skin
- the possibility of deliberate suffocation
- deliberate fabrication of fits
- removal of or tampering with medical monitoring equipment
- the introduction of foreign material into investigative tests.

### Immediate action when ill treatment or abuse is suspected

- A detailed history and full medical examination are required (including inspection of the genitals). Where possible, obtain the consent of the parent or carer and the child to carry out the medical examination.
- If consent is withheld, work urgently within the legal framework of the country concerned to examine and protect the child in conjunction with police, social services or civil society organisations.
- Ensure that the child (if they are old enough and able to speak) is given the opportunity away from their parent or carer to say how they were hurt (disclosure), at the same time avoiding interference with any police investigation.

When responding to disclosure:

- Remain calm. An over-reaction will make the child feel even more frightened and ashamed.
- Believe the child.
- Listen in a non-judgemental way.
- Use the child's language.
- Tell the child that you are glad they have told you what happened.
- Reassure the child that they did nothing wrong.

- Explain to the child that abuse is an unfair thing that happens to children, without condemning the offender.
- Determine the immediate need for safety.
- Don't make promises that you cannot keep.
- Let the child know what you will do.
- Set in motion the process of getting help for the child.
- Take care of yourself.

### Do's and don'ts of disclosure

**Do use phrases like this:** 'I believe you'; 'You did the right thing by telling someone'; 'I'm so sorry this has happened to you'; 'It's not your fault'; 'I will try to help you so that it won't happen again.'

**Don't use phrases like this:** 'Don't say such things!'; 'Are you sure it happened/is happening?'; 'Are you telling the truth?'; 'Why are you telling me?'; 'Why didn't you stop it?'; 'What did you do to make this happen?'

- Consider whether other children in the family may need to be examined and protected.
- Record a full history as it is spoken, and include an evaluation of the child-parent interaction.
- Carry out a careful examination in a well-lit room.
- Record the details of the history and examination legibly and contemporaneously in the child's medical notes. A form of the type available in the Appendix can be helpful.
- Include details of the child's demeanour and presentation, and their height and weight plotted on a centile chart. Ensure that an examination of the child's mouth, nose, ears and neck is undertaken, and complete a full systemic medical examination.
- Document any injuries on body diagrams (see Figure 7.6.1 and Appendix).
- Consider photo documentation (with the child's consent, if possible) of injuries, and ensure that the images can be stored safely and confidentially.
- Check whether the family is known to the police and/or social services.
- Consider whether any additional medical investigations need to be carried out (e.g. X-rays for bony injuries, a skeletal survey in children under 3 years of age, clotting studies) (see Table 7.6.2).
- Admit the child to hospital if observation or treatment is indicated, or to a place of safety if the child is considered to be at risk. Staff can then have the opportunity to talk further with the child.
- If the parents refuse to allow the child to be examined or admitted, urgent action to protect the child will be required within the legal framework of the country. This may mean referral to the duty social worker (if a referral has not already been made) or the police.

**A thorough medical examination should include the following:**

- observation of the child's demeanour
- height, weight and head circumference (in a preschool child) plotted on a centile chart
- examination of the mouth, nose, ears, neck and genitals
- inspection of skin surface for bruises, marks and cuts
- examination of the eyes for retinal haemorrhages (pupil dilatation may be needed) (see Section 5.15).
- systemic examination
- an assessment of the child's developmental age.

**Investigations to exclude medical causes should include the following:**

- full blood count, platelets and clotting screen
- a detailed skeletal survey (especially in children under 3 years) to look for new and old fractures; a chest X-ray

including the upper arms can be very valuable for identifying rib and humerus fractures

- investigations to exclude vitamin D deficiency, if there are fractures
- CT or MRI scan of the brain (if available), if non-accidental head injury is suspected.

**TABLE 7.6.2 Investigations in the differential diagnosis of child abuse**

Injury	Differential diagnosis	Investigation
Bruising	Coagulation disorder, idiopathic thrombocytopaenic purpura/Henoch–Schönlein disease, haemorrhagic disease of the newborn, septicaemia, connective tissue disorders, birth marks, dyes, tattoos, drug reactions, self-inflicted injuries, traditional treatments	Full blood count, blood film, coagulation studies Chest X-ray Consider skeletal X-ray survey in children under 3 years of age Opinion of expert in skin diseases (if available)
Bites	Animal or human Adult or child	DNA skin swab (if available) Photography Forensic dental assessment (if available)
Fractures	Accidental injury, birth injury, infection, malignancy, osteogenesis imperfecta, osteopaenia, nutritional deficiencies (including rickets)	Chest X-ray X-ray skeletal survey in children under 3 years of age Bone scan (if available) Radiology advice Blood calcium, phosphate, alkaline phosphatase and vitamin D levels (if available) CT scan for head injury (if available)
Scalds and burns	Other skin pathologies (e.g. staphylococcal and streptococcal infection), drug reactions, allergic reactions to plants (e.g. euphorbias)	Skin swabs Dermatology opinion (if available)
Head injury/unexplained fits or coma	Coagulation disorder, epilepsy or febrile convulsion, cerebral malaria, meningitis, poisoning	Retinal examination after pupil dilatation (see Section 5.15) CT scan (if available)

**TABLE 7.6.3 Differential diagnoses of genital and anal findings**

Concerning sign	Differential diagnoses
Vaginal bleeding	Accidental injury, especially straddle injury, urethral prolapse, precocious puberty, lichen sclerosis atrophicus, foreign body in genital tract, severe vulvo-vaginitis
Rectal bleeding	Anal fissures caused by hard stool, inflammatory bowel disease, infective diarrhoea, rectal polyps, rectal prolapse
Vulvo-vaginitis	Poor hygiene, skin disease (e.g. eczema, lichen sclerosis), allergies to detergents/bath products

**Additional considerations when performing examination of the genital and anal areas**

- Ensure that a good light source is available, including the use of colposcopy, if this is available.
- Conduct interviews and examinations of children with another professional person present.
- Instrumental examination is not normally required in pre-pubertal girls. Assessment of the hymen in post-pubertal girls may require use of a cotton tip swab or other techniques.
- Knowledge of local practice with regard to female genital cutting and male circumcision is important when interpreting clinical findings.
- Interpretation of anal signs is difficult, and needs to be undertaken in conjunction with a careful history of the child’s bowel pattern.
- If forensic facilities are available, ensure that clothing items and relevant swabs are taken in line with local

protocols, and that a chain of evidence is maintained to the forensic laboratory.

- Assess whether swabs for sexually transmitted infection (see Section 6.1.J) need to be taken immediately or at a follow-up review.
- Consider whether a pregnancy test needs to be carried out.
- Consider whether emergency contraception is needed.
- Consider the risks of HIV infection and whether post-exposure prophylaxis is needed in line with local protocols. This will vary depending on knowledge of the assailant, the nature of the injuries, and the country’s HIV prevalence rates.
- Consider whether hepatitis B immunisation (if available) is indicated.

**Special issues concerning the management of sexual abuse**

The child’s immediate needs are as follows:

- **To feel believed and acknowledged:** All interaction with the child should convey this message. Intrusive questioning, especially questions that imply some measure of blame (e.g. 'Why didn't you tell earlier?') can cause a child to refuse to speak further and even retract previous statements. The protective parent or carer should be briefed about this risk.
- **To be safe from further harm:** Protection usually involves the statutory services (if they exist). Police and social workers should be part of the multidisciplinary process that assesses the child's safe custody. The safety of siblings must also be considered at this stage, if not before.
- **To have all their health needs met:** Their immediate needs are for reassurance that they are healthy, and that any changes in the genital area will heal. Care should be taken to use the right language to inform the parent and the child about these changes. The use of phrases such as 'no longer a virgin' is highly inappropriate in this context, and indeed anatomically inaccurate in most cases.

Attention must be given to detection and treatment of all acquired sexually transmitted infection, including HIV, preferably within 2 weeks of an acute assault and possibly at the same time as the examination for long-standing abuse.

Pubescent girls should be offered emergency contraception where indicated.

All incidental findings (e.g. anaemia, rashes, heart murmurs) and reported health problems should be attended to and followed up where necessary.

### **Forensic sampling in acute sexual assaults**

A decision to undertake forensic sampling depends upon the following:

- Has contact abuse been reported? There is always a possibility of transferred material if there has been direct contact. Even if a condom was used, relevant lubricant or saliva may be detected.
- How long is it since the assault? If it is less than 72–96 hours, there is a possibility of trace material being found, especially within skinfolds.
- Has there been bathing or washing? Material may still be available, but this is less likely if the child has been washed thoroughly.
- How active is the child or adolescent? Children who are immobile for reasons of illness or disability may retain trace material well beyond the standard time, as drainage from the vagina is erratic.

### **What samples should be collected?**

The history should guide the practitioner in deciding where trace material is likely to be found. The history may direct one to unusual sites (e.g. swabs may identify traces of adhesive from a victim who has alleged being strapped down with masking tape; microscopic rope fibres may be recovered from around the ankles or wrists). It is sensible to collect duplicate swabs from each area sampled.

In general, swabs lightly moistened with sterile distilled water should be used to collect material that is visibly dried on or speculatively present. Dry swabs are used in moist areas such as the mouth, glans penis, anus and vagina.

If the child is very young or an infant, semen or saliva may be present over a wide area (e.g. in the hair, armpits,

abdomen, thigh creases). Damp swabs may be collected over all these areas in a young baby, whereas an adolescent is more likely to carry evidence over the breasts and in and around the vaginal area.

The use of an ultraviolet (UV) light in a dark room may help to identify both deposits of semen and saliva, and areas of deep trauma within the skin. These latter areas fluoresce because of disturbance of melanin, haemoglobin and collagen tissue. The UV light should be used with caution, as there is a risk of material denaturing with extended use.

An example of systematic head-to-toe trace evidence gathering could be as follows:

- hair combings over a sheet of white paper, then folded and placed in a special plastic bag\*
- cut areas of hair if dried material is visible
- specialised tooth brushings between the teeth and gum swabs if there has been oral ejaculation
- finger nail scrapings if there was violent resisted assault \*
- damp swabs pressed firmly and rolled over any bites noted around the neck or breasts
- swabs from the axillae and from within the umbilicus in a small infant
- pubic hair combings\*
- external vulval damp swabs
- dry high vaginal swabs
- swabs from the glans penis, behind the foreskin and over the shaft for saliva
- damp peri-anal swabs
- dry rectal swabs
- all clothing bagged individually as removed
- tampons and sanitary towels similarly bagged.

Every item collected should be fully labelled, bagged and sealed by the receiving witness, most commonly a police officer. It is sensible to allow a brief interval between samples to ensure that earlier samples have been correctly dealt with.

\* Forensic material obtained in this way is only relevant if the alleged perpetrator denies all contact with the victim, or is unknown and therefore also a potential serial offender. Finding the perpetrator's DNA in hair or other material on the victim is potent evidence in such cases.

### **Sexually transmitted diseases (STDs)**

A sexually transmitted infection may be the presenting feature in sexual abuse. Children who have experienced contact sexual abuse should be screened for STDs. The screening programme should take local prevalence factors into account, as should the decision to offer prophylactic antibiotics or antiviral treatment (see also Section 6.1.J).

*Neisseria gonorrhoeae* (especially non-conjunctival gonococcus) is not an expected infection outside the neonatal period, and is strong evidence for sexual abuse.

*Chlamydia trachomatis* similarly usually implies sexual abuse. There is evidence for vertical transmission at birth, and limited research evidence for the persistence of asymptomatic colonisation beyond the first year of life.

The presence of either of these organisms, especially if symptomatic in mid-childhood and beyond, should raise the strongest suspicion of abuse, regardless of the presence of maternal infection.

*Trichomonas vaginalis* may cause an offensive discharge in adolescents, and is a strong marker for sexual activity, consensual or otherwise. It is not known to infect the

pre-pubescent child, although it may be found colonising newborns from infected maternal secretions.

Human papillomavirus is a very common infection, and hand-to-skin transmission is so frequent that it is usually difficult to use this infection to resolve issues of sexual transmission. Transfer may be perinatal, and lesions may be seen in early childhood in the mouth and larynx. However, the presence of genital warts should mandate careful examination and screening for other STDs.

Herpes simplex virus (HSV) raises similar issues. Auto-innoculation and benign transfer cannot be excluded. Adolescents presenting with symptomatic genital HSV are likely to have had sexual contact. They need careful evaluation and screening for other STDs.

*Treponema pallidum* (syphilis) may be acquired through the placenta, and signs or symptoms of infection are highly unpredictable. Most studies in older children suggest transfer through sexual contact. The infection is exclusively sexually transmitted in adults. Sexual transmission should always be considered in a child presenting with symptoms. Infection in the parent does not exclude abuse.

Hepatitis B and hepatitis C are recognised as being sexually transferred in adults. There is insufficient research in children; however, screening of the sexually abused child is mandatory in high-risk situations, such as multiple or violent assaults and in high-prevalence regions.

Human immunodeficiency virus (HIV): The frequency of infection acquired through abuse will reflect the prevalence of HIV in the local population, and screening is strongly advised where the prevalence is high.

Screening for hepatitis and HIV will need to be timed to take account of time to seroconversion, which is usually a period of 6 or more weeks. Interval repeat screening for late conversion may be considered up to 12 weeks.

Most STDs can be screened for at 2 weeks from the date of contact.

*Neisseria gonorrhoeae* should be screened for at the first possible opportunity, preferably at the time of assessment if feasible, or within 48 hours.

Consideration should be given to hepatitis B vaccination if the child presents within a week or two after a penetrative assault.

Similar consideration may need to be given to HIV prophylaxis on occasion.

### Long-term needs

Those children who are going through the criminal justice process will need extensive support and counselling.

In well-managed sexual abuse allegations, most young children appear to function well. However, the disruption to their lives and the loss of familiar adults and objects around them does have an impact on many, and it is important that their carers are briefed.

Children who have been brutally sexualised may not recover, and may seek inappropriate affection and contact which makes them difficult to parent. Others may suffer nightmares, phobias and other symptoms of anxiety. Long-term psychological input may be necessary.

## Special issues involving sexual abuse

### Child trafficking

In 1994, the United Nations General Assembly defined trafficking as the 'illicit and clandestine movement of persons

across national and international borders, largely from developing countries and some countries with economies in transition with the end goal of forcing women and girl children into sexually or economically oppressive and exploitative situations for the profit of recruiters, traffickers, crime syndicates, as well as other illegal activities related to trafficking, such as forced domestic labour, false marriages, clandestine employment and false adoption.'

It is estimated that in the last 30 years, trafficking in women and children in Asia for sexual exploitation alone has victimised over 30 million people.

Children are trafficked for a number of purposes, including:

- sexual exploitation
- adoption
- child labour
- child soldiers
- forced marriage
- body parts
- ritual sacrifice.

Parents are promised education or jobs for their children. Some children are simply captured, then traded for whatever commodity is in demand (domestic work, sex work, drug carrying or beggary).

Children who are displaced are highly vulnerable to sexual and physical abuse. They fear seeking help and often do not have the language to do so.

Different cultural situations produce different types of exploitation. In Asia, for example, girls as young as 13 years may be exported as mail-order brides, and in Thailand around 100 000 women and girls from border countries are imported into the sex trade. Large numbers of children are being trafficked in West and Central Africa, mainly for domestic work but also for sexual exploitation, to work in shops or on farms, or to be scavengers or street hawkers. Nearly 90% of these trafficked domestic workers are girls. Many of these girls are traded on into the Middle East and Europe.

The International Organisation for Migration (IOM) has produced an extensive document that comprehensively deals with all aspects of victim management (see Further reading section at the end of this section).

Advice, both for the country of origin and for the receiving country, is structured based on two principles:

- **The child's interests are paramount.**
- **Above all, do no harm.**

The starting point is the assessment of risk both in the receiving country and in the country of origin if repatriated. Risk depends on numerous factors, including the following:

- the extent to which trafficking is controlled by organised criminal groups
- their known or estimated capacity to plan and implement reprisals against the victims and/or service delivery organisation staff
- the capacity of the local law enforcement agencies
- the extent of endemic corruption and how it adds to the level of risk.

It is critical that children have an appointed independent guardian who will act solely in their interest. Family members, including parents, may well be responsible or collusive in the trafficking, and drawing them in could greatly increase

the risk of serious harm, including death, or re-trafficking. In some cultures it may be socially acceptable for the family to shun or even kill a girl for having brought disgrace on her family.

Trafficked women may give birth to children within their repressive conditions. These children will be at very high risk of emotional abuse and neglect and early introduction into commercial sex. Babies are at risk of homicide.

Services provided for trafficked children should reflect the following needs (adapted from the IOM Report):

- **Approaches that demonstrate respect and promote participation** (e.g. children being allowed to express their views in the language they speak best).
- **An understanding of the complex ways in which their past experience has harmed them.** Children who are trafficked are subjected to a persistently threatening and dangerous environment. In the face of this type of chronic abuse and stress, children and adolescents develop a personality that is suited for survival, but that is ill adapted to cope in normal non-threatening situations. Healthcare practitioners are responsible for employing health-promoting strategies, programmes and activities that recognise the child's level of development and help children and adolescents to reclaim and further develop their competencies for an active and meaningful life. This involves addressing a range of needs, including nutritional, physical and psychological development and education needs.
- **Tailoring services to meet the needs of each age group** and in ways appropriate to the age and characteristics of the child concerned, never merely following programmes designed for adults. They should be assessed and managed by professionals trained in child development. Medical assessments need to be child friendly and provided by people with expertise.
- **Implementing strategies aimed at mitigating the effects of past trauma and fostering healthier patterns of development.** One example of such strategies is stepwise early re-integration into education and into a peer group.

### Rape as a weapon of war

The rape of adults and children of both sexes is a common phenomenon in conflict zones. As long ago as 1949, Article 29 of the Geneva Convention explicitly forbade degrading treatment, stating that 'Women shall be protected against any attack on their honour – especially rape, enforced prostitution and indecent assault.'

Rape as a crime against humanity was first prosecuted in the International Criminal Court in 2001 when three Bosnian Serbs were convicted of systematic sexual violence against Muslim women.

However, prosecution of these crimes by the relevant states has been negligible.

In Rwanda, the mass rapes of the Tutsi women and girls permanently destroyed the capacity to child bear for some, and forced others to bear children outside their ethnic group. Vast numbers of women and girls were rejected by their communities and became outcasts. Thousands of children witnessed the violence on their mothers and sisters.

As rape as a weapon of war demoralises and destabilises entire communities, it weakens ethnic communities and ties, and affects populations with the exploitation of the reproductive rights and abilities of its victims. When rape is

employed instead of a bullet, the weapon continues to wield its power beyond the primary victim. The battlefield may be the body, but the target is civil society. 'Rape, as with all terror-warfare, is not exclusively an attack on the body – it is an attack on the "body-politic." Its goal is not to maim or kill one person, but to control an entire socio-political process by crippling it. It is an attack directed equally against personal identity and cultural integrity.'

Thus in 1998, rape as an act of genocide was the decision of the International Criminal Tribunal for Rwanda. Despite these major precedents, prosecution of sexual crimes by the relevant states has been negligible. Rape has been a major feature of the war in South Sudan and in the Democratic Republic of Congo. Children as young as 5 years of age have been deliberately targeted. There is also strong anecdotal evidence that young soldiers barely in their teens have been ordered into gang rape to prove their 'manhood'.

The provision of care for victims of mass sexual abuse at this level is a daunting task, and should involve major planning and resources. Emergency care for severe physical wounding in the course of the assaults is logistically difficult.

Pratt and Werchick recommend expanding access through 'mobile teams of rape specialists' that could not only provide treatment themselves, but also transport medical supplies and transfer knowledge to any staff already on the ground. Medications, including emergency contraception, hepatitis vaccine, STD prophylaxis and antiretroviral drugs, need to be available. Such teams will need to have access to surgical facilities, especially when very young children are involved.

Gang rape, the use of instruments and other violence increases the risk of HIV/AIDS transmission significantly; intercourse is accompanied by injuries and bleeding which increases the transmission of the virus compared with transmission during consensual sex. Internal vaginal and rectal injury can be very serious, and in the very young may be fatal.

According to Human Rights Watch, 'children were reportedly forced to hold their mothers down while they were raped'. It is not difficult to see that a significant range of service provision is required at several levels to deal with such traumatic damage in childhood.

Therapeutic services in isolation without intensive educational programmes and a whole-community approach are probably doomed to fail. Rape as a weapon of war activates cultural beliefs that result in the marginalisation of its victims, especially women and children, thus preventing those victims from receiving psychosocial support, and depriving them of income. Women and girls are considered to be damaged and 'contaminated'. Wives may be denounced by their husbands, blamed for the rape, and regarded as 'married' to their rapists. Thus communities see their raped women and children as enemies and place them outside their sphere of moral obligation. Some communities may demand that their wives and children leave their villages.

Empowering young children and their mothers by providing education, and the teaching of new skills leading to longer-term economic stability, are also areas that need careful planning. Provision of safe housing and basic needs may be all that is possible in the immediate aftermath of sexual violence.

**Additional considerations when investigating fabricated and induced illness (FI)**

- The investigative process must involve early and continuing collaboration between all agencies, with detailed information sharing. Strategy planning meetings involving professionals from health, social services, police, education and legal departments can be very helpful.
- Draw up a health chronology using all accessible sources of information.
- Gather forensic or witness information.
- A decision must be made by the multi-agency team as to whether it is necessary to separate the child from the suspected perpetrator by voluntary or legal means.
- A decision must be made by the multi-agency team as to how and when to confront the parents.
- Ensure the child's safety throughout the investigative process.
- Work within the country's legal framework.

**Medical aftercare following childhood maltreatment**

It is important that these children are offered follow-up in order to:

- monitor the child's overall progress
- ensure healing of injuries

- investigate and treat any acquired infection
- facilitate access to psychological therapeutic support.

Healthcare workers involved in the hospital care of children who have been abused may be asked to provide a police statement and to attend court as a witness.

**Checklist after examination:**

- 1 Have you been able to give a clear opinion on the case?
- 2 Have you considered alternative explanations for the findings?
- 3 Does the social worker understand your findings and opinion?
- 4 If the injuries are serious or indicate serious risk, have you considered the need for police involvement?
- 5 Are you happy with plans for the immediate safety of the child?
- 6 Are you in agreement with the proposed long-term management?
- 7 Is it important for you to attend the case conference? If so, make sure that the social worker knows this.
- 8 Have you recorded your discussions?
- 9 Have you written a care plan?

# Section 8

## Procedures in children and newborn infants

## 8.1 Preparation for procedures

Practical procedures should first be explained to the child (if they are old enough to understand this information) and the parents, any risks discussed with them and their consent obtained. Procedures on young infants should avoid hypothermia. Good light is essential. Analgesia should be given where necessary, and invasive procedures only performed when essential.

### Analgesia and sedation for procedures

Some procedures have to be undertaken immediately, to save life, and many such procedures are described in this section. Clearly, there is no time to use analgesia in these circumstances, nor indeed much need to do so, as children who are in such severe collapse will have significantly

depressed conscious levels. Where there is consciousness, analgesia and/or sedation is a top priority.

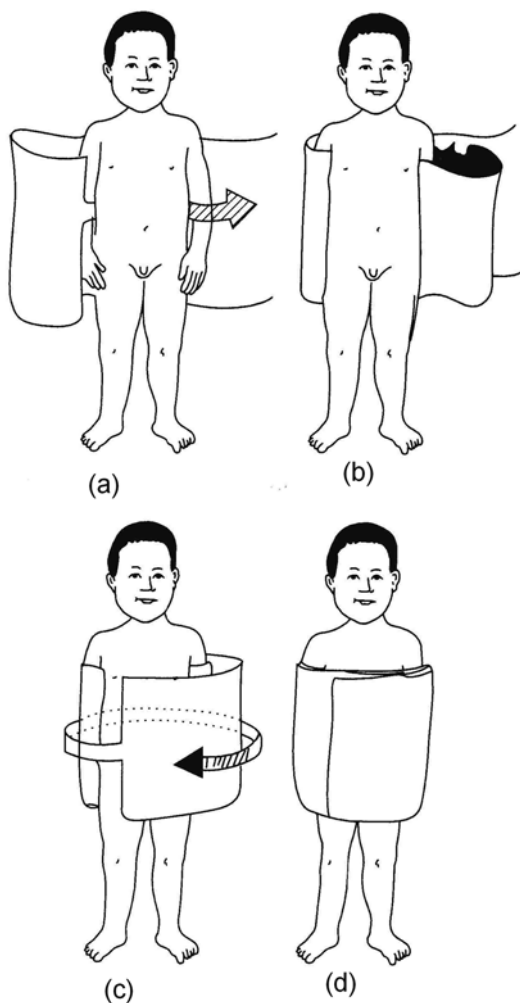

(For details on pain assessment and analgesia, see Section 1.15.)

For some procedures (e.g. chest tube insertion, dressing of burns), analgesia with a powerful drug such as ketamine should be considered, with a skilled healthcare worker (usually an anaesthetist) present and able to treat any adverse reactions immediately (see Section 1.24).

For planned intubation, anaesthesia is induced first (see Section 1.24). For some rarely used procedures such as defibrillation for cardiac arrest caused by a shockable rhythm (see Section 1.13), there is neither time nor need for sedation, as the patient is unconscious, whereas for defibrillation for an arrhythmia, sedation is necessary in most cases (see Section 5.4.C).

If ketamine is being used, give 2–4 mg/kg IM. This takes 5–10 minutes to act and the effects last for about 20 minutes. Ketamine can also be given slowly IV in this situation, 250–500 microgram/kg IV, and repeated as required to control pain. An anaesthetist or other expert in airway control must be present when ketamine is used.

When giving any analgesia, manage the child's airway, beware of respiratory depression and monitor oxygen

**FIGURE 8.1.1** Wrapping a child so that they can be held securely for a procedure. (a) and (b). One end of a folded sheet should be pulled through under the arms on both sides. (c) and (d). The other end is then brought across the front and wrapped round the child.

**FIGURE 8.1.2** Holding a child for examination of the eyes, ears and throat.

saturation with a pulse oximeter (if available). **Ensure that you have a resuscitation bag and mask available (and oxygen).**

### Restraining children for procedures

Restraint is important both for the child and for the clinician who is undertaking the procedure. Clearly, the procedure will be undertaken more quickly, safely and accurately if the child is kept still. However, to prevent a child with a chronic condition who will experience many such procedures being made fearful of further attempts, sedation should be strongly considered if facilities are available for this.

If facilities do not allow or if the procedure is unlikely to require repetition, physical restraint can be used. Ideally a parent or trusted friend or relative can actually hold the

child. It is also very helpful to use distraction techniques such as singing a song, telling a story or using a glove puppet. Blowing soap bubbles is a very useful distraction for children, and it costs very little to bend a piece of wire into a loop and make up some strong soap solution.

First explain to the child in an age-appropriate manner what is going to happen. **Never say 'This won't hurt' when you know it will.** Always use local analgesia if at all possible (see Section 1.15). Explain why they are to be wrapped up (a 'big cuddle'), what is to happen and what will happen afterwards. Give plenty of praise before, during and after the procedure.

Restraining a child for examination does not usually require wrapping, but it is wise to leave examination of the ears, nose and throat until the end of the examination.

## 8.2 Airway procedures

### Oropharyngeal airway

**For adjunct-free airway opening and airway positions, see Section 1.12.**

The oropharyngeal or Guedel airway is used in the unconscious or obtunded patient to provide an open airway channel between the tongue and the posterior pharyngeal wall. In the conscious patient with an intact gag reflex, it may not be tolerated and may induce vomiting. It is especially useful in the convulsing and post-ictal patient.

The oropharyngeal airway is available in a variety of sizes. A correctly sized airway when placed with its flange at the centre of the incisors, and then curved around the face, will reach the angle of the mandible. Too small an airway may be ineffective, and too large an airway may cause laryngospasm. Either may cause mucosal trauma or may worsen airway obstruction. Reassessment following placement is therefore a vital part of safe insertion of an airway device.

There are two methods for inserting the oropharyngeal airway in a child, depending on whether the child is small or large. However, there is no set age for switching from one to the other, as the choice of method depends on practicality and the skills of the operator. The important thing is not to push the tongue back, as that will obstruct the airway instead of keeping it open.

The twist technique is used for the larger child and in pregnancy, and means that the convex side of the airway is used to depress the tongue as the airway is pushed into the mouth. Insert the airway upside down until the tip has passed the soft palate, and then rotate it through 180 degrees so that the natural curve of the Guedel airway follows the curve of the tongue and pharynx.

However, in the infant and small child, as the tongue is larger relative to the size of the mouth, the airway cannot be rotated in the mouth without causing trauma. Therefore

**FIGURE 8.2.1** Oropharyngeal airway, showing sizing technique (correct size is illustrated).

**FIGURE 8.2.2** Oropharyngeal airway, showing position when inserted.

**FIGURE 8.2.3** Oropharyngeal airway shown being inserted concave side up, then in place concave side down.

**FIGURE 8.2.4** When inserting the airway without rotation, a tongue depressor can be helpful (not shown).

the tongue is depressed with a spatula and not by the reversed airway.

Ensure that insertion of one of these devices results in improvement in the patient's airway and breathing. If it does not improve the airway as shown by improved breathing, a reappraisal of the choice or size of airway is urgently required (see also Section 1.13).

## Tracheal intubation

### Aims

These are as follows:

- to secure the airway
- to protect the airway
- to facilitate prolonged and intra-operative ventilation
- for tracheo-bronchial toilet
- in the application of high airway pressures and positive end-expiratory pressure (PEEP)
- during cardiopulmonary resuscitation to improve ventilation and allow uninterrupted chest compressions.

### Choice of tube

An uncuffed tube is often recommended in children who weigh less than 25 kg, as the larynx is narrowest below the glottis at the circular non-distensible cricoid ring, and inexperienced use of the cuffed tube may cause damage at that point, although the cuffed tube gives better airway protection. The choice ultimately depends on the experience of the practitioner (see also Section 1.13).

The correctly sized tube is one that passes easily through the glottis and subglottic area with a small air

leak detectable at 20 cmH<sub>2</sub>O (sustained gentle positive pressure).

### Size of tube

The correct size of tube is:

- one that can just fit into the nostril **or**
- in preterm neonates, 2.5–3.5 mm internal diameter **or**
- in full-term neonates, 3.0–4.0 mm internal diameter **or**
- in infants after the neonatal period, 3.5–4.5 mm internal diameter **or**
- in children over 1 year:
  - the internal diameter (in mm) is age/4 + 4
  - the length of tube (in cm) is age/2 plus 12 for an oral tube, and age/2 plus 15 for a nasal tube.

### Aids to intubation

- Laryngoscope: blade (straight for neonates and infants because of long, floppy epiglottis, curved for older children), bulb and handle.

**FIGURE 8.2.5** Straight-blade laryngoscope, suitable for infants.

**FIGURE 8.2.6** Curved-blade laryngoscope, suitable for children.

- Magill's forceps.
  - Introducer (not further than the end of the tube itself).
  - Syringe (cuffed tube).
  - Gum elastic bougie (over which the tube can pass).
  - Cricoid pressure (can aid visualisation of larynx).
  - Suction apparatus (this must be available).

### Predicting difficulty

- Difficulty in opening mouth.
- Reduced neck mobility.
- Laryngeal/pharyngeal lesions.
- Congenital: Pierre-Robin syndrome, mucopolysaccharidoses.
- Acquired: burns, trauma.

If on viewing the infant's face from the side, the chin is unusually small (micrognathia), the intubation will be difficult, and **senior help is required** (but see below).

### Complications

- Displacement: oesophageal, endobronchial, out of larynx!
- Obstruction: kinking, secretions.
- Trauma: lips to larynx.
- Hypertensive response.
- Spasm: laryngeal, pharyngeal.
- Aspiration: gastric contents.

### Procedure

#### Prepare and check the equipment.

- Choose an appropriate tube size, with one size above and one size below it available.
- Get the tape ready to fix the tube.
- Suction must be available.
- Induce anaesthesia and give a muscle relaxant unless the patient is completely obtunded.
- **Do not attempt the procedure in a semi-conscious child.**

#### Position the child.

- Children over 3–4 years of age: the 'sniffing morning air' position (head extended on the shoulders, and flexed at the neck).
- Children under 3 years of age (especially neonates and infants): a neutral position (large occiput).
- Keep the child in a neutral position with in-line immobilisation in the case of unstable cervical spine (e.g. trauma, Down's syndrome).

#### Oxygenate the child using a face mask and reservoir (if patient is breathing) or bag and mask ventilation to provide high flow oxygen.

- Introduce the laryngoscope into the right side of the mouth.
- Sweep the tongue to the left.
- Advance the blade until the epiglottis is seen.
  - Curved blade: advance the blade anterior to the epiglottis. Lift the epiglottis forward by moving the blade away from your own body.
  - Straight blade: advance the blade beneath the epiglottis, into the oesophagus. Pull back, and the glottis will 'flop' into view.

#### Recognise the glottis.

- Insert the endotracheal tube gently through the vocal cords.
- Stop at a predetermined length.

#### Confirm the correct placement.

- The chest moves up and down with ventilation.
- Listen to breath sounds in the axillae and anterior chest wall.
- Confirm that there are no breath sounds in the stomach.
- Oxygen saturations do not go down.
- Carbon dioxide is measured from expired gases.

#### Secure the tube.

Secure with tape around the tracheal tube and on to the patient's face (see below).

#### Nasal intubation.

Although oral intubation is quicker and more reliable in an emergency, for prolonged ventilation nasal intubation is preferable, if a skilled operator is available, as the tracheal tube is more securely fixed. The technique is similar, but with the additional use of the Magill's forceps to grasp and guide the tracheal tube as it emerges into the posterior pharynx downward into the trachea through the vocal cords.

#### Intubation of the newborn infant without a laryngoscope

It is possible to intubate a newborn baby using a finger rather than a laryngoscope. This can be very helpful if you do not have a functioning laryngoscope, or if the child has facial or oral deformities that interfere with your ability to insert a laryngoscope or to see the larynx (e.g. severe micrognathia).

#### Procedure

- Insert the index finger of the left hand into the baby's mouth, with its palmar surface sliding along the tongue. Use the little finger if the baby is small.

**FIGURE 8.2.7** Finger intubation of the trachea in a newborn. (From Hancock PJ and Peterson G (1992) Finger intubation of the trachea in newborns. *Pediatrics*. **89**: 325–7. Reproduced with permission.)

- Slide the finger along the tongue until it meets the epiglottis. This feels like a small band running across the root of the tongue.
- Slide the finger a little further until the tip lies behind and superior to the larynx and the nail touches the posterior pharyngeal wall.
- Slide the tube into the mouth between the finger and the tongue until the tip lies in the midline at the root of the distal phalanx of the finger.
- At this point place the left thumb on the baby's neck just below the cricoid cartilage in order to grasp the larynx between the thumb on the outside and the fingertip on the inside.
- While the thumb and finger steady the larynx against side-to-side motion, the right hand advances the tube a short distance (about 1–2 cm).
- A slight 'give' can sometimes be felt as the tube passes into the larynx, but **no force is needed for insertion**.
- When the tube is in the trachea the laryngeal cartilages can be felt to encircle it. If it has passed into the oesophagus it can be felt between the finger and the larynx.

**Fixation of endotracheal tubes**

Two people should be available to do this, one of whom should hold the tube at all times.

- Cut two strips of sticky zinc oxide tape (see below); they should reach from just in front of the ear across the cheek and above the upper lip to the opposite ear.

**FIGURE 8.2.8** Tape for tracheal tube fixation.

- If available, apply some benzoin tincture to the cheeks, above the upper lip and under the chin, which will make the tape stick well.
- Make sure that the endotracheal tube is clean and that no old tape is left on it.
- Start with the broad end of the tape, and stick this on to the cheek. Then wrap one of the thinner ends carefully around the tube. It is useful if it is still possible to see the endotracheal tube marking at the lips.
- Tape the other half across the philtrum to the cheek.
- The second tape starts on the other cheek, and the thinner half is stuck across the chin, while the other half is also wrapped around the tube (see below).

**FIGURE 8.2.9** Taped tracheal tube.

**Cricothyroidotomy**

Cricothyroidotomy is indicated if a patent airway cannot be achieved by other means. It must be performed promptly and decisively when necessary.

**Call a surgeon and an anaesthetist (if available).**

In children under the age of 12 years, needle cricothyroidotomy can be performed rather than a full surgical cricothyroidotomy. In adolescents, either technique can be used, but the surgical technique allows better protection of the airway. The relevant anatomy is shown in Figure 8.2.10.

**FIGURE 8.2.10** Anatomy of the larynx.

In a very small baby, or if a foreign body is below the cricoid ring, direct tracheal puncture using the same technique can be used.

**Needle cricothyroidotomy**

This technique is simple in concept, but far from easy in practice. In an emergency situation the child may be struggling, and attempts to breathe or swallow may result in the larynx moving up and down.

**Procedure**

- Attach a cricothyroidotomy cannula-over-needle (or if this is not available, an IV cannula and needle) of appropriate size to a 5-mL syringe.
- Place the patient in a supine position.
- If there is no risk of cervical spine injury, extend the neck, perhaps with a sandbag under the shoulders.
- Identify the cricothyroid membrane by palpation between the thyroid and cricoid cartilages.
  - Prepare the neck with antiseptic swabs.
  - Place your left hand on the neck to identify and stabilise the cricothyroid membrane, and to protect the lateral vascular structures from needle injury.

**FIGURE 8.2.11** Penetrating the cricothyroid membrane.

- Insert the needle and cannula through the cricothyroid membrane at a 45-degree angle caudally towards the feet, aspirating as the needle is advanced (see Figure 8.2.11).
- When air is aspirated, advance the cannula over the needle, being careful not to damage the posterior tracheal wall. Withdraw the needle.
- Re-check that air can be aspirated from the cannula.
- Attach the hub of the cannula to an oxygen flow meter via a Y-connector. Initially the oxygen flow rate (in litres) should be set at the child's age (in years).
- Ventilate by occluding the open end of the Y-connector with a thumb for 1 second, to direct gas into the lungs. If this does not cause the chest to rise, the oxygen flow rate should be increased by increments of 1 litre, and the effect of 1 second of occlusion of the Y-connector reassessed.
- Allow passive exhalation (via the upper airway) by releasing the thumb for 4 seconds.
- Observe chest movement and auscultate breath sounds to confirm that there is adequate ventilation.
- Check the neck to exclude swelling from the injection of gas into the tissues rather than the trachea.
- Secure the equipment to the patient's neck.
- Having completed emergency airway management, arrange to proceed to a more definitive airway procedure, such as tracheotomy.

#### Note

There are two common misconceptions about transtracheal insufflation. The first is that it is possible to ventilate a patient via a needle cricothyroidotomy using a self-inflating bag. The maximum pressure from a bag is approximately 4.41 kPa (45 cmH<sub>2</sub>O) (the blow-off valve pressure), and this is insufficient to drive gas through a narrow cannula. In comparison, wall oxygen is provided at a pressure of 4 atmospheres (approximately 392 kPa or 4000 cmH<sub>2</sub>O). The second misconception is that expiration can occur through the cannula, or through a separate cannula inserted through the cricothyroid membrane. This is not possible. The intratracheal pressure during expiration is usually less than 2.9 kPa (30 cmH<sub>2</sub>O) (less than 1% of the driving pressure in inspiration). Expiration must occur via the upper airway, even in situations of partial upper airway obstruction. Should upper airway obstruction be complete, it is necessary to reduce the gas flow to 1–2 litres/minute. This provides some oxygenation but little ventilation.

Nevertheless, insufflation buys a few minutes in which to attempt a surgical airway.

#### Surgical cricothyroidotomy

- 1 Place the patient in a supine position.
- 2 If there is no risk of neck injury, consider extending the neck to improve access. Otherwise, maintain a neutral alignment.
- 3 Identify the cricothyroid membrane in the following manner. Place your finger over the most prominent part of the thyroid cartilage (the Adam's apple). Move the finger downwards (i.e. towards the chest), keeping strictly in the midline. The first dip felt is the area of cricothyroid membrane.
- 4 Prepare the skin and, if the patient is conscious, infiltrate with local anaesthetic.
- 5 Place the index and middle fingers of your left hand on each side of the midline of the neck to stabilise the cricothyroid membrane, and to protect the lateral vascular structures from injury.
- 6 Make a small vertical incision in the skin, and press the lateral edges of the incision outwards, to minimise bleeding.
- 7 Make a transverse incision through the cricothyroid membrane, being careful not to damage the cricoid cartilage.
- 8 Insert a tracheal spreader, or use the handle of the scalpel by inserting it through the incision and twisting it through 90 degrees to open the airway.
- 9 Insert an appropriately sized endotracheal or tracheostomy tube. It is advisable to use a slightly smaller size than would have been used for an oral or nasal tube (e.g. size 6.0 mm internal diameter for age 12–16 years).
- 10 Ventilate the patient and check that this is effective.
- 11 Secure the tube to prevent dislodgement.

#### Complications of cricothyroidotomy

These include the following:

- asphyxia
- aspiration of blood or secretions
- haemorrhage or haematoma
- creation of a false passage into the tissues
- surgical emphysema (subcutaneous or mediastinal)
- pulmonary barotrauma
- subglottic oedema or stenosis
- oesophageal perforation
- cellulitis.

## 8.3 Breathing procedures

### Emergency needle thoracocentesis

This procedure is used for the rapidly deteriorating patient who has a life-threatening tension pneumothorax (see Section 7.3.A). If this technique is used in a patient who

does not have a tension pneumothorax, there is a 10–20% risk of producing a pneumothorax or causing damage to the lung, or both. In such cases, immediate insertion of a chest drain is mandatory. **Patients who have undergone**

this procedure should ideally have a chest radiograph, and may require chest drainage if they subsequently need assisted ventilation.

#### Minimum equipment

- Swabs for disinfecting the skin.
- Large over-the-needle IV cannula (16-gauge, but 20- to 22-gauge in preterm infants).
- 20-mL syringe.

#### Procedure (see Figure 8.3.1)

**FIGURE 8.3.1** Position for inserting over-the-needle cannula for thoracocentesis.

- 1 Identify the second intercostal space in the mid-clavicular line on the side of the pneumothorax (the **opposite** side to the direction of tracheal deviation and the **same** side as the hyper-resonance).
- 2 Swab the chest wall with surgical preparation solution or an alcohol swab.
- 3 Attach the syringe to the over-the-needle IV cannula, ideally via a three-way tap.
- 4 Insert the cannula vertically into the chest wall, just above the rib below to avoid blood vessels, aspirating all the time.
- 5 If air is aspirated, remove the needle, leaving the plastic cannula in place.
- 6 Tape the cannula in place and proceed to chest drain insertion as soon as possible.

#### Complications

These include the following:

- local cellulitis
- local haematoma
- pleural infection
- empyema
- pneumothorax.

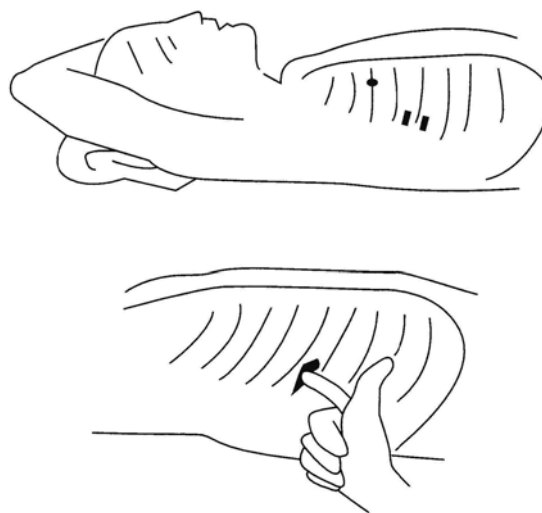

#### Insertion of a chest drainage tube

In a trauma emergency that requires a chest drainage tube, fluid resuscitation through at least one large calibre IV cannula, and monitoring of vital signs should be ongoing. Usually the patient will be receiving oxygen through a face mask with a reservoir.

Chest drain placement should be performed using the open technique described here, as this minimises lung damage. In general, the largest size of drain that will pass between the ribs should be used.

#### Minimum equipment

- Skin disinfectant and surgical drapes.
- Scalpel with fine straight blade.
- Blunt forceps.
- Artery forceps.
- Large clamps × 2.
- Suture.
- Local anaesthetic if the child is conscious.
- Scissors.
- Chest drain tube.
- Underwater seal or Heimlich flutter valve.

**FIGURE 8.3.2** Sites for chest drain: 4th or 5th intercostal space in the anterior or mid-axillary line.

#### Procedure

- 1 Consider using analgesia or sedation in a small or apprehensive child.
- 2 Wash your hands and arms to the elbows, and wear a mask, surgical hat (bonnet), sterile gown and sterile surgical gloves.
- 3 Prepare the underwater seal with an assistant and take the sterile end of the tube, ready to connect to the chest tube once inserted. The 'seal' end should be covered by no more than 1–2 cmH<sub>2</sub>O.
- 4 Decide on the insertion site (usually the fourth or fifth intercostal space in the anterior or mid-axillary line) on the side with the pneumothorax (see Figure 8.3.2).
- 5 Swab the chest wall with surgical preparation or an alcohol swab.
- 6 Use local anaesthetic if the child is conscious. Morphine (100 micrograms/kg IV over 10 minutes) should also be given if the child is conscious, but in the preterm infant who is not ventilated this may precipitate apnoea. Facilities to provide bag-and-mask ventilation and/or intubation should be immediately available, together with staff trained in their use.
- 7 Make a 2- to 3-cm skin incision along the line of the intercostal space, **immediately above the rib below to avoid damage to the neurovascular bundle which lies under the inferior edge of each rib.**
- 8 Using artery forceps, bluntly dissect through the subcutaneous tissues just over the top of the rib below, and puncture the parietal pleura with the tip of the forceps.

- 9 Put a gloved finger into the incision and clear the path into the pleura. This will not be possible in infants or small children, in which case continue to use the artery forceps.
  - 10 Advance the chest drain tube (use the largest size that can comfortably pass between the ribs) into the pleural space without the trocar in place, but using the artery forceps to help to guide it into the pleural cavity if necessary. Pass about 3 cm and then connect to the underwater seal. Ideally advance the chest drain tube into the pleural space during expiration.
  - 11 Ensure that the tube is in the pleural space by looking for fogging of the tube during expiration.
  - 12 Ensure that all of the drainage holes of the chest drain tube are inside the chest.
  - 13 Connect the chest drain tube to an underwater seal. Check that the tube is in the right place by observing intermittent bubbling of the water in the drainage bottle.
  - 14 Secure the tube using a suture passed through the skin at the incision site (after ensuring that adequate local anaesthetic has been administered) and tied around the tube.
  - 15 Cover the puncture site in the chest wall with a sterile dressing, and tape the chest tube to the chest wall.
  - 16 Obtain a chest radiograph if at all possible.
- Wash your hands and put on sterile gloves.
  - Lie the child on their back.
  - Clean the skin over the chest with an antiseptic solution (e.g. 70% alcohol).
  - Select a point in the mid-axillary line (at the side of the chest) just below the level of the nipple (fifth intercostal space; see Figure 8.3.2).
  - Inject about 1 mL of 1% lignocaine into the skin and subcutaneous tissue at this point.
  - Insert a needle or needle-over-catheter through the skin and pleura, and aspirate to confirm the presence of pleural fluid. Withdraw a sample for microscopy and other tests and place it in a container.
  - If the fluid is clear (straw-coloured or brownish), pull out the needle or catheter after withdrawing enough fluid to relieve distress, and put a dressing over the puncture site. Consider a differential diagnosis of tuberculosis (see Section 6.1.N).
  - If the fluid is thin pus or cloudy (like milk), leave the catheter in place so that you can draw out more pus several times a day. Make sure that you seal the end of the catheter so that no air can get in.
  - If the fluid is thick pus which cannot pass easily through the needle or catheter, insert a chest tube as described above.

**If the chest drainage tube is satisfactorily positioned and working, occasional bubbles will pass through the underwater seal. The water level in the tube may also rise and fall slightly with the respiratory cycle.**

#### **Complications of chest drainage tube insertion**

- Dislodgement of the chest drain tube from the chest wall or disconnection from the drainage bag.
- Drainage bag elevated above the level of the chest, and fluid flowing into the chest cavity, unless there is a one-way valve system.
- Chest drain tube kinking or blocking with blood clot.
- Damage to the intercostal nerve, artery or vein. This might convert a pneumothorax to a haemopneumothorax, or result in intercostal neuritis or neuralgia.
- Damage to the internal thoracic artery if the puncture is too medial, resulting in haemopneumothorax.
- Incorrect tube position, inside or outside the chest cavity.
- Introduction of pleural infection (e.g. thoracic empyema).
- Laceration or puncture of intrathoracic or abdominal organs. This can be prevented by using the finger technique before inserting the chest tube.
- Leaking drainage bag.
- Local cellulitis.
- Local haematoma.
- Mediastinal emphysema.
- Persistent pneumothorax from a large primary defect; a second chest tube may be required.
- Subcutaneous emphysema (usually at the tube insertion site).

#### **Tapping the chest for diagnostic tests in pleural effusions or empyema**

##### **Diagnostic procedure**

- Consider giving the child analgesia or light anaesthesia with ketamine.

#### **Non-invasive respiratory support (see Section 1.25)**

Respiratory support is needed when the patient fails to sustain adequate ventilation despite treatment of the respiratory condition. Respiratory failure may result from any of the following:

- respiratory illnesses
- severe shock
- coma
- convulsions
- meningo-encephalitis
- neuromuscular disorders
- raised intracranial pressure (e.g. from trauma).

Infants and young children are more likely to progress to respiratory failure because:

- they are more susceptible to infection
- their airways are smaller
- their thoracic cage is more compliant
- their ribs are (nearer) horizontal
- their respiratory muscles are more prone to fatigue.

Women and girls who are pregnant are also more susceptible to respiratory failure. They have reduced immune function, an expanding abdominal mass which impairs lung expansion, and are more prone to gastro-oesophageal reflux and aspiration of gastric contents.

As respiratory failure progresses, it will ultimately lead to cardiorespiratory arrest and death. Thus recognition of the severity of the conditions that lead to respiratory failure, followed by appropriate treatment, will reduce morbidity and mortality.

**Signs** that indicate the adequacy of breathing include the following:

- intercostal, sub-costal and supra-sternal recession
- respiratory rate
- inspiratory and expiratory noises

- use of accessory muscles
- adequacy of breath sounds and chest expansion
- heart rate
- skin colour
- mental status.

To help to assess the development of respiratory failure, it is necessary to assess changes in the above clinical signs. In the following situations, however, these signs are less useful because there is absent or decreased effort of breathing:

- 1 with fatigue or exhaustion (e.g. after prolonged respiratory effort)
- 2 with loss of cerebral drive from raised intracranial pressure, poisoning or encephalopathy
- 3 in children with neuromuscular disease.

**In these cases, pay more attention to the chest expansion, heart rate, skin colour, mental status and, if available, SaO<sub>2</sub> measurement.**

Pulse oximetry is of additional value to measure the arterial oxygen saturation through the skin (SpO<sub>2</sub> or SaO<sub>2</sub>). Values of SpO<sub>2</sub> of less than 92–94% in air (at sea level; see Section 1.13 for values at high altitude) are abnormal, and would warrant at least initial treatment with additional inspired oxygen. Values of less than 95% when the child is in oxygen are low, but even values of more than 95% in oxygen may be associated with significant hypoventilation. It is essential to remember that, in respiratory failure, normal SaO<sub>2</sub> while receiving additional inspired oxygen is likely to be associated with significant hypoventilation or intra-pulmonary shunting. Measurement of transcutaneous, end-expired or blood carbon dioxide levels will confirm this.

**TABLE 8.3.1 Modes of respiratory support for different conditions**

Mode of support	Interface with patient	Level of nursing care	Associated medical treatment	Clinical use	Examples of conditions treated
High-flow high-humidity oxygen	Nasal cannulae	Home, ward, HD	Nil	To provide a flow above the patient's needs, that helps to wash out dead space, and improves comfort and clearance of the airways. It may provide mild CPAP	Bronchiolitis, post-operative, chronic lung disease of prematurity
Continuous positive airways pressure (CPAP)	Nasal cannulae or nasopharyngeal tube	High dependency (HD)	Sedation or analgesia may be needed	To keep upper and lower airways patent and maintain adequate lung volume (oxygenation)	Neonatal respiratory distress syndrome, <b>bronchiolitis</b>
	Nasal mask or face mask	Home, ward, HD Intensive care (IC)	Nil Sedation or analgesia may be needed		Sleep-related upper airway obstruction Acute upper airway obstruction before, <b>instead of</b> or after extubation
Intermittent positive pressure ventilation (IPPV)	Nasal mask or pillows, face mask (NIPPV)	Home to IC	Nil	To treat hypoventilation (raised CO <sub>2</sub> ) when airway control and clearance are adequate	Chronic (e.g. central, neuromuscular) Acute (e.g. after surgery)
	Endotracheal tube	IC	Anaesthesia for intubation Sedation or analgesia will be needed	To treat hypoventilation when clearance and/or support of airway(s), or close control of ventilation needed	Procedures or surgery requiring anaesthesia Severe respiratory illnesses, raised intracranial pressure
	Tracheostomy	Home to IC	ENT surgical procedure	Long term ventilation where day and night support needed	Brainstem/high spinal injury or neuromuscular disease
Continuous negative extrathoracic pressure (CNEP)	Chamber or jacket	Home to IC	Nil	To keep lower airways patent and maintain adequate lung volume	Bronchiolitis and other severe lower respiratory infections, especially where the nose is blocked by secretions
Intermittent negative pressure ventilation (INEP or INPV)				To treat hypoventilation where airway control and clearance are adequate or maintained by CPAP	Central hypoventilation (e.g. apnoea of prematurity, neuromuscular disease)

Shaded areas denote those that require a lower dependency of care (e.g. that have been used in the home setting), but may be useful in acute conditions.

Bold type denotes high-risk situations in which CPAP may be ineffective and intubation may be required.

When respiratory fatigue is severe, oxygenation is poor or deteriorating, or carbon dioxide levels are raised, respiratory support should be used, if available. The various forms of respiratory support are outlined in Table 8.3.1, along with their indications.

#### **Notes on the use of positive pressure ventilation**

- 1 Monitoring of patient status and airway or mask pressures is necessary when undertaking any form of respiratory support (see below).
- 2 Positive airway pressure involves a flow of air or other gas mixture to the patient's airways. This flow may be continuous (as in CPAP) or intermittent (as in IPPV). It may vary with inspiration and expiration (as in BiPAP), or to accommodate the leaks or variable compliance of ventilator tubing, airways or lung units.
- 3 Mask ventilation can be well tolerated by children, but it may be more difficult for infants and young children to tolerate appliances on their face.
- 4 In the presence of excess airway secretions or an open mouth, nasal masks and nasal cannulae may not produce as effective airway pressures as ventilation with tracheal intubation (or relatively higher pressures may be needed for the same effect).
- 5 The pressures used with masks and cannulae may be higher than those used with tracheal intubation, because of the greater potential for air leaks and other volume loss in compliant upper airway structures.
- 6 Infants and young children will sometimes tolerate masks and cannulae only with the use of sedation, in which case close monitoring of respiratory failure must be undertaken in case full intubation and ventilation is needed.
- 7 Endotracheal intubation should be undertaken with rapid sequence drug or gaseous induction, and subsequent analgesia, anxiolysis and sedation should be provided.
- 8 Positive pressure ventilation administered through an endotracheal tube must be accompanied by adequate humidity of the inspired gases.
- 9 Oxygen may be administered either using a built-in mixer in the ventilator, or by entraining a supply in the ventilator tubing nearer to the patient.
- 10 Positive pressure ventilators should be able to provide manipulation of either the pressure or volume administered, and the time intervals for inspiration and expiration. There should be alarms for failure to cycle, and for excessive pressure and/or volume administered.

#### **Continuous positive airway pressure (CPAP)**

CPAP has several effects on the airway and lungs of the preterm and full-term infant. These include prevention of alveolar collapse, increased functional residual capacity (FRC), and splinting of the airway. It is therefore of most value when used early in the course of respiratory disease (i.e. before too much alveolar collapse has taken place). Several units around the world use it successfully as first-line ventilatory support in even the smallest infants (< 750 grams birth weight).

#### **Indications for CPAP**

These include the following:

- signs of significant respiratory distress (tachypnoea, recession, grunting, nasal flare)
- diseases with low FRC (respiratory distress syndrome, transient tachypnoea of the newborn, pulmonary oedema)
- meconium aspiration syndrome
- apnoea and bradycardia of prematurity
- tracheomalacia.

#### **Requirements**

- Low-resistance delivery system.
- Large-bore tubing.
- Short wide connection to patient.
- Consistent and reliable pressure generation.
- Appropriate snug-fitting nasal cannulae.
- Well-positioned and secured nasal cannulae.
- Prevention of leaks, mainly via the mouth, with a chinstrap.
- Optimally maintained airway.
- Ideally warmed humidified gas.
- Prevention of neck flexion or over-extension with a neck roll.
- Regular suction to remove secretions.
- Meticulous and consistent technique.

#### **Monitoring**

- Continuous heart and respiratory rate monitoring.
- Continuous pulse oximetry, ideally pre-ductal.
- Blood gas measurements. These need not be done regularly in the stable baby with low oxygen needs unless they are required in order to assess the degree of metabolic acidosis, but in those with high oxygen requirements ( $FiO_2 > 40\%$ ) or in the unstable baby they should be checked regularly via an arterial line.

#### **Complications**

- **Nasal septum erosion/necrosis:** this is a result of ill-fitting nasal cannulae, and can be avoided by the fitting of snug, but not tight, cannulae (blanching of the overlying skin suggests that the cannulae are too large) which are held firmly in place to prevent rubbing as the child moves.
- **Pneumothorax:** all methods of artificial ventilation are associated with this problem. However, the more effective the CPAP is the less the work of breathing and therefore the lower the risk of pneumothoraces should be. Any pneumothorax that does occur should be drained appropriately. It is inappropriate to discontinue the CPAP.
- **Gastric distension from swallowed air:** this is important and is easily overcome by the venting of any such air via an open orogastric tube.

**Insertion and securing of nasal cannulae and administration of CPAP**

**FIGURE 8.3.3** Securing nasal cannulae for giving continuous positive airway pressure (CPAP) in a baby. A special bonnet is used from which tapes hold the pipe carrying the air/oxygen mixture to the nasal cannulae to the forehead and a separate tape above the mouth to ensure the cannulae do not come out of the nasal passages..

**FIGURE 8.3.4** Simplified diagram of Hudson continuous positive airway pressure (CPAP). The gas flow is adjusted until a continuous trail of bubbles starts to appear in the water bottle, which is at the same height as the baby. This generates a CPAP of +5 cmH<sub>2</sub>O.

**Continuous negative extra-thoracic pressure**

Continuous negative extra-thoracic pressure (CNEP) is a method by which sub-atmospheric pressure is applied to the outside of a child's chest by nursing them in a specially designed chamber. The patient's head is kept outside the chamber, thereby allowing the nose, mouth and all the airways into the lungs to remain at atmospheric pressure. As a result of this pressure difference, the chest is expanded and air is encouraged to enter the lungs. Areas of lung that were previously poorly inflated may be expanded, and this allows more chance for recovery from the lung disease.

The use of CNEP depends upon continued breathing efforts by the child to move air into and out of the lungs.

When the child is inside the chamber, the breathing rate falls, the effort of breathing is reduced, and thus less energy is needed for breathing.

**Indications**

- Respiratory failure due to lung problems:
  - bronchiolitis
  - other causes of acute respiratory infection where the nasal airway is blocked and nasal CPAP is not possible.
- Respiratory failure due to weakness of respiratory muscles:
  - poliomyelitis.

**Advantages**

The absence of airway invasion:

- avoids trauma to the airways
- reduces the need for suctioning
- lowers the risk of introducing infection into the lungs
- is more comfortable for the patient, so there is less need for sedation.

Less complex equipment:

- can be managed on a general ward or at home
- is not difficult for healthcare workers and parents to learn how to use
- means that there is less utilisation of intensive care resources
- is quick to institute, not requiring medical or anaesthetic staff.

Physiological (compared with positive pressure) ventilation:

- does **not** increase pulmonary vascular resistance
- is less likely to significantly reduce cardiac output
- enhances lung perfusion, as well as ventilation.

**Disadvantages**

Negative pressure generated in the upper airway on

inspiration may be increased, thus exacerbating **pre-existing** upper airway obstruction.

Respiratory support may need to be interrupted for short periods.

- This means it is less suitable where the need for support to ventilation is critical and continuous
- It is also not suitable if the patient's own ventilatory efforts are inadequate to remove carbon dioxide.

Maintenance of body temperature in newborn infants may require specific attention.

### Components of negative pressure system

**FIGURE 8.3.5** Negative pressure system.

#### The chamber

For low-birth-weight infants the chamber is built on to an incubator base incorporating a cabinet and heater, the latter providing servo-controlled circulation of hot air into the interior of the chamber. Particular features of the chamber shown in Figure 8.3.5 include the following:

- 1 release for the head section
- 2 rods upon which the head section slides out away from the chamber base
- 3 headbox
- 4 latex rubber neck seal fixed on to the arch of the lid
- 5 gas strut hinges
- 6 foam gasket or cuff on the porthole
- 7 porthole for infusions, monitoring leads, etc.
- 8 footplate to support the infant when the chamber is tilted up
- 9 compressible rubber strips below which leads, etc. can enter the chamber
- 10 tubing to the pressure monitor.

#### The neck seal

This is a piece of latex rubber with a circular hole 2–5 cm in diameter, situated near the bottom end. This is fitted around the infant's neck overlying the neck protector.

#### The neck protector

This is a piece of two or four thicknesses of ribbed cotton tubular stockinet. Two holes cut in the sides allow this to be fitted like a polo-necked vest over the infant.

#### The suction unit

This incorporates an electrical fan with a valve which provides variable levels of continuous suction. The valve is adjustable by a pressure control knob. A suction hose connects from the suction unit to the base of the chamber.

#### The pressure monitor

This can be a simple calibrated U-tube containing coloured

**FIGURE 8.3.6** (a) Neck seal. (b) Neck protector. The neck seal is a piece of stretchy latex rubber with a circular hole 2–5 cm in diameter, which is stretched and fitted around the infant's neck, overlying the neck protector.

alcohol or other fluid, **or** a more sophisticated pressure monitor.

#### Safety

- 1 Special care must be taken not to trap the fingers or toes when closing the lid.
- 2 To avoid damaging the monitor leads, these must pass either (1) through the diaphragm at the base of the chamber, or (2) between a rubber strip at the foot end of the chamber and a second rubber strip on the lower edge of the lid. The monitor leads will be damaged and pressure lost if they are brought out through the sides of the chamber between the unprotected Perspex edge of the lid and the rubber seal on the base.

#### Care of infants who are receiving CNEP Feeding

While receiving negative pressure, the patient would not usually be fed orally. Feeds should be given via a nasogastric tube, and this tube should be clamped off when not in use. Do not leave the tube open to air or the stomach may become distended.

If the baby develops problems with abdominal distension, the stomach should not be left on free drainage in the conventional way. Either frequent aspiration of the stomach contents should be performed, with the tube clamped off in the intervening time, or the end of the tube can be put through the neck seal (in between the silicone gel and the vest) and the tube left on free drainage inside the chamber.

If the baby's clinical condition allows this, they may be taken out of the chamber at regular intervals for breastfeeding or cup feeds.

#### Procedures

Most procedures, such as re-siting of an IV line, can be performed while the infant is receiving negative pressure.

When the arms are inserted through the portholes, sub-atmospheric pressure can be maintained by the close-fitting cuffs around the forearms.

Excessive body movement may occur during sudden loss of negative pressure when the porthole is opened or the arm removed from the cuff. This may be quite disruptive to the baby. Therefore it is preferable to minimise the number of times this occurs by taking into the chamber all the items which are needed for the procedure. When the cuffs or gaskets become soiled or torn, they must be replaced immediately.

### Neck care

Pay particular attention to the patient's neck, observing it for soreness frequently, at 6- to 8-hourly intervals if possible when the patient is turned. It is important to ensure that all the layers of the neck seal are in place and that the latex does not come into contact with the baby's skin. It is not necessary to replace the neck seal components unless they are soiled or damaged. If they are in place for a prolonged period, especially in the case of a newborn preterm baby whose skin may scale and shed, it is probably better to wash and dry the neck at regular intervals when the clinical condition allows, preventing colonisation by skin commensal bacteria.

It is also important to frequently check the neck to ensure that the latex does not become too tight if the baby becomes oedematous. If this happens it is important to replace the latex with a larger size.

### Controlling body temperature

The important principle to follow in the control of body temperature of babies who are receiving negative pressure is the prevention of hypothermia, rather than its treatment. Due to convective and radiant heat loss the baby is much more likely to cool rapidly and be more difficult to warm up than in the conventional incubators.

Plastic sheeting or bubble wrap may be placed over the infant's body to create a 'micro-environment'.

An overhead radiant heater may be used as an additional heat source over the headbox or chamber.

### Management of problems that may arise

#### Inadequate pressure

- Excess leak at neck:
  - Slacken the latex into the arch in the lid.
  - Move the baby upwards.
  - Reposition the latex.
  - Double the thickness of stockinet collar under the latex.
  - Use latex with a smaller hole (if a large leak is present).
- Excess leak between chamber and base of chamber:
  - Tighten the quick-release lid and base catches.
  - Replace the rubber strip gasket around the chamber base.
- Excess leak at the portholes:
  - Renew the cuffs or foam gaskets.
  - Tighten or secure the iris diaphragm porthole.
- Inadequate suction pressure:
  - Check that the hose is plugged in at both ends.
  - Check that the access hole for suction inside the chamber is not blocked (e.g. by the sheet).
  - Check the pressure achieved by the suction unit after directly occluding the hose at the end.

### Unsettled baby

- Baby breathing too hard:
  - There may be an inadequate negative pressure.
  - Check for upper airway obstruction.
  - Check for stridor, tracheal tug and carbon dioxide retention.
  - A different method of respiratory support may be needed.
- Anxiety:
  - Give reassurance and/or sedation to make the baby comfortable.
- Sore neck:
  - Check the neck and treat sore areas to relieve discomfort.

### Abdominal distension

- Air swallowing:
  - Close the nasogastric tube.
  - Undertake more frequent suction or free drainage inside the chamber.

### Cold baby

- Excess leak:
  - See the section on 'Inadequate pressure'.
- Cold environment:
  - Provide an overhead heater.
  - Humidify the chamber.
  - See the guidelines on temperature.

### Problem: neck soreness

- Pressure or contact allergy:
  - Ensure that at the neck seal there is at least a fourfold thickness of stockinet between the latex and the skin.
  - If the latex is stretched too tightly, the baby may be suspended at the neck. Release and pleat it as described above.
  - The hole in the latex may be too small, so revise it if necessary.

### Inadequate oxygen in the headbox

- Excess leak at the neck:
  - See the section on 'Inadequate pressure'.
- Inadequate oxygen:
  - Seal the top and sides of the headbox (e.g. with cling film).
  - Adjust the flow and/or concentration.
  - Two supplies of high-flow humidified 100% oxygen may be needed to provide a high concentration in the headbox.

### Physiotherapy for suppurative lung diseases

Therapy for bronchiectasis, cystic fibrosis and other conditions with excess airway secretions is described here.

### Postural drainage

This is positioning to allow drainage by gravity from lung segments to central airways.

For infants, use a maximum of five positions in 10 minutes, progressing in older children to two to three positions in up to 30 minutes.

1 Apical segments upper lobes

5 Apical segments of lower lobes

2 Posterior segment right upper lobe (reverse for left)

6 Anterior segments of lower lobes

3 Anterior segments upper lobes

7 Posterior segments of lower lobes

4 Right middle lobe (reverse for left)

8 Lateral segments of right lower lobes (reverse for left)

FIGURE 8.3.7 Positions for postural drainage.

**Upper lobe**

- Apical segments: sitting (1).
- Posterior segments: prone, one pillow below the affected side (2).
- Anterior segment: supine (3).

**Middle lobe/lingual**

- Chest tipped 15 degrees below the horizontal, lying supine, with a pillow supporting the ipsilateral hip and shoulder (4).

**Lower lobe**

- Apical segments: prone (5).
- Anterior basal: chest tipped 20 degrees below the horizontal, lying supine (6).
- Lateral basal: chest tipped 20 degrees below the horizontal, lying on the unaffected side (7).
- Posterior basal: chest tipped 20 degrees below the horizontal, lying on the unaffected side (8).

Figure 8.3.7 shows all of these positions in sequence.

**Equipment**

Carer's lap (in the case of an infant), otherwise bean bags, pillows or a tilted bed.

**Adjuncts to postural drainage**

The following may be combined with postural drainage:

- **chest clapping:** done over the area to be cleared with a cupped hand
- **chest shaking:** fine manual shaking in line with rib motion during the expiratory phase of breathing
- **active cycle of breathing:** relaxed tidal breathing, four deep breaths to maximal inspiration with hold, and relaxed expiration. Huff – that is, forced expiration at mid

to low lung volumes with the glottis open (as if misting glass), cough to clear secretions, and repeat the cycle until the chest is clear.

Note where bronchoconstriction is an issue:

- 1 Increase the amount of time spent doing tidal volume breathing.
- 2 Omit percussion.
- 3 Increase tidal volume breathing and omit percussion.

Consider the use of inhaled bronchodilators (e.g. salbutamol 200–500 micrograms inhaled through a spacer) (see Section 5.2.B).

**Relative contraindications**

These include the following:

- raised intracranial pressure
- severe hypertension
- after abdominal surgery
- after major haemoptysis
- pulmonary oedema
- surgical emphysema
- after treatment of tension pneumothorax
- cardiac arrhythmias
- gastro-oesophageal reflux (only omit postures with upper body dependent).

**Patient positioning**

- To maximise ventilation–perfusion matching (e.g. in pneumonia, asthma, pneumothorax) in self-ventilating patients, position with the better ventilated lung uppermost.
- In severely breathless patients, use sitting with a forward lean, or the recovery position. Use pillows to raise and support the chest if the patient cannot tolerate lying flat.

## 8.4

## Circulatory procedures

Access to and support for the circulation is vital in emergency care, to draw blood samples for diagnosis and monitoring, to infuse fluid to restore circulating volume and improve perfusion, to transfuse blood and to give treatment drugs. This section describes and illustrates many means of access to the circulation, and includes guidance on safe drug and fluid infusion.

Also included are circulatory support procedures such as defibrillation and pericardiocentesis, and techniques for other non-parenteral routes of drug administration, including intramuscular (IM), subcutaneous (SC) and intradermal (ID) injections.

### 8.4.A Minimising error in drug and fluid administration: giving injections

**General points on safety**

The information given below is adapted from the *Neonatal Formulary*, 11th edition (BMJ Books).

- 1 Drug vials once reconstituted do not contain preservatives or antiseptic. Therefore multiple sampling from them is potentially hazardous.

- 2 For infants, dilute drugs to ensure that volumes can be accurately measured. For example, do not use doses of less than 0.1 mL for a 1-mL syringe.
- 3 Serious errors can occur if the dead space in the hub of the syringe is overlooked during dilution. For example, if the active drug is drawn into a 1-mL syringe up to the 0.1-mL mark, the syringe will contain between 0.19 and 0.23 mL. If the syringe is then filled with diluent to 1 mL, the syringe will contain approximately twice as much drug as was intended. Dilution must involve first half filling the syringe with **diluent** and then adding active drug by using the distance between two graduations on the syringe. Mix the two by moving the plunger, and then finally add further diluent to the total planned volume of active drug and diluent. For dilutions of more than 10-fold, use a small syringe to inject the active drug, connected by a sterile three-way tap to a larger syringe. Then add diluent to the large syringe to obtain the desired volume.
- 4 Many drugs are equally effective whether given orally or parenterally. Oral administration is safer and less expensive. The following antibiotics are as effective given orally as given IV in a baby who is taking feeds: amoxicillin, ampicillin, chloramphenicol, ciprofloxacin, co-trimoxazole, erythromycin, flucloxacillin, fluconazole, isoniazid, metronidazole, pyrimethamine, rifampicin, sodium fusidate, and trimethoprim.
- 5 If a drug is given down an orogastric or nasogastric tube, a proportion of the drug will remain in the tube unless it is flushed through.
- 6 Rectally administered drugs are less reliably absorbed than drugs given orally. Liquid formulations are better than suppositories in infants.
- 7 When giving IV drugs, do so slowly in all cases. After it has been injected into the line (ideally through a three-way tap), the normal IV infusion rate of the fluid going into the cannula can be used to drive the drug slowly into the patient.
  - If there is no background infusion, give sufficient follow-up (flush) of fluid (0.9% saline, sterile water or 5% glucose) to ensure that the drug does not remain in the cannula or T-piece. Give the flush over 2 minutes to avoid a sudden surge of drug (remember the hub).
  - If the IV drug needs to be given rapidly (e.g. adenosine), do this by administering a 2-mL bolus of 0.9% saline via a second syringe, not by temporarily increasing the infusion rate (sometimes the temporary increase becomes prolonged and dangerous).
- 8 Do not mix incompatible fluids IV.
- 9 For IV drug infusions (using a syringe/infusion pump: if available) given in addition to background IV infusions:
  - Adjust the total 24-hour IV fluid intake.
  - Never allow a surge of a vasoactive drug such as dopamine or epinephrine.
  - Never put more drug or background IV into the syringe or burette than is needed over a defined period of time.
  - Check and chart the rate of infusion, and confirm this by examining the amount left every hour.
- 10 Intramuscular injections need special precautions:
  - IM injections are unsafe in shock, as they will be poorly absorbed from poorly perfused muscle tissue initially, and then (especially, for example, with opiates) a high dose may be released once recovery of the circulation occurs.
  - To avoid nerve damage, only the anterior aspect of the quadriceps muscle in the thigh is safe in a small wasted infant under 1 year of age.
  - Alternate between the legs if multiple injections are required.
  - Do not give IM injections if a severe bleeding tendency is present.
  - It is essential to draw back the plunger to ensure that the needle is not in a vein before injecting potentially dangerous drugs IM (e.g. adrenaline, magnesium sulphate, lidocaine).

### Care of intravascular lines

- 1 Placement of central venous lines: check with a lateral X-ray that the line is placed well into a major vein, and if near the heart with the catheter tip ideally in the superior vena cava at the entrance to the right atrium.
- 2 Placement of an umbilical arterial line should either be above the diaphragm in the thoracic aorta, or below the two renal arteries (at L4) to minimise the risk of renal or mesenteric artery thrombosis.
- 3 All arterial lines can result in life-threatening haemorrhage or occlusion leading to ischaemia. Procedures to ensure that these complications do not occur should be in place.
- 4 Never give a drug into an IV cannula that has started to tissue. Some drugs (e.g. those containing calcium) can cause severe scarring. Inspect the cannula tip site before and while injecting any drug IV.
- 5 Local infection can become systemic, especially in neonates or in the immunosuppressed.
  - Always remove the cannula if there is erythema in tissue around it and if lymphangitis is seen. If lymphangitis is present always take a blood culture from a separate vein and start IV or IM antibiotics.
  - Always place cannulae aseptically and keep the site clean.
  - There is no evidence that frequent changes of cannula site or infusion kit are of benefit. However, it is a good idea to change the giving set after blood transfusion or if a line of blood has entered the infusion tubing from the vein and clotted there, as this can act as a site for bacterial colonisation. Otherwise change the lines every 3 or 4 days.
- 6 Air embolism: if air reaches the heart, unlike blood it will stay there, especially if the patient is lying flat.
  - Unless it is immediately aspirated, air in the heart can block the circulation.
  - Umbilical venous and other central venous lines are particularly dangerous. There must be a tap or syringe on the catheter at all times, especially during insertion.
  - An alternative source of air embolus is through the giving set, especially when pumps are being used.
- 7 Blood loss.
  - In neonates this can occur from the umbilical stump.
  - From central venous or arterial lines, it can rapidly be fatal, and therefore all connections must be Luer locked and the connections to the cannula and its entry must be observable at all times.

- Ideally, arterial lines should be connected to a pressure transducer and alarm.

### Use of intravenous/intra-arterial (IV/IA) access

- 1 When sampling from an IV/IA line, clear the dead space first (by three times its volume).
  - Blood glucose levels cannot be accurately measured from any line through which a glucose solution is infused, even if many times the dead space has been cleared.
  - For blood culture, always use a separate fresh venous 'needle stab' sample.
- 2 Never add anything to a line carrying total parenteral nutrition (TPN).
- 3 Certain infusions, such as glucose > 10%, adrenaline and dopamine, are better given through a central vein.
 

**In an emergency, dopamine and adrenaline infusions can be given through a peripheral vein.**
- 4 If a continuous infusion is not required, a peripheral cannula can be stopped off with a sterile bung after flushing the drug in with 0.9% saline, sterile water or 5% glucose to clear the dead space (there is no evidence that a heparin lock is needed for a cannula in peripheral veins).
- 5 Central venous catheters must be firmly anchored to the skin so they do not migrate into or out of position.
  - After individual drug injections and without continuous infusion, a heparin lock is appropriate to prevent clotting of the line (10 units of heparin per 1 mL of 0.9% saline), particularly in double-, triple- or quadruple-lumen catheters (always use Luer lock connections to minimise extravasation).
- 6 Peripheral artery lines should never be used for giving drugs.
  - To maintain patency, a continuous low-rate (0.5–1.0 mL/hour) infusion of heparinised 0.9% or 0.18% saline is useful (heparin at 1 unit/mL). Clear the 1-mL dead space of the catheter before and after sampling, which must be done aseptically.
- 7 In neonates and infants, frequent flushing with saline 0.9% can result in sodium overload. Therefore consider using 0.18% saline or sterile water to achieve flushing.
- 8 Central arterial lines (usually in the aorta) can be safely used to give glucose or total parenteral nutrition if the catheter tip site is checked radiologically (not near mesenteric or renal arteries). Most drugs (except inotropes) can also be safely given by this route by slow infusion (not by boluses).
- 9 Do not add drugs to any line containing blood or blood products.
- 10 Most IV drugs can be given into an infusion containing 0.9% saline or up to 10% glucose (the exceptions include amphotericin B, phenytoin and erythromycin).
- 11 If only one line is being used for an infusion and more than one drug needs to be given, try to wait 10 minutes between them. If this is not possible, separate by 1 mL of 0.18% saline/4% glucose, 0.9% saline or sterile water for injections. This is very important with an alkaline drug such as sodium bicarbonate. Always give the flush slowly over at least 2 minutes to ensure that the drug already in the line/vein does not move forward in the patient in a sudden rapid surge (especially

if the catheter/vein contains an inotrope or vasoactive drug such as aminophylline, cimetidine, phenytoin or ranitidine, which can cause an arrhythmia).

- 12 When two IV drugs need to be given together and there is only one IV catheter, terminal co-infusion using a T- or Y-connector next to the catheter can be used. It is important to know whether this is safe for the drugs in question.

### Minimising IV infusion and IV drugs errors

Errors of both commission and omission occur. For example, excess IV fluids can be dangerous by causing circulatory overload, and inadequate IV fluids can be dangerous by causing hypoglycaemia (especially in the neonate, and commonly when a blood transfusion is being given and the infant is relying on IV glucose).

Extravasation can also result in the absence of a vital drug (e.g. morphine infusion for pain). Errors will always occur where human actions are involved, and it is essential to have systems in place to minimise these.

### Steps to reduce errors and their impact

- Prescribe or change infusion rates as infrequently as possible, ideally once or twice daily.
- Never have more than one IV infusion line running at the same time unless this is absolutely necessary (e.g. in major trauma or shock, where two lines are needed for volume replacement and also in case one line is lost at a critical time).
- Use a burette in which no more than the prescribed volume is present (especially in infants and young children).
- Record hourly the amount given (from the burette, syringe or infusion bag) and the amount left.
- Check the infusion site hourly to ensure that extravasation has not occurred.
- Ensure that flushes are only used when essential, and are given slowly over at least 2 minutes.
- Ensure that flushes do not overload the patient with sodium.
- Be particularly careful with potassium solutions given IV (use the enteral route whenever possible).
- Check and double check the following:
  - Is it the right drug? Check the ampoule as well as the box.
  - Is it the right concentration?
  - Is the shelf life of the drug within the expiry date?
  - Has the drug been constituted and diluted correctly?
  - Is the dose right? (Two people are needed to check the prescription chart.)
  - Is it the correct syringe? (Deal with one patient at a time.)
  - Is the IV line patent?
  - Is a separate flush needed? If so, has the flush been checked?
  - Are sharps (including glass ampoules) disposed of?
  - Has it been signed off as completed (and ideally countersigned)?

### Writing a prescription

- Use block capitals.
- Use approved names.

- The dosage should be written in grams (g), milligrams (mg) or micrograms. **Always write micrograms in full.**
- Volumes should be written in millilitres (mL).
- Avoid using decimal places whenever possible. If this is not possible, they should be prefaced by a zero. For example, write 500mg, not 0.5g, and if a decimal place is used, write 0.5mL **not** .5mL.
- Write times using the 24-hour clock.
- Routes of administration can be abbreviated as follows: IV (intravenous), IM (intramuscular), PO (orally), SC (subcutaneous), NEB (nebuliser), RECT (rectally).
- 'As required' prescriptions must be specific about how much, how often and for what purpose (indicate the maximum 24-hour dose).
- Each drug should be signed for individually by a registered doctor.
- Stop dates for short-course treatments should be recorded when first prescribed.

### IV drug infusions in severely ill or injured children in high-dependency care

#### **Adrenaline: in 5% dextrose or 0.9% saline. Do not mix with bicarbonate**

Dose: 0.05–2 micrograms/kg/minute: this is equivalent to 0.6mL/kg of 1 in 1000 (600 micrograms/kg) in 100mL run at 0.5–20mL/hour.

As a short-term measure, place 1mg (1mL of 1 in 1000 adrenaline) in 50mL of 0.9% saline. Give 2–5mL (40–100 micrograms) to a child (depending on size) and 1mL (20 micrograms) to an infant under 1 year of age. Give IV slowly. Repeat as required (with ECG monitoring).

#### **Aminophylline: in 5% dextrose or 0.9% saline**

Loading dose (**do not give aminophylline if theophylline has been received in the last 24 hours**).

IV infusion over 20–30 minutes, 5mg/kg for children under 12 years of age, and 250–500mg total if over 12 years of age.

Then give 1mg/kg/hour if under 12 years and 500 micrograms/kg/hour if over 12 years: this is equivalent to 50mg/kg in 50mL run at 1mL/hour for those under 12 years, and 0.5mL/hour for those over 12 years.

#### **Dopamine: in 5% dextrose or 0.9% saline or undiluted (ideally via a central line). Do not mix with bicarbonate**

This can be mixed with dobutamine.

Give 2–20 micrograms/kg/minute (renal = up to 5 micrograms/kg/minute): this is equivalent to 30mg/kg in 50mL run at 0.2–2mL/hour.

#### **Ketamine: in 5% dextrose or 0.9% saline**

Give 10–45 micrograms/kg/minute: this is equivalent to 50mg/kg in 50mL run at 0.6–2.7mL/hour (maximum concentration 50mg/mL).

#### **Midazolam: in 5% dextrose or 0.9% saline or undiluted**

Give 1–6 micrograms/kg/minute (60–360 micrograms/kg/hour): this is equivalent to 6mg/kg in 50mL run at 0.5–3mL/hour.

Or give undiluted (5mg/mL), run at 0.012–0.072mL/kg/hour.

#### **Morphine: in 5% dextrose or 0.9% saline**

Give 10–60 micrograms/kg/hour: this is equivalent to 1mg/kg in 50mL run at 0.5–3mL/hour.

#### **Salbutamol IV: in 5% dextrose or 0.9% saline**

Give 0.6–5 micrograms/kg/minute: this is equivalent to 3mg/kg in 50mL run at 0.6–5mL/hour.

### Giving injections

First, find out whether the child has reacted adversely to drugs in the past. Wash your hands thoroughly. **Use disposable needles and syringes.** Clean the chosen site with an antiseptic solution. Carefully check the dose of the drug to be given and draw the correct amount into the syringe. Expel the air from the syringe before injecting. Always record the name and amount of the drug given. Discard disposable syringes in a safe container.

#### **Intramuscular route**

In children over 2 years of age, give the injection in the upper outer quadrant of the buttock. Choose the site carefully, well away from the sciatic nerve. In younger or severely malnourished children, use the outer side of the thigh midway between the hip and the knee, or over the deltoid muscle in the upper arm. Hold the muscle at the injection site between the thumb and first finger and push the needle (23- to 25-gauge) into the muscle at a 90-degree angle (45 degrees in the thigh). Draw back the plunger to make sure that there is no blood (if there is, withdraw slightly and try again). Give the drug by pushing the plunger slowly until the end. Remove the needle and press firmly over the injection site with a small swab or cotton wool for at least two minutes.

**FIGURE 8.4.A.1** Holding a child for an intramuscular injection in the thigh.

### Subcutaneous route

Select the site as described above for intramuscular injection. Pinch up skin and subcutaneous tissue between your finger and thumb. Push the needle (23- to 25-gauge) under the skin at an angle of 30–45 degrees into the subcutaneous fatty tissue. Do not go deep to enter the underlying muscle. Draw back the plunger to make sure that there is no blood (if there is, withdraw slightly and try again). Give the drug by pushing the plunger slowly until the end. Remove the needle and press firmly over the injection site with cotton wool for at least two minutes.

FIGURE 8.4.A.2 Giving a subcutaneous injection.

### Intra-dermal route

Select an area of skin which has no infection or damage for the injection (e.g. over the deltoid in the upper arm). Stretch the skin between the thumb and forefinger of one hand. With the other hand, slowly insert the needle (25-gauge), **bevel upwards**, for about 2 mm just under and almost parallel to the surface of the skin. Considerable resistance is felt when injecting intra-dermally. A raised blanched bleb showing the surface of the hair follicles is a sign that the injection has been given correctly.

FIGURE 8.4.A.3 Giving an intradermal injection.

## 8.4.B Gaining circulatory access

### Peripheral venous cannulation

#### Preparation of kit

The following equipment is needed:

- 18- to 25-gauge IV cannula or butterfly needles
- 2-mL syringe and T-piece containing Ringer-lactate or Hartmann's solution or 0.9% saline for flushing
- tape or plaster of Paris for scalp veins
- a small splint (this can be made from a wooden spatula covered with gauze)
- alcohol swabs for skin cleaning
- local anaesthetic cream if available
- tourniquet (or assistant)
- cannula size:
 

neonates:	24–25G
infants:	22–24G
children:	20–22G
adolescents:	18–20G.

#### Procedure

Apply the tourniquet to distend the vein (do not forget to remove it after cannulation).

Choose a vein:

- forearm
- long saphenous vein (anterior to the medial malleolus)
- back of the hand or front of the wrist
- scalp.

Useful sites to cannulate include the dorsum of the feet and hands. The saphenous and antecubital veins are larger, but can be useful for percutaneously inserted 'long lines'. The antecubital veins are also useful for venepuncture for laboratory studies.

- If possible, place the cannula close to the bone where it is more fixed.
- Decide the direction of blood flow.

- Clean the skin with antiseptic.
- Fix and slightly stretch the skin with your other hand.
- Pass the cannula through the skin at a slight angle (10–20 degrees). **Be decisive.**
- Stop once you are through the skin.
- Flatten the cannula to the skin and advance with the long axis of the cannula in the same direction as the vein. **Be decisive.**
- Aim to pass it into the vein at the first attempt with steady advancement.
- Always watch for blood appearing in the hub of the cannula.
- As soon as blood is seen, stop.
- Hold the needle still, and advance the cannula over the needle until the hub is at the skin.
- Hold the cannula still.
- Withdraw the needle.
- Connect the connector, flush and fix. No subcutaneous swelling should be seen and there should be no resistance to injection.
- If no blood is seen on advancing the cannula, but it is felt to be beyond the vein, **stop**.
- Gently pull the cannula back in the same direction as advancement; if blood appears, **stop** once again. Follow the same procedure as if blood was seen on first advancement (transfixion technique).
- Connect the T-piece and flush the cannula gently with Ringer-lactate or Hartmann's solution or 0.9% saline to confirm that it is in the vein.
- If the cannula is satisfactorily inserted, tape it in place by looping a thin piece of the tape under the hub and round to form a 'V' shape fixing it to the skin.

When splinting, try to 'double back' the tape (i.e. put a short

piece and a long piece back to back, leaving just the ends of the longer piece sticky). This helps to prevent excessive amounts of tape sticking to the baby, which is particularly important in the case of more immature babies whose skin is easily damaged.

**FIGURE 8.4.B.1** Inserting an intravenous cannula into a vein on the back of the hand. The hand is flexed to obstruct venous return and thus make the veins visible.

**FIGURE 8.4.B.2** Arm splinted to prevent bending of the wrist.

#### Note on flushing lines

The smaller the syringe used, the greater the pressure exerted on fluid in the line. Therefore avoid using 1-mL syringes to flush a blocked line, as the line may rupture or tissue may be damaged by infiltration.

#### Care of the IV cannula

Secure the cannula when it has been introduced. This may require the splinting of neighbouring joints to limit the movement of the catheter. Keep the overlying skin clean and dry. Fill the cannula with Ringer-lactate or Hartmann's solution or 0.9% saline immediately after the initial insertion and after each injection.

#### Blood sampling from the IV cannula

If the patient needs blood samples at the time of cannulation it is often possible to take these as the cannula is inserted. Blood can be dripped from the end of the cannula into the appropriate bottles, or a syringe can be used to **gently** aspirate blood from the cannula. If the cannula has been flushed prior to insertion, the first 0.5–1 mL of blood should be discarded.

#### Common complications

Superficial infection of the skin at the cannula site is the commonest complication. The infection may lead to thrombophlebitis, which will occlude the vein and result in fever, and may progress to septicaemia. The surrounding skin is red and tender. Remove the cannula **immediately** to reduce the risk of further spread of the infection. Antibiotic

treatment (effective against *Staphylococcus aureus*) should be given.

#### IV drug administration through an indwelling cannula

Attach the syringe containing the IV drug to the injection port of the cannula and introduce the drug. Once all of the drug has been given, inject 0.5 mL of Ringer-lactate or Hartmann's solution or 0.9% saline into the cannula until all of the drug has entered the circulation and the catheter is filled with the infusion fluid.

#### Safe IV infusions where no burettes are available

- Mark the infusion bottle with tape for each hour to be given, and label each hour, **or**
- Empty until only the necessary amount to be given is left in the bottle.

#### Special sites for IV cannulae

##### Scalp veins

##### Procedure

- 1 Restrain the child.
- 2 Shave the appropriate area of the scalp with a sterile razor.
- 3 Clean the skin.
  - Have an assistant distend the vein by holding a taut piece of tubing or bandaging perpendicular to it, proximal to (nearest to the child's body) the site of puncture.
- 4 Fill the syringe with Ringer-lactate or Hartmann's solution or 0.9% saline and flush the butterfly set.
  - Disconnect the syringe and leave the end of the tubing open.
- 5 Puncture the skin and enter the vein. Blood will flow back through the tubing.
  - Infuse a small quantity of fluid to see that the cannula is properly placed and then tape it into position.
  - **Care should be taken not to cannulate an artery, which is recognised by pulsation on palpation. If there is a pulsatile spurting of blood, withdraw the needle and apply pressure until the bleeding stops. Then look for a vein.**

**FIGURE 8.4.B.3** Inserting a scalp vein needle.

Scalp drips are generally more precarious than ones in the limbs, and need to be carefully observed. Infiltration into the soft tissues of the scalp can spread quickly and cause extensive necrosis if irritant. Shave the hair from an area about 2–3 cm around the site selected in order to allow for fixation by tape. Always ensure that the tip of the needle is not covered by dressings, so that infiltration is quickly seen.

### External jugular vein

#### Procedure

- 1 Place child in a 15–30-degree head-down position (or with padding under the shoulders so that the head hangs lower than the shoulders). Wrapping may be necessary to restrain the child (see above).
- 2 Turn the head away from the site of puncture. Restrain the child as necessary in this position.
- 3 Clean the skin over the appropriate side of the neck.
- 4 Identify the external jugular vein, which can be seen passing over the sternocleidomastoid muscle at the junction of its middle and lower thirds.
- 5 Have an assistant place their finger at the lower end of the visible part of the vein just above the clavicle. This stabilises it and compresses it so that it remains distended.
- 6 Puncture the skin and enter the vein pointing in the direction of the clavicle.
- 7 When free flow of blood is obtained, ensure that no air bubbles are present in the tubing, and then attach a giving set.
- 8 Tape the cannula securely in position. One of the most important points is to ensure that the cannula is properly secured in the vein by high-quality fixation. It is easily removed by the child, so use plenty of tape!

FIGURE 8.4.B.4 Position of the external jugular vein.

**Be aware that there is a higher risk of air embolism than with peripheral venous cannulation.**

If infusion through a peripheral vein or scalp vein is not possible, and it is essential to give IV fluids to keep the child alive:

- set up an intra-osseous infusion
- or use a central vein
- or perform a venous cut-down.

All of these procedures are described below.

### Central venous cannulation

This should not be used routinely. It should only be performed when IV access is urgent and, in the case of central veins, only by those who have been trained in the technique

(it is best done by an anaesthetist). Remove the cannula from a central vein as soon as possible (i.e. when IV fluids or drugs are no longer essential, or when a peripheral vein can be cannulated successfully).

The aims of central venous cannulation are as follows:

- to obtain venous access when peripheral cannulation is not possible (**however, in an emergency, intra-osseous cannulation is faster and easier**).
- to monitor central venous pressure
- to obtain prolonged vascular access
- to obtain large-bore vascular access
- to administer certain drugs
- during resuscitation.

#### Procedure

Several routes are possible, but the most widely used are the femoral and internal jugular approaches. The femoral approach is easiest in the emergency situation. A subclavian approach may be useful in the older child.

#### Preparation of kit

The following equipment is needed:

- sterile pack
- sterile Seldinger wires
- cannula: single 16- to 22G cannula
- single, double or triple lumen if available (5 FG 5–8 cm length for neonate, 7 FG 8–15 cm length for child)
- syringe and Ringer-lactate or Hartmann's solution or saline
- suture and tape for fixing
- local anaesthetic with fine 25G needles.

#### Preparation of the child

- Explain what is going to happen (if the child is conscious).
- Position the child.
- **Sterilise the skin and maintain sterile technique.**
- Apply local analgesia to the skin (if the child is conscious).

**Two insertion techniques are available**, namely:

- the same as in peripheral cannulation
- the Seldinger technique (wire)
- ideally an ultrasound probe can help identify the vein and ensure the cannula when inserted is in the correct position in the lumen of the vein.

#### Seldinger method

- 1 Identify the vein with cannula on syringe (same approach as for peripheral cannulation); there must be good flow.
- 2 Stop, and pass the cannula over the needle.
- 3 Disconnect the syringe.
- 4 Pass the wire through the cannula to three-quarters the length of wire (if there is any resistance, stop, withdraw the wire with needle, and start again).
- 5 Holding the wire firmly, withdraw the needle over the wire.
- 6 Pass the dilator over the wire (it is sometimes necessary to make a small cut at the skin) and, holding the wire firmly, withdraw the dilator.
- 7 Pass the cannula/catheter filled with Ringer-lactate or Hartmann's solution or 0.9% saline over the wire (passage of the cannula should be smooth, meeting no resistance).
- 8 Hold the cannula, and withdraw the wire (gently if it sticks, do not force it).

- 9 Confirm correct placement by aspiration of blood.
- 10 Suture and fix with antiseptic ointment over the entry site.
- 11 Confirm the position with an X-ray.

### Femoral cannulation

This is adequate for almost all needs, is technically much easier and has lower complication rates, particularly in neonates and infants. However, if it is not a sterile procedure, there is a risk of causing septic arthritis in the hip joint.

- 1 Position the patient supine with the leg slightly abducted. Place a towel under the buttocks to raise the pelvis.
- 2 Clean the skin and drape with sterile towels. Locate the vein by finding the femoral arterial pulsation 2 cm below the midpoint of the inguinal ligament. The vein lies immediately medial to the artery. If the child is conscious, infiltrate the skin and subcutaneous area with 1% lignocaine.
- 3 With a finger on the femoral artery introduce the needle with syringe attached at an angle of 30–45 degrees to the skin along the line of the vein pointing towards the umbilicus. Advance the needle while aspirating.
- 4 When blood 'flashes back' into the syringe, stop advancing and remove the syringe from the needle. Feed the Seldinger guide wire through the needle, keeping hold of one end of the wire at all times.
- 5 Withdraw the needle over the wire, then feed the catheter over the wire into the vein.
- 6 Withdraw the wire and aspirate for blood to confirm the position. Then flush the catheter with Ringer-lactate or Hartmann's solution or 0.9% saline.
- 7 Suture the catheter in place.

FIGURE 8.4.B.5 Femoral vein cannulation.

**If you are unsure whether you are in a vein or an artery, consider transducing the pressure waveform.**

### Internal jugular vein

Use a head-down position for the internal jugular and subclavian approaches, as this increases vein distension and reduces the risk of air embolism.

### Procedure

- 1 Place the child in a 30-degree head-down position and

turn their head to the left-hand side for the right-sided approach, which avoids the lymphatic duct. Place a towel or roll under the shoulders to extend the neck.

- 2 Clean the skin and drape with towels, exposing the neck to the clavicle.
- 3 Identify the apex of the triangle formed by the two heads of the sternocleidomastoid and clavicle, and infiltrate local anaesthetic (if the child is conscious). Alternatively, identify carotid pulsation medial to the sternomastoid at the level of the lower border of the thyroid cartilage, and the vein (usually) just lateral to this. Aim the needle at 30 degrees to the skin and towards the ipsilateral nipple (note that the neck is very short and the vein is superficial in the very young). Estimate the length of catheter from the point of skin entry to the nipple.
- 4 Direct the needle at 30 degrees to the skin, pointing towards the right nipple, and puncture the skin at the apex of the triangle.
- 5 Holding this position, advance the needle, aspirating all the time. If blood 'flashes back', stop advancing and remove the syringe from the needle. (If you do not cannulate the vein, withdraw the needle, but not out of the skin, and advance again slightly more laterally.)
- 6 Feed the Seldinger guide wire through the needle, always having control of one end of the wire.
- 7 Withdraw the needle over the guide wire and then feed the catheter over the wire into the superior vena cava.
- 8 Withdraw the wire, aspirate for blood and attach the infusion set. **Do not leave the catheter open, as this may lead to an air embolism.**
- 9 Suture the catheter in place and obtain a chest X-ray (if possible) to check for a pneumothorax and the position of the catheter tip, which should be in the superior vena cava (SVC), ideally at the junction of the SVC and the right atrium, but not in the right atrium.

FIGURE 8.4.B.6 Position of the internal jugular and subclavian veins.

### Subclavian vein

- 1 Place the patient in a supine position, turn the head to the contralateral side, position a roll to extend the neck a little, and identify the midpoint of the clavicle.
- 2 Aim for the suprasternal notch, and pass the needle just beneath the clavicle at the midpoint. The vein lies anterior to the subclavian artery and is closest at the medial end of the clavicle.
- 3 Subclavian artery puncture is not uncommon (it is not

possible to use compression to stop the bleeding, but this is rarely a problem unless coagulopathy is present).

### Complications

These are fewer and less severe in femoral cannulation, but include the following:

- arterial puncture
- nerve damage
- pneumothorax in neck access veins
- extravasation-administered fluids/drugs
- septicaemia if the procedure is not sterile or if the cannula is in place for more than 5 days.

## Cut-down venous cannulation

### Indication

Continuous IV access is needed where percutaneous attempts have failed. **In the emergency situation, intraosseous access is faster and easier.** Cut-down is less appropriate if speed is essential.

### Preparation of kit

The following equipment is needed:

- skin prep (iodine, alcohol)
- scalpel
- suture
- IV cannula
- local anaesthetic
- curved artery forceps
- syringe and hypodermic needle
- sterile drapes.

### Procedure

Identify landmarks. The **long saphenous vein** at the ankle is superior and medial to the medial malleolus of the ankle. The **brachial vein** at the elbow is lateral to the medial epicondyle of the humerus.

#### Brachial vein:

- Infant: one finger breadth lateral to the medial epicondyle of the humerus.
- Small child: two finger breadths lateral to the medial epicondyle of the humerus.
- Older child: three finger breadths lateral to the medial epicondyle of the humerus.

#### Long saphenous vein:

- Infant: half a finger breadth superior and anterior to the medial malleolus.
  - Small child: one finger breadth superior and anterior to the medial malleolus.
  - Older child: two finger breadths superior and anterior to the medial malleolus.
- 1 Immobilise the lower leg and clean the skin, as described above. Identify the long saphenous vein, which lies half a finger breadth (in the infant) or one finger breadth (in the small child) superior and anterior to the medial malleolus.
  - 2 Clean the skin and drape with sterile towels.
  - 3 Infiltrate the skin with 1% lignocaine using a fine 24- to 25G needle, and make an incision through the skin perpendicular to the long axis of the vein. Bluntly dissect the subcutaneous tissue with haemostat forceps.
  - 4 Identify and free a 1–2 cm section of vein. Pass a proximal and distal ligature.

- 5 Tie off\* the distal end of the vein, keeping the ties as long as possible for traction.
- 6 Make a small hole in the upper part of the exposed vein, gently dilate the opening with the tip of a closed haemostat, and insert the cannula (without the needle/trocarr in it) into this, while holding the distal tie to stabilise the position of the vein.
- 7 Secure the cannula in place with the upper ligature.
- 8 Attach a syringe filled with Ringer-lactate or Hartmann's solution or saline and ensure that the fluid flows freely up the vein. If it does not, check that the cannula is in the vein or try withdrawing it slightly to improve the flow.
- 9 Tie the distal ligature\* around the catheter, and then close the skin incision with interrupted sutures.
- 10 Place antiseptic ointment (e.g. iodine) over the wound, and suture or tape the catheter to the skin (ensure that local anaesthetic is used at the suture site if the child is conscious). Cover with sterile dressing.

\* It is also possible to dispense with the proximal and distal ligatures and simply penetrate the vein directly with a plastic over-the-needle cannula as you would if penetrating the skin externally. Once in the vein, remove the inner needle and secure in position.

**FIGURE 8.4.B.7** Cut-down incision showing vein: position of cut-down on long saphenous vein at ankle.

### Complications

These include the following:

- haemorrhage or haematoma
- perforation of the posterior wall of the vein
- nerve transection
- phlebitis
- venous thrombosis.

## Umbilical vein catheterisation

### Indications

- Where there is urgency during resuscitation of the newborn to give IV fluids and drugs.
- Temporarily for exchange transfusion. The catheter should not be left in position between exchanges.

**Time of insertion**

Catheterisation is usually easy in the first 4 days of life, and possible from 5 to 7 days.

**Passing an umbilical vein catheter is the quickest and easiest way to access the circulation in the newborn.**

**Preparation of kit**

The following equipment is needed:

- gown and gloves
- sterile instruments including:
  - fine scissors
  - forceps
  - scalpel
- silk suture for retaining
- 5 French gauge umbilical catheter
  - a sterile feeding tube may be satisfactory if an umbilical catheter is not available, but measure the length first so that you will know how much you have passed by measuring the length from the hub to the umbilical insertion. Cannulae designed for use as umbilical vein cannulae are usually marked in 5-cm increments
- a three-way tap
- 0.5% chlorhexidine or 10% povidone-iodine for cleaning the skin
- sterile cotton wool balls
- sterile towels or drapes to cover the baby's abdomen
- sterile 2-mL syringe and connector filled with Ringer-lactate or Hartmann's solution or 0.9% saline.

**FIGURE 8.4.B.8** Insertion and securing of a catheter in the umbilical vein. (a) Preparation of the umbilical cord. (b) Inserting the catheter into the umbilical vein, which is the larger thin-walled structure towards the head. Note the two umbilical arteries, which are thick-walled and towards the legs of the baby. (c) Securing the inserted catheter to prevent kinking.

**Procedure**

- 1 Assemble the syringe, three-way tap and catheter. Flush and fill the catheter with sterile 0.9% saline. Then close the tap to prevent air entry (which may cause air embolus).
- 2 Clean the umbilical cord and surrounding skin with 0.5% chlorhexidine or 10% povidone-iodine, and then loosely tie a suture around the base of the cord.

- 3 Cut back the cord to about 2 cm from the base.
- 4 Cover the skin with towels to form a sterile working surface.
- 5 Hold the cord at an edge with forceps.
- 6 Identify the vein. It is usually gaping, larger, and well separated from the two small thicker-walled arteries.
- 7 Hold the catheter approximately 2 cm from the end with non-toothed forceps, and insert the tip into the vein. Gently advance the catheter, which should pass easily.
- 8 Insert the catheter for a distance of 4–6 cm.
- 9 Check that the catheter is not kinked and that blood draws back easily. If there is a block, pull gently on the cord, pull back the catheter partly and reinsert.
- 10 The catheter can be secured by winding a suture round it several times and then passing a stitch through the cord base. An additional safeguard is to form two wings of tape which can then be taped to the abdominal wall, always remembering that it is preferable to use as little tape as possible in smaller babies. However, it is essential that the catheter does not fall out.

Occasionally the umbilical vein is kinked and advance of the catheter is blocked at 1–2 cm beyond the abdominal wall. Gentle traction on the cord usually relieves this.

If obstruction occurs at more than 2 cm, and only partly gives way with pressure, the catheter is probably either wedged in the portal system or coiled up in the portal sinus. It is advisable to withdraw the catheter part way and reinsert it.

**Care of indwelling catheters**

Leave the cord exposed to air. Remove blocked catheters.

**Removal of the catheter**

- 1 Use sterile technique.
- 2 Remove a specimen of blood for culture.
- 3 If possible, place a purse-string suture around the vessel at the base of the umbilicus and withdraw the catheter slowly.
- 4 Tighten the purse-string suture.
- 5 Apply pressure to the umbilical stump for 5–10 minutes.

**Time of removal of catheter**

Remove the catheter as soon as possible as dictated by the clinical state of the baby. The infection rate rises after 24 hours. Complications are more common with venous catheters than with arterial ones, so venous catheters should rarely be left in.

**Complications**

These include the following:

- thrombosis survivors may develop portal vein thrombosis
- embolism from clots in the catheter, or from injected air
- vascular perforation
- vascular damage from hypertonic solutions (more common when the tip is in the portal system)
- haemorrhage from a disconnected catheter
- necrotising enterocolitis or bowel perforation may occur as a complication of exchange transfusion
- infection
- there is no evidence that prophylactic antibiotics are of any value.

## Intra-osseous needle insertion

Intra-osseous infusion is a safe, simple and reliable method of giving fluid and drugs in an emergency when venous access is not possible (e.g. in shock).

### Site for needle

The first choice for the puncture is the proximal tibia. The site for needle insertion is in the middle of the antero-medial surface of the tibia, at the junction of the upper and middle third, to avoid damaging the epiphyseal plate (which is higher in the tibia), 2–3 cm below the tibial tuberosity. An alternative site for needle insertion is the distal femur, 2 cm above the lateral condyle.

### Intra-osseous needles (15- to 18-gauge)

If a purpose-made intra-osseous needle is not available, a number of alternatives can be used, including bone-marrow needles, short lumbar puncture needles or a large-calibre venepuncture needle. For example, a green needle can be used in a neonate. The disadvantage of venepuncture needles is that they may carry a fragment of bone into the marrow. This is not dangerous, but it may block the needle. Also the bevel of these needles is long, and extravasation of fluid is more likely than with a purpose-made intra-osseous needle.

**FIGURE 8.4.B.9** (a) Intra-osseous needle tibial site (X). (b) Section through bone. Image reprinted with permission from Medscape Reference (<http://emedicine.medscape.com/>), 2014, available at: <http://emedicine.medscape.com/article/940993-overview>.

### Other equipment needed

This includes the following:

- 1 a sterile 2-mL syringe containing 1–2% lignocaine to be used whenever the patient is conscious (otherwise the procedure will be very painful)
- 2 two sterile 5-mL syringes
- 3 sterile 20- or 50-mL syringes and ideally a three-way tap.

### Procedure

- 1 Place padding under the child's knee so that it is bent at 30 degrees from the straight (180-degree) position, with the heel resting on the table.
- 2 Locate the correct position (described above and shown in Figure 8.4.B.9).
- 3 Wash your hands and put on sterile gloves. (To avoid osteomyelitis, the procedure must involve strict asepsis using an antiseptic solution and sterile gauze to clean the site, with the operator wearing sterile gloves.) Clean the skin over and surrounding the site with an antiseptic solution.
- 4 Infiltrate with lidocaine down to the periosteum if the child is conscious.

- 5 Ask an assistant to stabilise the proximal tibia by grasping the thigh and knee above and lateral to the cannulation site, with the fingers and thumb wrapped around the knee but not directly behind the insertion site.
- 6 Insert the needle at a 90-degree angle with the bevel pointing towards the foot. Advance the needle slowly using a gentle but firm twisting or drilling motion.
- 7 Stop advancing the needle when you feel a sudden decrease in resistance or when you can aspirate blood. The needle should now be fixed in the bone and stand up by itself.
- 8 Remove the stylet.
- 9 Aspirate the marrow contents (which look like blood), using the 5-mL syringe, to confirm that the needle is in the marrow cavity and to provide bone marrow/blood for the following tests when appropriate: blood glucose, haemoglobin, group and cross-matching, blood culture and urea and electrolytes. Hb, glucose and electrolyte measurements may not be accurate after infusions have been previously given. Note that **failure to aspirate bone-marrow contents does not mean that the needle is not correctly placed**.
- 10 Attach the second 5-mL syringe filled with Ringer-lactate or Hartmann's solution or 0.9% saline. Stabilise the needle and slowly inject 3 mL while palpating the area for any leakage under the skin. If no infiltration is seen, start the infusion.
- 11 Attach the 50-mL syringe, usually containing Ringer-lactate or Hartmann's solution or saline, but compatible blood or 10% glucose can be used if hypoglycaemia is suspected, and push in the infusion fluid in boluses. **It is not possible to infuse fluid through the intra-osseous needle using a standard IV giving set.** The fluid has to be pushed in under light pressure, and if large volumes are needed (e.g. when giving boluses of fluid to treat shock) then 20-mL or 50-mL syringes should be used.
- 12 Check that the calf does not swell during the injections of fluid.
- 13 Secure IV access as soon as possible.
- 14 When the needle has been removed, cover with a sterile dressing.

Do not place distal to a major fracture or where there is infection.

**Give prophylactic antibiotics** after the immediate emergency has been managed.

**All drugs and fluids that are given IV (including 10% glucose) can be given into the bone marrow, and they will reach the heart and general circulation as fast as if they had been given through a central vein.**

**Remove the intra-osseous needle as soon as venous access is available.** In any case, it should not be in place for more than 8 hours.

### Complications

These include the following:

- dislodgement
- misplacement (penetration through posterior cortex, failure to penetrate cortex), resulting in:
  - haematoma
  - tissue necrosis
  - compartment syndrome

- skin infection
- osteomyelitis
- tibial fracture in babies.

### The scalp vein needle as an intra-osseous device

In infants, a green 'butterfly' (scalp vein) needle can be used as an intra-osseous needle with the same precautions as above.

### Battery-powered intra-osseous device

The EZ-IO drill is a powered device that enables rapid insertion of an intra-osseous needle.

Unfortunately the disposable needles are extremely and prohibitively expensive for low resource settings.

Various sizes of needle are available (see Figures 8.4.B.10 and 8.4.B.11) for different-sized patients.

FIGURE 8.4.B.10 EZ-IO power drill and needles.

The landmarks are as before, using the upper end of the tibia. In adults in particular, the upper outer aspect of the humerus can also be used.

FIGURE 8.4.B.11 Site for EZ-IO needle in the proximal humerus in an adult or large child.

The procedure is less painful for the conscious patient due to its rapidity, the drilling effect and the sharpness of the needles. The EZ-IO needles are available in two sizes, for patients under 40kg and over 40 kg.

The procedure for insertion is as follows:

- 1 Take universal precautions for sterile procedure.
- 2 Clean the site.
- 3 Choose an appropriate size of needle and attach it to the drill. It will fix magnetically.
- 4 Remove the safety cap from the needle.
- 5 If the patient is conscious, control their movement during insertion.
- 6 Hold the drill and needle at 90 degrees to the skin surface and push through the skin without drilling, until bone is felt. Ensure that at least 5 mm of the needle is visible at this point.

- 7 Squeeze the drill button and drill continuously, applying gentle steady downward pressure until there is sudden loss of resistance – there is a palpable 'give' as the needle breaches the cortex. Release the trigger and stop insertion at this point.

If the driver stalls and will not penetrate the bone you may be applying too much downward pressure.

If the driver fails (this is rare) remove it, grasp the needle kit by hand and twist it into the bone marrow.

- 8 Remove the drill and unscrew the trochar.
- 9 Aspirate the bone marrow if possible directly from the needle.
- 10 Attach the pre-prepared connection tube containing sterile Ringer-lactate or Hartmann's solution or 0.9% saline before any infusion is given.

FIGURE 8.4.B.12 EZ-IO needle in place, with stylet removed.

Do not attach a syringe directly to the EZ-IO catheter hub except when drawing blood with the needle set stabilised by hand (sterile).

- 11 There is an optional device for securing the needle, but this is not essential.
- 12 Proceed with the required therapy. It should be noted that rapid infusion of fluid may be painful for the conscious patient.
- 13 Apply a sterile dressing.
- 14 When removing the catheter, attach a Luer lock syringe, and continuously rotate it clockwise while slowly and gently applying traction to the catheter. Do not rock or bend the catheter during removal.
- 15 Do not leave the catheter in place for more than 24 hours.

### Needle pericardiocentesis

Needle pericardiocentesis is a rarely used skill but can be life-saving when indicated.

#### Indications

This procedure is used:

- to reduce a pericardial effusion that is causing haemodynamic compromise
- to diagnose pericarditis.

In the trauma situation this procedure is performed when cardiac tamponade is suspected. This is usually, but not always, caused by a penetrating injury between the nipple line and the shoulder blades. The clinical findings are shock, muffled heart sounds (although this is a difficult sign to elicit with confidence) and distended neck veins. It is important

to differentiate between this and tension pneumothorax, in which the trachea is deviated and air entry reduced on the affected side. Ideally this procedure should be carried out under ECG control, but if that is not available, extra care must be taken.

**If available, ultrasound is the easiest/safest way of making a diagnosis of cardiac tamponade.**

### Preparation of kit

The following equipment is needed:

- ECG monitor
- syringe
- skin prep
- local anaesthetic
- over-needle cannula (16- to 18-gauge)
- sterile drapes.

### Technique

- 1 Position the patient supine and attach the ECG. Stand on the patient's right with the ECG monitor at the patient's head so that you can see it easily.
- 2 Clean the skin from nipples to umbilicus and drape with sterile towels to expose the peri-xiphoid region. This must be a sterile procedure. Infiltrate local anaesthetic at the costal margin just below the xiphoid process.
- 3 Attach the cannula to the syringe. Insert the cannula just below and to the left of the xiphoid process. Angle the needle at 45 degrees to the skin and pointing towards the tip of the left scapula.
- 4 Advance the needle, holding this position, aspirating all the time and watching the cardiac monitor. As you enter

**FIGURE 8.4.B.13** Position for insertion of needle in pericardiocentesis. The pericardiocentesis needle is inserted as close to the sternum as possible in order to avoid the internal mammary artery.

the distended pericardial sac, fluid will flow back into the syringe. If the myocardium is touched, the ECG pattern will change (arrhythmia, ectopics, 'injury' pattern). If you can aspirate large amounts of bright red blood you have entered the ventricle, in which case you should withdraw slightly.

- 5 If successful, cardiac function should improve immediately. Withdraw the needle, attach a three-way tap, and secure the cannula for further aspirations.
- 6 This is a temporary procedure, and some patients will require a formal pericardiectomy. **Pericardial aspiration may not work well for viscous fluids (e.g. clotted blood) in the pericardial sac.**

### Defibrillation

There are two indications for this procedure:

- 1 In cardiac arrest when the rhythm is ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT) (see Section 1.13). The dose is 4 joules/kg in children.
- 2 In supraventricular tachycardia (SVT) or ventricular tachycardia without shock (see Section 5.4.C). The dose is 0.5 joules/kg, rising to 1 joule/kg then 2 joules/kg if the first shocks were unsuccessful.

In any patient who is not *in extremis*, anaesthesia/sedation must be given before the DC shock is administered.

### Safety

A defibrillator delivers enough current to **cause** cardiac arrest. **The user must ensure that other rescuers are not in physical contact with the patient (or the trolley) at the moment when the shock is delivered.** The defibrillator should only be charged when the paddles are either in contact with the child or replaced properly in their storage positions. **Oxygen must be discontinued and be moved right away from the patient.**

### Procedure

**Basic life support should be interrupted for the shortest possible time (see steps 5 to 9 below).**

- 1 Apply gel pads or electrode gel.
- 2 Select the correct paddles (paediatric paddles for patients weighing less than 10 kg). If only adult paddles are available for a small child, put one on the front of the child's chest and one on the back.
- 3 Select the energy required.
- 4 Place the electrodes on the pads of gel, and apply firm pressure.
- 5 Press the charge button.
- 6 Wait until the defibrillator is charged.
- 7 Shout 'Stand back!'
- 8 Check that all of the other rescuers are standing clear.
- 9 Deliver the shock.

### Correct paddle placement

The usual placement is antero-lateral. One paddle is put over the cardiac apex in the mid-axillary line, and the other is placed just to the right of the sternum, immediately below the clavicle.

### Good paddle contact

Gel pads or electrode gel should always be used (if the latter is used, care should be taken not to join the two

areas of application). Firm pressure should be applied to the paddles.

### Correct energy selection

The recommended level in VF or pulseless VT cardiac arrest is 4 joules/kg (with no patient sedation).

In arrhythmias with a pulse, the dose is 0.5 joules/kg, then 1 joule/kg, then 2 joules/kg if the previous doses were unsuccessful (always with sedation).

### Automatic external defibrillators (AEDs)

Automatic external defibrillators (AEDs) are used in adults both to assess cardiac rhythm and to deliver defibrillation (see Section 1.13 for details). In children, AEDs can accurately detect ventricular fibrillation at all ages, but there is concern about their ability to identify tachycardic rhythms

in infants correctly. At present, therefore, AEDs can be used to identify rhythms in children but not in infants.

Many AEDs now have paediatric attenuation pads which decrease the energy to a level more appropriate for the child (aged 1–8 years), or leads that reduce the total energy to 50–80 joules. This means that AEDs can be used for all children over the age of 1 year. Institutions that treat infants who might need defibrillation must provide manual defibrillators.

### Guidance

- With a manual defibrillator use 4 joules/kg to defibrillate patients of all ages.
- With an unattenuated AED (see above), children over 8 years of age can be defibrillated.
- With an AED with paediatric pads or paddles, children aged 1–8 years can be defibrillated.

## 8.5 Other procedures

### Insertion of an orogastric or nasogastric tube

**FIGURE 8.5.1** Inserting a nasogastric tube. (a) The distance from the nose to the ear and then to the epigastrium is measured. (b) The tube is then inserted to the measured distance.

The nasogastric tube is used to feed any child who is unable to take food by mouth.

### Preparation of kit

The following equipment is needed:

- nasogastric tube
- lubricant
- pH indicator paper or litmus paper
- syringe
- stethoscope
- adhesive tape.

In preterm infants:

- 4 French gauge tube is used for infants who weigh  $\leq$  1000 grams
- 6 French gauge tube is used for infants who weigh  $>$  1000 grams (and most neonates)
- 8 to 10 French gauge tube is used for abdominal decompression (e.g. in infants with ileus or who are receiving continuous positive airway pressure).

### Procedure

- 1 Place the child supine with their head in the 'sniffing' position.
- 2 Measure the length of the tube from the nose via the earlobe to the midpoint between the xiphoid and the umbilicus. Mark the tube at this point with indelible pen.
- 3 Feed the tube lubricated with KY Jelly or saline through either the nose or the mouth directly backwards. (The neonate is a nose breather, and therefore if there is respiratory distress the oral route may be preferred.) Try to advance the tube as the child swallows. If a baby has respiratory distress, a gastric tube is best passed through the mouth.
- 4 Check the position of the tube by very gently aspirating 0.2–0.5 mL of stomach contents using a small (2- or 5-mL) syringe (larger ones can damage the gastric mucosa) and checking the change in the pH indicator

paper (the pH should be 5.5 or less, or the litmus paper should change colour from blue to pink), or flush the tube with 2–3 mL of air (only 1 mL in the neonate) and listen over the stomach area with the stethoscope. If in doubt, X-ray the chest and/or abdomen. (Note that the acidity of the gastric fluid may be reduced in preterm infants.)

- 5 If there is any doubt about the location of the tube, withdraw it and start again. Withdraw immediately if the child starts coughing, as the tube may then be in the airway.
- 6 Secure the tube by taping it to the cheek, and record the length of tube outside the nose or mouth.
- 7 When the tube is in place, fix a 50-mL syringe (without the plunger) to the end of the tube, and pour food or fluid into the syringe, allowing it to flow by gravity.

The nasal route is more comfortable and secure, but if the infant has respiratory distress or is receiving CPAP, an orogastric tube is best (if passed through the nose the tube increases upper airway resistance).

**Never pass a nasogastric tube in a head-injured patient.**

An orogastric tube is safe. If there is a base-of-skull fracture, a nasal tube could be pushed into brain tissue.

**Cervical spine immobilisation**

All patients with major trauma should have full spinal stabilisation if feasible from the moment of injury, and should be treated as if they have a cervical spine injury until proven otherwise. Immobilisation can be achieved:

- by holding the head still and in line (manual in-line immobilisation)
- or by applying a semi-rigid collar (which has been correctly fitted), sandbags on either side of the head, and tape across the forehead and the chin piece of the collar to prevent the head from being lifted upward from the bed.

**FIGURE 8.5.2** Immobilisation of the cervical spine using head blocks and straps with a cervical collar in place.

**Exceptions**

Two groups of patients may prove to be difficult:

- the frightened uncooperative child (most common)
- the hypoxic combative patient.

In both of these cases, over-enthusiastic efforts to immobilise the neck may increase the risk of spinal injury as the patient struggles to escape. The area of greatest mobility in the cervical spine is the C7/T1 junction, and this is at increased risk in the combative patient.

It is best to try to apply just a collar and then address the patient's other clinical needs (see Section 7.3).

**Log roll**

When examining the back of the patient with major injury, it is important to minimise the risk associated with unrecognised spinal injury. It is essential to examine the back of the patient at the end of the primary survey (or even during it if there is suspicion of serious injury to the back of the chest or abdomen).

The aim of the log roll is to maintain the orientation of the spine during turning of the patient. It requires four people for a mother or child and three for an infant. In addition, one person is required for the examination of injuries.

**TABLE 8.5.1** Position of staff for log roll

Staff number	Position of staff for log roll	
	Infant or small child	Larger child or mother
1	Examination of back	Examination of back
2	Stabilisation of head and neck – in charge of the procedure	Stabilisation of head and neck – in charge of the procedure
3	Chest	Chest
4	Pelvis and legs	Pelvis
5		Legs

**FIGURE 8.5.3** Log rolling a child.

**FIGURE 8.5.4** Log rolling an infant.

**Incision and drainage of abscess**

**Indications**

- The collection of localised infection.
- If there is uncertainty whether a hot red mass is an abscess, aspirate for pus before proceeding to incision and drainage.
- Multiple/recurrent abscesses may be associated with HIV, TB, malnutrition, diabetes mellitus, anaemia or foreign bodies.

**Preparation of kit**

The following equipment is needed:

- skin preparation materials
- scalpel
- microbiology swab
- curette
- sterile gauze.

**Procedure**

- 1 If the patient is systemically unwell, take blood cultures (before giving antibiotics).
- 2 Antibiotics are only indicated if the patient is systemically unwell or if spreading cellulitis is present.
- 3 Use general anaesthesia for certain sites (perianal, breast, cervical, etc.). Regional blocks may be used for limbs in older children. (Note that local infiltration produces poor anaesthesia in inflamed tissue.)
- 4 Clean the skin.
- 5 Incise over the most superficial tender point in the direction of skin creases. Take a sample of pus for culture and staining, including the Ziehl-Neelsen stain if indicated.  
**The commonest error is to make the incision too small.**
- 6 Insert a curette spoon or finger to break down any loculi. Send a sample of the wall of the abscess for TB if indicated.
- 7 Irrigate the cavity with 0.9% saline to flush out necrotic material.
- 8 If a large cavity exists, loosely pack it with sterile gauze. For a small cavity place a 'wick' (e.g. a piece of rolled gauze) into the wound, forming a track. Cover the wound loosely with absorbent dressing. Change the gauze packing after 24 hours, giving analgesia beforehand if needed. Remove the wick after 48 hours.
- 9 As the cavity discharges pus it should heal from a depth to superficially through the open skin incision.

**Abdominal paracentesis****Indications**

- To detect intra-abdominal injury after blunt trauma in the haemodynamically unstable child in the absence of CT or ultrasound scanning facilities. **Haemodynamic instability after penetrating trauma always requires a laparotomy.**
- To identify peritonitis.
- To identify ruptured bowel.

**Preparation of kit**

The following equipment is needed:

- local anaesthetic (ideally with adrenaline)
- sterile drapes
- over-needle catheter, 16- to 20-gauge
- 20-mL syringe
- warmed normal saline and infusion set
- urinary catheter and nasogastric tube
- skin prep (iodine/alcohol).

**Procedure**

- 1 The procedure must be sterile.
- 2 Decompress the bladder and stomach with a urinary catheter and nasogastric tube.
- 3 Prepare the abdomen (from the costal margin to the

pubis). Drape the area with sterile towels, exposing the peri-umbilical region.

- 4 If the patient is conscious, infiltrate local anaesthetic in the midline (a third of the distance between the umbilicus and the pubis). If pelvic trauma is suspected, infiltrate above the umbilicus.
- 5 Insert the catheter over needle. Remove the needle and aspirate.
- 6 If more than 10 mL of fresh blood **or** turbid or bile-stained fluid **or** faeces **or** food debris are present in the aspirate, there is a serious problem, possibly indicating the need for a laparotomy.
- 7 If none of the above abnormalities are seen on aspiration, instil 10 mL/kg of warm sterile normal saline into the abdomen and allow 5 minutes for it to circulate. Then retrieve the fluid.

**Interpreting the results of analysis of the retrieved fluid**

Abnormal findings include the following:

- red blood cell count (unspun) > 100 000/mL: may need laparotomy if unstable
- white blood cell count (unspun) > 500/mL
- bile staining
- faeces
- Gram stain/microscopy positive.

If laparotomy is indicated, withdraw the catheter and cover the wound with a sterile dressing. Then transfer the patient to theatre.

**Lumbar puncture****Preparation of kit**

The following equipment is needed:

- iodine
- sterile gloves
- sterile dressings pack
- spinal needle with stylet
- collodion
- small adhesive dressing
- local anaesthetic
- sedation (in some cases).

**Indications**

- As part of septic screen in case meningitis is present.
- For investigating the possible cause of seizures.
- For investigating the possible cause of apnoeic episodes due to meningitis.
- As therapy in post-haemorrhagic hydrocephalus.
- For administration of drugs in leukaemia.

**Contraindications**

- Signs of raised intracranial pressure, such as deep coma (P or U on the AVPU scale), unequal pupils, rigid posture or paralysis in any of the limbs or the trunk, or irregular breathing.
- Skin infection in the area through which the needle will have to pass.
- Significant bleeding disorder.

If contraindications are present, the potential value of the information gained from a lumbar puncture should be carefully weighed against the risk of the procedure. If in doubt, it

might be better to start treatment for suspected meningitis, and delay performing a lumbar puncture.

### Precautions

- Do not perform a lumbar puncture in the very sick patient (it may precipitate apnoea in an infant and shock in an older child).
- Excessive neck flexion when positioning can lead to hypoxaemia and acute respiratory deterioration.
- If a spinal needle is unavailable and a normal (non-stylet) needle is used, the needle bore may become blocked with skin on insertion and therefore obstruct flow. There is also the risk of tissue implantation leading to a dermoid cyst.

### Procedure

There are two possible positions:

- the child lying down on the left side (particularly for young infants)
- the child in the sitting position (particularly for older children).

**FIGURE 8.5.5** Holding a child lying on their left side for a lumbar puncture. Note that the spine is curved to open up the spaces between the vertebrae.

**FIGURE 8.5.6** Restraining an older child in a sitting position for a lumbar puncture.

When the child is lying on their side a hard surface should be used. Place the child on their side so that the vertebral column is parallel to this surface and the transverse axis of the back is vertical (see Figure 8.5.5).

It is helpful to have an experienced assistant present to hold the patient. Flex the spine maximally, but avoid excessive neck flexion. Make sure that the airway is not obstructed and the child can breathe normally. Take particular care when holding young infants. The assistant should not hold a young infant by the neck or flex the neck to avoid airway obstruction.

### Prepare the site

- Use aseptic technique. Scrub your hands and wear sterile gloves.
- Prepare the skin around the site with an antiseptic solution.
- Sterile towels may be used.
- In older children who are alert, give a local anaesthetic (1% lignocaine) infiltrated in the skin and subcutaneous tissue over the site.

### Identify site of insertion

Locate the space between the third and fourth lumbar vertebrae or between the fourth and fifth lumbar vertebrae. (The third lumbar vertebra is at the junction of the line between the iliac crests and the vertebral column.)

Use an LP needle with a stylet (22 gauge for a young infant, and 20 gauge for an older infant and child; if these are not available, routine hypodermic needles may be used). Insert the needle into the middle of the inter-vertebral space and aim the needle towards the umbilicus.

Advance the needle slowly. The needle will pass easily until it encounters the ligament between the vertebral processes. More pressure is needed to penetrate this ligament, and less resistance is felt as the dura is penetrated. In young infants this decrease in resistance is not always felt, so advance the needle very carefully.

Stop advancing when a 'give' or puncture sensation is felt on entering the subarachnoid space (this is often not felt in neonates). Frequent stylet withdrawals during the procedure should be undertaken to see if the CSF flows, indicating that the subarachnoid space has been successfully entered. The subarachnoid space is only 0.5–0.7 cm below the skin in premature infants and 1 cm below it in term infants, so it is easy to over-penetrate by mistake. Over-penetration leads to puncturing of the anterior vertebral venous plexus and a bloody sample, so that CSF microscopy is less informative or perhaps impossible. The needle should be withdrawn and the procedure repeated in another disc space.

Withdraw the stylet. Obtain a sample of 0.5–1 mL of CSF and place it in sterile containers, allowing six drops of CSF to drip into each sample container.

Replace the stylet.

Withdraw the needle and stylet completely and apply pressure to the site for a few seconds. Put a sterile dressing over the needle puncture site, and cover the whole site with adhesive dressing.

Send samples for the following:

- 1 microscopy, cell type and counts, Gram and Ziehl-Neelson staining, culture and sensitivity (including for TB) and virology.
- 2 biochemistry (glucose, protein).

## Suprapubic aspiration of urine

### Indications

Usually in sick infants where urgent diagnosis is required and there is a palpable bladder that does not respond to manual expression for a clean catch.

**FIGURE 8.5.7** Position for carrying out suprapubic aspiration of urine in an infant. (a) Side view. (b) Abdominal view. Note the angle of insertion of the needle.

### Procedure

Use a sterile technique throughout. Advance a 23- to 24-gauge needle attached to a syringe to a depth of 3 cm in the midline at the proximal transverse crease above the pubis. Withdraw the urine into a sterile syringe and transfer it to a sterile urine container,

Do this only in a child with a bladder containing sufficient urine, which can be demonstrated by percussion. Do not use urine bags to collect urine, as the specimens may become contaminated.

Have a clean urine jar ready in case the child passes urine during the procedure.

### Microscopy of urine

- Urinary tract infections (UTIs) are common in children.
- Although many of these infections are not serious, some of them cause kidney damage and lead to scarring.
- Kidney scars can lead to high blood pressure, and to kidney failure later in life.
- A child with a UTI can develop kidney damage very fast, in just a few days. The only way to prevent this is to make the diagnosis and treat it at once.
- Urine microscopy is the only way to diagnose UTIs immediately and reliably.

In a patient with a UTI the urine contains:

- one species of **bacterium** at a concentration of at least 100 000/mL
- an excess of **white blood cells**.

### Bacterial numbers

Most children with a UTI have in the range of 10–1000 million bacteria/mL. In fact, 100 000/mL is a very small number of bacteria. When urine is collected from children, it often becomes contaminated with a very small number of bacteria, and these are often of just one species. This means that if you rely on laboratory culture to make the diagnosis of UTI, you are likely to have many false-positives, perhaps one for every genuine case. Remember that every child diagnosed as having a UTI in this way will undergo investigations, sometimes including invasive procedures.

### White blood cells

**Children frequently have extra urinary white blood cells without a UTI.**

- Around 10% of febrile children have hundreds of extra white blood cells.
- Girls void some urine into the vagina, so vaginal white blood cells are readily washed into the urine (as are vaginal epithelial cells, which are seen in the urine of most girls after puberty).

**Children with UTIs often have no excess of white blood cells.**

- White blood cells do not last long in urine, especially if it is alkaline, so it must be examined soon after collection.
- Ill infants may be unable to mount a white blood cell response.

Therefore white blood cells alone are an unreliable and potentially misleading sign.

### How to count bacteria

#### Laboratory culture

This is the most widely used method, and the traditional approach. It remains acceptable, but if you use it you will:

- **have to accept that some positive reports will be false**
- **have to wait at least 48 hours for the result.** In real life, it is often several days or a week before a positive lab report reaches the doctor, and treatment starts. Remember that kidney damage can become permanent within 3 days
- **have to recall patients a few days later if the culture grows a mixture of bacteria.** This is usually caused by the contamination of urine as it is collected, and is common. It must be repeated in case a UTI was present as well
- **miss the occasional UTI caused by anaerobes.**

#### Advantages of urine microscopy

If you use this method you can:

- discard sterile urines, and reassure the child's family at once
- repeat a contaminated urine sample at once
- treat children with UTIs immediately
- diagnose anaerobic UTIs as easily as aerobic ones
- save time and money because it is quicker and cheaper than urine culture.

**Choice of microscope**

With an ordinary **light microscope**, bacteria are only easy to see after they have been stained.

**Phase-contrast microscopes** enable you to see unstained bacteria very easily, just using a drop of fresh urine on a glass slide. They look and work exactly the same as ordinary light microscopes, except that the lens (objective) and the condenser (underneath) are specially modified.

**How to do urine microscopy**

You can microscope fresh urine on a slide with a counting chamber. There is no need to stain or spin the urine.

The slide has two chambers, each of which has a grid etched on to the glass surface. In certain clinical situations, such as examination of peritoneal dialysis fluid for suspected peritonitis, the grid can be used to make accurate counts of the concentrations of elements present.

Usually this degree of accuracy is unnecessary. However, the grid is always useful because it confirms that the microscope is focused on the urine. If you examine a specimen with no cells or bacteria on a plain slide it is impossible to be certain otherwise.

Clean the slide and a coverslip with a tissue. Breathe over the slide to create a 'mist' on it, and quickly push the coverslip into place. This creates a chamber 0.1 mm deep with a grid etched on the bottom (see Figure 8.5.8).

**FIGURE 8.5.8** Side view of grid slide with coverslip in place.

Test the urine with a dipstick (to check for blood, protein and glucose). Then touch the tip of the dipstick on the slide so that a small amount of urine is drawn into the chamber by capillary action.

**Bacteria**

- Most bacteria that cause UTIs are bacilli (**rod-shaped**).
- They are easy to identify, as they look like straight lines, usually about 3 mm long.
- Mostly they remain still, or just move slightly, like a shimmer. This movement is caused by Brownian motion (which occurs when they are hit by water molecules), and is not due to them swimming.
- Rarely will you see moving bacteria.

**FIGURE 8.5.9** Rod-shaped bacteria.

Infections also sometimes occur with streptococci, which are bacteria that resemble strings of beads. There are always some strings that are four or more cocci long. If you think that you can see 'cocci' individually, or in clumps, these are in fact phosphate crystals. If they appear to be moving, this is just the result of Brownian motion.

**White blood cells**

These are round, and between 3 and 5 mm in diameter. All white blood cells have a 'granular' appearance to their cytoplasm. In the case of the larger ones you can often make out the individual granules shimmering and moving within the cell, and the nucleus (which is lobed in neutrophils).

**FIGURE 8.5.10** White blood cells.

**Red blood cells**

These are smaller than white blood cells, and do not have any content or granular appearance.

If the red cells are present because of trauma (e.g. after an injury, or post surgery) or a UTI, they will either look just like red cells in the blood (i.e. biconcave discs), or they will all appear slightly shrunken and wrinkled, or slightly swollen. The important thing is that they all look the same.

**FIGURE 8.5.11** Red blood cells.

If the red blood cells are in the urine because of kidney inflammation (glomerulonephritis), they are usually smaller, but they are also all different shapes. This is probably because they get damaged as they pass down the tubules of the kidney. Sometimes the red cells are very bizarre shapes. They are referred to as 'glomerular' red cells.

**Epithelial cells**

These are very large flat cells with an easily visible round nucleus. They are from the vagina, and are only seen in the

FIGURE 8.5.12 Glomerular red blood cells.

urine of older girls, in which they are common. If large numbers of epithelial cells are present this suggests particularly heavy vaginal contamination.

FIGURE 8.5.13 Epithelial cells.

#### Casts

These indicate kidney inflammation (glomerulonephritis). Casts consist of abnormal kidney tubule contents that have solidified and have retained the shape of the tubule as they passed into the urine.

Pure protein casts look glass-like, and are described as hyaline. Those consisting of debris (e.g. dead tubule cells in acute tubular necrosis) are called granular casts. Some casts are composed of red or white cells. Many casts consist of a mixture of these.

FIGURE 8.5.14 Casts.

#### Debris

Contaminated urine samples often contain a variety of debris. Some elements have an obvious origin, such as cotton fibres, but others cannot be identified.

FIGURE 8.5.15 Debris.

#### Crystals

Urine samples often contain obvious crystals, whose shape allows their chemical origin to be identified. However, this is rarely of clinical significance.

The commonest 'crystals' in fact look more like small black dots, either singly, or in clumps (and even in casts). They move slightly (or 'shimmer') as a result of Brownian motion, and can be mistaken by the unwary for small round bacteria (cocci).

FIGURE 8.5.16 Crystals.

#### Diagnosing urinary tract infections (UTIs)

UTIs are primarily diagnosed by looking for bacteria.

#### Infected urine

About 99% of urine infections are caused by rod-shaped bacteria known as **bacilli**.

In most UTIs, every field you view will have many bacteria (in some cases thousands), and they all look the same. Therefore when you see many bacteria in fresh urine, all with the same appearance, you can be sure that the child has a UTI.

If you see at least one rod, but less than 10 rods in the centre of the grid (square 5), you have to consider the possibility of contamination, so collect another sample to see whether the finding persists (and think about vaginal lactobacilli; see below).

#### What to do if you find a positive microscopy

You can start treatment immediately with an appropriate antibiotic. In addition, send the urine for culture with **direct sensitivities**.

The laboratory will grow the bacteria to confirm which species they are, and to test their sensitivity to a range of different antibiotics. Without direct sensitivity testing this takes 2 days, but with it you will usually obtain the result the next day.

#### Sterile urine

Most urine samples will be sterile. If you see **no bacteria** or cells, check by looking at five 'size-A' squares (i.e. about five fields).

If you see nothing in that area, then you can be certain that the urine is not infected.

Even if you can see other elements, if there are no bacteria, it is not a UTI. Remember that you will see white blood cells in the urine of many children with fever (e.g. due to tonsillitis or pneumonia). Also remember that many girls have white blood cells in their urine from the vagina (and often epithelial cells, too).

#### Contaminated urine

If you see any of the following, **collect a repeat sample**, as the first sample is likely to have been contaminated:

- more than one shape of bacterium

- some bacteria, but also a large amount of debris (e.g. cotton fibres or many epithelial cells)
- many bacteria in a urine sample that was collected several hours ago, or from a nappy that had been on the baby for several hours.

If necessary, you need to go on collecting repeat urine samples until one is either definitely sterile or definitely infected.

**Vaginal contamination**

Girls void some of their urine into the vagina, so normal female urine will contain vaginal washings. In young girls this makes little difference to the microscopy findings. In older girls it is normal to see some epithelial cells (see Figure 8.5.13).

Also, in many older girls lactobacilli are washed into the urine. These are long rods, up to 4 mm or more. It is unusual for there to be large numbers, but they can cause confusion with a UTI. If you are uncertain, ask the lab either to Gram stain them or to culture them. Unlike the bacteria that cause UTIs, lactobacilli are Gram-positive.

They do not grow in conventional UTI culture media, so the lab will report a sterile urine. If you want to be absolutely certain, ask the lab to culture the urine anaerobically.

**Recording the results**

Labels can be printed to stick on the clinical notes. This is important because negative urine samples will be discarded, and this will be the only record of the test.

A typical format is as follows:

**URINE PHASE CONTRAST MICROSCOPY**

Name: ..... Date: .....

MICRO – Bacteria: .....  
 WBC: ..... RBC: .....  
 Casts, etc.: .....

STICKS – Protein: ..... Blood: .....  
 Glucose: .....  
 Other: .....

**ACTION – (tick one of the three options)**

- Urine not infected: sample discarded
- Urine contaminated: sample repeated
- UTI: urine sent for culture and direct sensitivities, and antibiotics started

SIGN and PRINT NAME:.....

**Counting what you see**

- For most clinical purposes it is not necessary to count the exact concentration of cells or bacteria that you see, and estimates such as ‘many’ or ‘few’ are enough.
- Sometimes it is helpful to quantify the findings more carefully (e.g. to monitor the numbers of casts in a child with glomerulonephritis).
- Occasionally it is essential to count the exact numbers (e.g. the number of white blood cells is critical for the diagnosis and treatment of peritonitis in children on peritoneal dialysis from a dialysis sample).

Calculate all the counts per microlitre (µL). Count at least 10 of each element of interest. The number and size of the

squares you need to count will therefore depend on the concentration of the elements in the urine.

Figure 8.5.17 shows the etched counting grid for microscopy.

- The central square (‘3’) is 1 × 1 mm.
- With the cover-slip on, the chamber is 0.1 mm deep, so the central square has a volume of 0.1 µL.
- Therefore the whole grid of nine similar squares has a total volume of 0.9 µL.
- Note that 1 microlitre is one-thousandth of a mL.
- Therefore a count of 100 000 bacteria/mL is equivalent to 100/µL, so a ‘significant’ culture in a urinary tract infection would mean at least 100 bacteria/µL, or 100 bacteria in the central square of the grid.

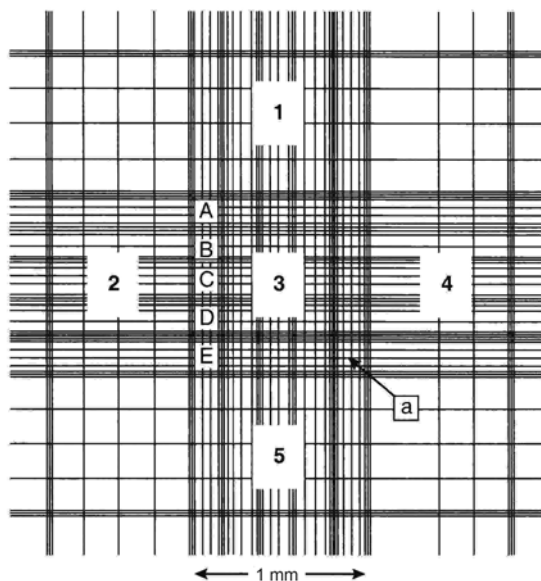

FIGURE 8.5.17 Counting grid for microscopy.

**How to count**

**Very infrequent elements**

Count all those in squares 1, 2, 3, 4 and 5, and multiply by 2.

**Infrequent elements**

Count all those in square 5, and multiply by 10.

**Frequent elements**

Count all those in five smaller squares (e.g. squares A, B, C, D and E), and multiply by 50.

**Very frequent elements**

Count all those in square A, and multiply by 250 (for ease of calculation, multiply by 1000 and divide by 4).

**Overwhelmingly frequent elements (usually bacteria)**

Count all those in one of the smallest squares and multiply by 4000.

**Measuring blood glucose levels**

Blood glucose levels can be measured with rapid diagnostic tests (e.g. Dextrostix, BM Stix) at the bedside, which provide an estimate of blood glucose concentration within a few minutes. There are several brands on the market, which differ slightly in how they should be used. Therefore

**FIGURE 8.5.18** Blood glucose colour scale on side of bottle.

it is important to read the instructions on the box and the package leaflet before using these tests.

Generally, a drop of blood is placed on the reagent strip and left for 30 seconds to 1 minute, depending on the brand of strip. The blood is then wiped off, and after another fixed period of time (e.g. a further 1 minute), the colour change on the reagent field of the strip is read. For this, the resulting colour is compared with a colour scale printed on the box. This allows the user to estimate the glucose level to be within a certain range (e.g. between 2 mmol/litre and 5 mmol/litre), but it does not provide exact values.

**FIGURE 8.5.19** Electronic reading device for glucose strip. The strip is inserted into the side of the machine after the sample has been timed for the reaction to take place and the blood has been wiped off the strip.

Some strips come with a battery-powered electronic reading machine. After the blood has been wiped off, the strip is inserted into the reading machine, which provides a more accurate value.

As the reagents deteriorate with exposure to ambient humidity, it is important that they are kept in a closed box, and that the box is closed immediately after a strip has been removed.

## 8.6

## Assessing nutrition, growth and development

### Measuring nutritional status

#### Calculating the child's weight for length

This is the most relevant measurement in nutritional assessment.

#### Measuring length

##### At $\leq 2$ years

Ideally two people are needed to take this measurement, and the child should be supine on a flat surface.

The first person should:

- assist in positioning the child face up on the measuring board, supporting the head and placing it against the headboard
- position the crown of the head against the headboard, compressing the hair
- check that the child lies straight along the centre line of the board and is not slanted, and does not change position (it is usual for this person to stand or kneel behind the headboard).

The second person should:

- support the trunk as the child is positioned on the board
- lie the child flat along the board
- place one hand on the shins above the ankles or on the

knees and press down firmly, and with the other hand place the foot-piece firmly against the heels

- measure the length (to the nearest 0.1 cm) and record it immediately.

The measuring board should be checked for accuracy every month.

##### At $\geq 3$ years

- This measurement should be taken without the child wearing shoes.
- The child should stand with their heels and back in contact with an upright wall.
- The head is held to look straight forward with the lower eye sockets in line with the ears. The nose must not be tilted upward.
- A weighted block at right angles to the wall is then lowered on to the head and a scale fixed to the wall is read.
- During measurement the child should be asked to stretch their neck to be as tall as possible, but their heels must not leave the ground. The measurer should help to stretch the neck by firm pressure upward under the mastoid processes.
- Measure the height immediately to within 0.1 cm.

**Measuring weight**

**At ≤ 2 years**

- Leave a cloth in the weighing pan to prevent chilling of the child.
- Adjust the scales to zero with the cloth in the pan.
- Place the naked child gently on the cloth in the weighing pan.
- Wait for the child to settle and the weight to stabilise.
- Measure the weight (to the nearest 10 grams) and record it immediately.

Standardisation of the scales should be performed weekly or whenever the scales are moved.

**At ≥ 3 years**

- The child should be weighed naked or, if pants are worn, 0.1 kg should be subtracted from the weight measured.
- The bladder should be emptied before weighing.

**Determining the child's percentage weight for length or SD weight for length**

See Figure 8.6.1.

- Locate the row containing the child's length in the central column of the table.
- Look to the left in that row for boys, and to the right for girls.
- Note where the child's weight lies with respect to the weights recorded in this row.
- Select the weight closest to that of the child.
- Look up this column to read the weight for length of the child.

**Note:** Although the interpretation of a fixed percent-of-median value varies across age and height, and generally

Boys' weight (kg)					Length (cm)	Girls' weight (kg)				
-4 SD	-3 SD	-2 SD	-1 SD	Median		Median	-1 SD	-2 SD	-3 SD	-4 SD
1.7	1.9	2.0	2.2	2.4	45	2.5	2.3	2.1	1.9	1.7
1.8	2.0	2.2	2.4	2.6	46	2.6	2.4	2.2	2.0	1.8
2.0	2.1	2.3	2.5	2.8	47	2.8	2.6	2.4	2.2	2.0
2.1	2.3	2.5	2.7	2.9	48	3.0	2.7	2.5	2.3	2.1
2.2	2.4	2.6	2.9	3.1	49	3.2	2.9	2.6	2.4	2.2

**FIGURE 8.6.1** Weight-for-length reference chart (below 87 cm). SD = standard deviation score or Z-score. Based on World Health Organization data.

the two scales cannot be compared, the approximate percent-of-the median values for -1 SD and -2 SD are 90% and 80% of the median, respectively (*Bulletin of the World Health Organization*, 1994, **72**, 273-83).

Length is measured below 85 cm; height is measured at 85 cm or above. Recumbent length is on average 0.5 cm greater than standing height, although the difference is of no importance to the individual child. A correction may be made by deducting 0.5 cm from all lengths above 84.9 cm if the standing height cannot be measured.

**Example 1.** Boy of length 61 cm and weight 5.3 kg: this child is -2 SD weight for length (84% of the median: 5.3 divided by 6.3 × 100).

**Example 2.** Girl of length 67 cm and weight 4.3 kg; this child is less than -4 SD weight for length (less than 60% of the median: 57%).

**Monitoring weight gain**

**Calculating weight gain**

The example below is for weight gain over 3 days, but the same procedure can be applied to any interval.

- Subtract the child's weight (in grams) that was measured 3 days earlier from their current weight.
- Divide by three to calculate the average daily weight gain (grams/day).
- Divide by the child's average weight (in kg) to calculate the daily weight gain per unit body weight (grams/kg/day).

**Monitoring charts: explanation of the charts on the following pages**

Figure 8.6.2 shows a weight chart which has been used to monitor the weight gain of a severely malnourished child. The horizontal 'x' axis represents the number of days after admission, while the vertical 'y' axis represents the weight of the child in kilograms (kg).

**FIGURE 8.6.2** Personalised weight chart for child.

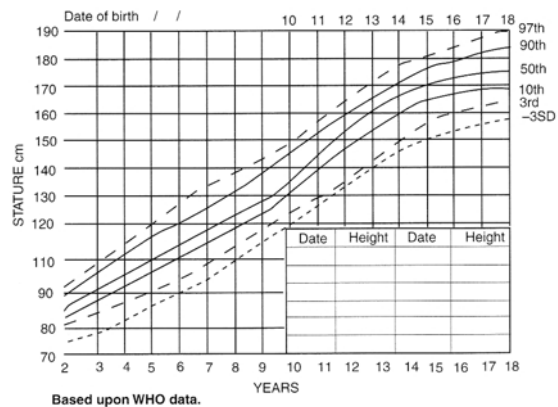

**FIGURE 8.6.7** Supine length and head circumference chart for boys from birth to 2 years. Based on World Health Organization data.

**FIGURE 8.6.8** Weight chart for girls aged 2–18 years. Based on World Health Organization data.

**FIGURE 8.6.9** Weight chart for boys aged 2–18 years. Based on World Health Organization data.

**FIGURE 8.6.10** Height chart for boys aged 2–18 years. Based on World Health Organization data.

**FIGURE 8.6.11** Height chart for girls aged 2–18 years. Based on World Health Organization data.

**Measurement of head circumference**

- Use a non-stretchable tape.
- Measure around the forehead above the eyebrows to the maximum occipital point.
- Measure twice for accuracy.

**Assessment of pubertal state**

**Girls**

The following should be recorded.

**Breast development**

- **Stage 1.** Pre-adolescent: elevation of papilla only.
- **Stage 2.** Breast bud stage: elevation of breast and papilla as a small mound, and enlargement of areola diameter.
- **Stage 3.** Further enlargement and elevation of breast and areola, with no separation of their contours.
- **Stage 4.** Projection of areola and papilla to form a secondary mound above the level of the breast.

- **Stage 5.** Mature stage: projection of papilla only, due to recession of the areola to the general contour of the breast.

#### **Pubic hair**

- **Stage 1.** Pre-adolescent: the vellus over the pubes is not further developed than that over the abdominal wall (i.e. there is no pubic hair).
- **Stage 2.** Sparse growth of long, slightly pigmented downy hair, straight or slightly curled, chiefly along the labia.
- **Stage 3.** Hair is considerably darker, coarser and more curled, and spreads sparsely over the junction of the pubes.
- **Stage 4.** Hair is now adult in type, but the area covered is still considerably smaller than in the adult; there is no spread to the medial surface of the thighs.
- **Stage 5.** Hair is adult in quantity and type, with distribution of the horizontal (or classically 'feminine') pattern; there is spread to the medial surface of the thighs but not up the linea alba or elsewhere above the base of the inverse triangle (spread up the linea alba occurs late, and is rated as Stage 6).

**Document whether axillary hair is present.**

**Document age at menarche.**

#### **Boys**

The following should be recorded.

#### **Genital (penis) development**

- **Stage 1.** Pre-adolescent: the testes, scrotum and penis are of about the same size and proportion as in early childhood.
- **Stage 2.** Enlargement of the scrotum and testes. The skin of the scrotum reddens and changes in texture. There is little or no enlargement of the penis at this stage.
- **Stage 3.** Enlargement of the penis, which initially is mainly an increase in length. Further growth of the testes and scrotum.

- **Stage 4.** Further enlargement of the penis, with an increase in breadth and development of the glans. The testes and scrotum are larger, and the scrotal skin is darkened.
- **Stage 5.** Genitals are adult in size and shape.

#### **Pubic hair**

- **Stage 1.** Pre-adolescent: the vellus over the pubes is not further developed than that over the abdominal wall (i.e. there is no pubic hair).
- **Stage 2.** Sparse growth of long slightly pigmented downy hair, straight or slightly curled, chiefly at the base of the penis.
- **Stage 3.** Hair is considerably darker, coarser and more curled, and spreads sparsely over the junction of the pubes.
- **Stage 4.** Hair is now adult in type, but the area covered is still considerably smaller than in the adult; there is no spread to the medial surface of the thighs.
- **Stage 5.** Hair is adult in quantity and type, with spread to the medial surface of the thighs but not up the linea alba or elsewhere above the base of the inverse triangle (spread up the linea alba occurs late, and is rated as Stage 6).

**Document whether axillary hair is present.**

#### **Testicular volume**

The approximate volume at each genital stage is shown.

- **Stage 1:** 1.5–3 mL.
- **Stage 2:** 4–6 mL.
- **Stage 3:** 6–10 mL.
- **Stage 4:** 10–12 mL.
- **Stage 5:** 15–20 mL.

# **Section 9**

## **Appendix**

## Normal values for vital clinical signs

### Estimating the weight of a child in an emergency

For an infant (defined as up to 12 months old), the birth weight:

- doubles by 5 months
- triples by 1 year

- quadruples by 2 years.

After 12 months, the following formula can be applied, but it may need to be modified according to whether the child is small or large compared with the average:

$$\text{Weight (kg)} = 2 (\text{age in years} + 4).$$

## Normal vital signs

**TABLE 9.1** Normal vital signs by age in children and in pregnant women and girls

Age (years)	Heart rate (beats/minute)	Systolic blood pressure (mmHg)	Respiratory rate (breaths/minute)
< 1	110–160	70–90 (> 60)	30–40
1–2	100–150	80–95 (> 70)	25–35
2–5	95–145	80–100 (> 75)	25–30
5–12	80–120	90–110 (> 75)	20–25
> 12	60–100	100–120	15–20
Pregnant women and girls	70–110*	95–135	15–20

\*Heart rate in pregnancy increases by 10–15 bpm.

WHO defines tachycardia as > 160 bpm if < 1 year; > 120 bpm if 1–5 years and if > 110 bpm in pregnancy consider shock may be developing or present.

WHO considers fast breathing is present if < 2 months respiratory rate  $\geq$  60 bpm; for children aged 2 months to 12 months if respiratory rate is  $\geq$  50 bpm and for children 1–5 years if respiratory rate is  $\geq$  40 bpm.

**TABLE 9.2** Normal heart rates when awake and asleep

Age group	Heart rate when awake (beats/minute)	Heart rate when asleep (beats/minute)
Newborn to 3 months	90–190	90–160
3 months to 2 years	80–150	80–120
2–10 years	70–120	70–90
10 years to adulthood	55–90	50–90

**TABLE 9.3** Normal systolic and diastolic blood pressure

Age group	Systolic blood pressure (mmHg)	Diastolic blood pressure (mmHg)
Birth (12 hours, 3 kg)	50–70	25–45
Neonate (96 hours)	60–80	20–60
Infant	80–90	53–66
2–4 years	95–105	53–66
7 years	97–112	57–71
15 years	112–128	66–80
In pregnancy	95–135*	60–85

\*In pregnancy if systolic BP is < 90 mmHg consider shock may be present and if < 95 mmHg investigate for possible indicators of developing shock.

Blood pressure is difficult to measure and interpret in infants and children under 5 years of age. Do not base decisions to treat hypertension on the results of electronic sphygmomanometers, as they can be inaccurate. Always check with a hand-pumped machine.

The following quick formula can be used to calculate normal systolic pressure in children:

$$\text{Median (50th centile) systolic blood pressure in children} = 85 + (2 \times \text{age in years}).$$

**Capillary refill time**

The normal capillary refill time (CRT) is up to 3 seconds. It is important to be aware that in colder environments peripheral CRT is not a reliable test of perfusion.

**Urine output**

WHO recommendations are as follows:

- Infants: 2 mL/kg/hour
- Children: 1 mL/kg/hour
- Pregnant adults: > 30 mL/hour or > 100 mL every 4 hours.

**Normal core body temperatures**

- Infants: 36.5–37.5°C (97.7–99.5°F)
- Children: 36.0–37.2°C (96.8 – 98.6°F).

If an infant or child has a temperature of 37.5°C or more, a fever is present.

To convert °C to °F multiply by 9, then divide by 5 then add 32.

To convert °F to °C deduct 32, then multiply by 5, then divide by 9.

**Circulating blood volume**

- At birth: 100 mL/kg
- At 1 year of age: 80 mL/kg
- At 12 years of age: 70 mL/kg
- In pregnancy: 100 mL/kg.

**Normal values for laboratory measurements****Haematology****TABLE 9.4** Normal laboratory values for haemoglobin concentration

Age	Haemoglobin concentration (grams/dL)
1–3 days	14.5–22.5
2 weeks	14.5–18.0
6 months	10.0–12.5
1–5 years	10.5–13.0
6–12 years	11.5–15.0
12–18 years:	
Male	13.0–16.0
Female	12.0–16.0

**TABLE 9.5** Normal laboratory values for platelet count

Age group	Platelet count ( $\times 10^9$ /litre)
Newborn	84–478
Child	150–400

**TABLE 9.6** Normal laboratory values for erythrocyte sedimentation rate (ESR), white blood cell count (WBC) and lymphocyte count

Age group	ESR (mm/hour)
All ages	0–10
Age group	WBC ( $\times 10^9$ /litre)
1–2 days	9.0–34.0
Neonate	6.0–19.5
1–3 years	6.0–17.5
4–7 years	5.5–15.5
8–13 years	4.5–13.5
$\geq 13$ years	4.5–11.0
Age group	Median lymphocyte count ( $\times 10^9$ /litre)
> 1 year	4.1–6.0

**Chemistry****TABLE 9.7** Chemistry: normal laboratory values

Substance	Age	Normal range	
Albumin (grams/litre)	Preterm	18–30	
	Full term to 7 days	25–34	
	< 5 years	39–50	
	5–19 years	40–53	
Amylase (units/litre)	All ages	30–100	
ASO titre (Todd units)	2–5 years	120–160	
	6–9 years	240	
	10–12 years	320	
Bicarbonate (mmol/litre)	All ages:		
	Arterial	21–28	
	Venous	22–29	
Bilirubin (conjugated) ( $\mu\text{mol/litre}$ )	> 1 year	0–3.4	
Calcium (mmol/litre)	0–24 hours	2.3–2.65	(1.07–1.27 ionised)
	24 hours to 4 days	1.75–3.00	(1.00–1.17 ionised)
	4–7 days	2.25–2.73	(1.12–1.23 ionised)
	Child	2.15–2.70	(1.12–1.23 ionised)
Chloride (mmol/litre)	Neonate	97–110	
	Child	98–106	
Creatinine ( $\mu\text{mol/litre}$ )	Neonate	27–88	
	Infant	18–35	
	Child	27–62	
Glucose (mmol/litre)	Preterm neonate	1.4–3.3	
	0–24 hours	2.2–3.3	
	Infant	2.8–5.0	
	Child	3.3–5.5	
Magnesium (mmol/litre)	0–7 days	0.48–1.05	
	7 days to 2 years	0.65–1.05	
	2–14 years	0.60–0.95	
Osmolarity (mosmol/litre)	Child	276–295 (serum)	
Potassium (mmol/litre)	< 2 months	3.0–7.0	
	2–12 months	3.6–6.0	
	Child	3.5–5.5	
Sodium (mmol/litre)	Neonate	136–146	
	Infant	139–146	
	Child	135–145	
Urea (mmol/litre)	Neonate	1.0–5.0	
	Infant	2.5–8.0	
	Child	2.5–6.6	

**Oxygen saturation (SpO<sub>2</sub>)**

The normal range is 95–100%, although oxygen saturation depends on altitude, and corrections will be needed for those living more than 1000 metres above sea level.

Table 9.8 lists the oxygen saturation levels measured in studies conducted at a range of different geographical locations above sea level.

**TABLE 9.8 SpO<sub>2</sub> levels measured at a range of different altitudes**

Altitude	Location	n	Age group	SpO <sub>2</sub> (%)	Author(s)	Year of study
Sea level	UK	70	2–16 years Mean 8 years	Range: 95.8–100 Median: 99.5	Poets <i>et al.</i>	1993
Sea level	Peru	189	2 months to 5 years	Range: 96–100 Mean: 98.7	Reuland <i>et al.</i>	1991
1610 m	Colorado	150	< 48 hours  3 months	95% CI: 88–97 Mean: 93 95% CI: 86–97 Mean: 92.2	Thilo <i>et al.</i>	1991
1670 m	Nairobi	87	7 days to 3 years	Range: 89.3–99.3 Mean: 95.7	Onyango <i>et al.</i>	1993
2640 m	Bogota	189	5 days to 2 years	Range: 84–100 Mean: 93.3	Lozano <i>et al.</i>	1992
2800 m	Colorado	72	3–670 days	Range: 88–97 Mean: 91.7	Nicholas <i>et al.</i>	1993
3100 m	Colorado	14	6 hours to 4 months 1 week 4 months	Range: 81–91 Mean: 80.6±5.3 Mean: 86.1±4.6	Niemeyer <i>et al.</i>	1993
3658 m	Tibet*	15	6 hours to 4 months	Immigrant: 76–90 Indigenous: 86–94	Niemeyer <i>et al.</i>	1995
3750 m	Peru	153	2–60 months	Range: 81–97 Mean: 88.9	Reuland <i>et al.</i>	1991

Values shown are those in quiet sleep.

\*Ranges are values for those born to immigrant Chinese mothers and for those indigenous babies whose families have lived at that altitude for innumerable generations.

**Blood gases (normal arterial range)**

- pH: 7.35–7.45.
- pCO<sub>2</sub>: 4.5–6.0 kPa (35–45 mmHg).
- pO<sub>2</sub>: 10–13 kPa (75–98 mmHg).
- Standard bicarbonate: 21–27 mmol/L

In pregnancy:

- pH: 7.40–7.46
- pCO<sub>2</sub>: 3.7–4.2 kPa (28–32 mmHg)
- Standard bicarbonate: 18–21 mmol/L

**Circulating blood volume**

- At birth: 100 mL/kg.
- At 1 year: 80 mL/kg.
- At 12 years: 70 mL/kg.
- In pregnant women and adolescent girls: 100 mL/kg.

**Equivalent values for certain drugs used in an emergency**

1 mg of prednisone or prednisolone is equivalent to 4 mg of hydrocortisone and 150 micrograms of dexamethasone or betamethasone.

Adrenaline (epinephrine) 1 in 1000 contains 1000 micrograms in 1 mL.

Adrenaline (epinephrine) 1 in 10 000 contains 100 micrograms in 1 mL.

**Measurements of medical supplies****Uncuffed tubes in children under 25 kg in weight (aged 6–7 years)**

**Internal diameter** of endotracheal tube:

- Full-term baby: 3.0–3.5 mm.
- Age < 1 year: 4.0–4.5 mm.
- Age > 1 year: size of tube = age/4 + 4 mm.

**Length** of endotracheal tube:

$$\frac{\text{Age in years} + 12 \text{ in cm (oral tube)}}{2}$$

$$\frac{\text{Age in years} + 14 \text{ in cm (nasal tube)}}{2}$$

French gauge Fr = circumference of tube in mm.

Urinary catheters: for neonate to 1 year of age\* 5–6 Fr; from 2 to 8 years 6–8 Fr; from 8 to 12 years 10–2 Fr; from 13 to 18 years 12–16 Fr and in pregnancy from 14–16 Fr.

\*Feeding tubes may be used but are not ideal

Nasogastric tubes: birth to 5 months size 8 Fr; 6 to 12 months size 10 Fr; 1 to 3 years 10–12 Fr; 4 to 7 years 12 Fr; 8 to 12 years 12–14 Fr; 12 to 18 years 14–18 Fr; in pregnancy 16–20 Fr.

## Fluid and electrolyte management

### Normal requirements for fluid

The blood volume is about 100 mL/kg at birth, falling to about 80 mL/kg at 1 year of age. The total body water content ranges from 800 mL/kg in the neonate to 600 mL/kg at 1 year of age and thereafter. Of this, about two-thirds (400 mL/kg) is intracellular fluid, the rest being extracellular fluid. Thus initial expansion of vascular volume in a state of shock can be achieved with relatively small volumes of fluid: 20 mL/kg (a quarter of the blood volume) will usually suffice. However, this volume is only a fraction of that required to correct dehydration, as the fluid has been lost from all body compartments in this condition. Clinically, dehydration is not detectable until more than 3–5% (30–50 mL/kg) of the body fluid has been lost.

It is important to remember that although fluid must be given quickly to correct loss of circulating fluid from the blood compartment (i.e. in shock, except in malnutrition; see Section 5.10.B), it must be given carefully in dehydration (see Section 5.5.B).

**TABLE 9.9** Normal fluid requirements

Body weight	Volume of fluid (mL/24 hours)	Volume of fluid (mL/hour)	Na <sup>+</sup> (mmol/24 hours/kg)	K <sup>+</sup> (mmol/24 hours/kg)	Energy (kcal/24 hours)	Protein (grams/24 hours)
First 10 kg	100	4	2.0–4.0	1.5–2.5	110	3
Second 10 kg	50	2	1.0–2.0	0.5–1.5	75	1
Subsequent kg	20	1	0.5–1.0	0.2–0.7	30	0.75

For example:

- an infant weighing 6 kg would require 600 mL per day
- a child weighing 14 kg would require 1000 + 200 = 1200 mL per day
- a child weighing 25 kg would require 1000 + 500 + 100 = 1600 mL per day.

In practice, the healthy child only drinks when they are thirsty, but it is useful to have an idea of how much fluid a child should be expected to need. Of course, if there are excess losses, as in diarrhoea or fever, or if the ambient temperature is especially high, leading to high insensible losses, more fluid is required. Except in cardiac or renal disease, a good way to check whether a child is taking in enough fluid is to see whether they have a satisfactory urine output of at least 2 mL/kg/hour.

Average fluid requirements in pregnancy are 1500–2500 mL/day. This depends on levels of activity, ambient temperature and whether or not the mother has a fever.

### Rehydration

Fluid deficit + normal fluid requirements + ongoing losses (sweat, diarrhoea, vomit, etc.).

**Fluid deficit (mL)** = percentage dehydration × weight (kg) × 10.

### Ongoing losses:

- After each loose stool:
  - age < 2 years: 50–100 mL
  - age ≥ 2 years: 100–200 mL
- After each vomit: 2 mL/kg body weight.

Fluids in neonates after the first 3 days of life are often prescribed on the basis of 150 mL/kg/day. However, this is not related to fluid needs, but is merely the volume of standard formula milk required to give an adequate protein and calorie intake.

Fluid requirement can be divided into four types:

- 1 for replacement of **insensible losses** (through sweating, respiration, gastrointestinal loss, etc.)
- 2 for replacement of **essential urine output** (the minimal urine output to allow excretion of the products of metabolism, etc.)
- 3 extra fluid to maintain a **modest state of diuresis**
- 4 fluid to replace **abnormal losses** (e.g. blood loss, severe diarrhoea, diabetic polyuria losses, etc.).

A useful formula for calculating normal fluid requirement is provided in Table 9.9. It is simple, can be applied to all age ranges and is easily subdivided. The formula gives total fluid requirements – that is, types (1), (2) and (3) listed above.

### Some useful information about biochemical measurements

- 1 ounce = 28 mL
- Percentage solution = number of grams in 100 mL (e.g. 10% dextrose = 10 grams in 100 mL).
- One millimole = molecular weight in milligrams.
- Some useful atomic weights:
 

hydrogen	1.0
carbon	12.0
nitrogen	14.0
oxygen	16.0
sodium	23.0
phosphorus	31.0
chlorine	35.5
potassium	39.1
calcium	40.1

Therefore, for example:

1 mmol NaCl = 58.5 mg  
 1 mmol NaHCO<sub>3</sub> = 84 mg  
 1 mmol KCl = 74.6 mg.

- The equivalent weight of an electrolyte = molecular weight/valency (e.g. Ca = 40/2).
- Useful figures to know:
  - 30% NaCl = 5 mmol/mL each of Na<sup>+</sup> and Cl<sup>-</sup>
  - 0.9% NaCl = 0.154 mmol/mL each of Na<sup>+</sup> and Cl<sup>-</sup>
  - 15% KCl (15 grams/100 mL) = 2 mmol/mL each of K<sup>+</sup> and Cl<sup>-</sup> (also called concentrated or strong KCl)
  - 10% calcium gluconate (10 grams/100 mL) = 0.225 mmol/mL (note that 1 mL of calcium chloride 10% is equivalent to 3 mL of calcium gluconate 10%)
  - 8.4% NaHCO<sub>3</sub> = 1 mmol Na<sup>+</sup> and 1 mmol HCO<sub>3</sub><sup>-</sup>/mL

- 1 mL/hour of normal saline = 3.7 mmol Na<sup>+</sup> in 24 hours.
- Serum osmolarity = 2(Na<sup>+</sup> + K<sup>+</sup>) + glucose + urea (normally 285–295 mosmol/litre).

### Normal requirements for electrolytes (unless there are excessive losses)

There are obligatory losses of electrolytes in stools, urine and sweat, and these require replacement. Any excess is simply excreted in the urine.

**TABLE 9.10** Electrolyte content of body fluids

Fluid	Na <sup>+</sup> (mmol/litre)	K <sup>+</sup> (mmol/litre)	Cl <sup>-</sup> (mmol/litre)	HCO <sub>3</sub> <sup>-</sup> (mmol/litre)
Plasma	135–145	3.5–5.5	98–108	20–28
Gastric fluid	20–80	5–20	100–150	0
Intestinal fluid	100–140	5–15	90–130	13–65
Diarrhoea	7–96	34–150	17–164	0–75
Sweat	< 40	6–15	< 40	0–10

**TABLE 9.11** Normal water and electrolyte requirements in pregnancy

Maintenance requirements/24 hours	Volume of fluid (mL/day)	Sodium requirement (mmol/day)	Potassium requirement (mmol/day)
	1500–2500	150	100

### Commonly available crystalloid and colloid fluids

**TABLE 9.12** Commonly available crystalloid fluids

Fluid	Na <sup>+</sup> (mmol/litre)	K <sup>+</sup> (mmol/litre)	Cl <sup>-</sup> (mmol/litre)	Energy (kcal/litre)
<i>Isotonic crystalloid fluids</i>				
Saline 0.9% (normal)	150	0	150	0
Glucose 5% (50 mg/mL)	0	0	0	200
Hartmann's solution or Ringer-lactate solution*	131	5	111	0
<i>Hypertonic crystalloid fluids</i>				
Saline 0.45%, glucose 5%	75	0	75	200
Glucose 10% (100 mg/mL)	0	0	0	400
Glucose 50%	0	0	0	2000

\*Hartmann's or Ringer-lactate solution also contains HCO<sub>3</sub><sup>-</sup> as lactate 29 mmol/litre and calcium 2 mmol/litre.

To make 10% glucose/dextrose solution in Ringer-lactate/Hartmann's or 0.9% saline, remove 100 mL from a 500 mL bag and inject into it in a sterile manner 100 mL of 50% dextrose/glucose.

To make 5% glucose/dextrose solution in Ringer-lactate/Hartmann's or 0.9% saline, remove 50 mL from a 500 mL bag and inject into it in a sterile manner 50 mL of 50% dextrose/glucose.

To make a 10% solution of glucose for injection in treating hypoglycaemia and if there is only 50% dextrose/glucose solution available:

- either dilute 10 mL of the 50% solution in 40 mL of sterile water
- OR add 10 mL of 50% dextrose to 90 mL of 5% glucose which will give an approximate 10% glucose solution.

**TABLE 9.13** Commonly available colloid fluids

Colloid	Na <sup>+</sup> (mmol/litre)	K <sup>+</sup> (mmol/litre)	Ca <sup>2+</sup> (mmol/litre)	Duration of action (hours)	Comments
Albumin 4.5%	150	1	0	6	Protein buffers
Gelofusine	154	< 1	< 1	3	Gelatine
Haemaccel	145	5	12.5	3	Gelatine
Pentastarch	154	0	0	7	Hydroxyethyl starch

### Drop factor for IV infusions

Fluids can be calculated in drops/minute as follows. First identify from the IV giving set what the 'drop factor' is (for standard giving sets this may be 10, 15 or 20 drops = 1 mL). For micro-drop systems, which often accompany

giving sets with burettes, 1 mL = 60 drops. When setting the infusion rate with the flow controller on the giving set below the chamber where the drops occur, always set and count the rate over a full minute.

### Estimating body surface area

In paediatrics, body surface area is commonly used to calculate some drug dosages. This is because in children beyond the neonatal period, metabolic rate, renal clearance and some other bodily functions vary more closely with surface area than they do with weight.

In practice, using surface area as the basis for prescribing means that smaller children receive relatively more drug than they would if weight was being used.

For many drugs, the therapeutic margin is wide enough for it not to matter which method of dosage calculation is used, but for some it makes a significant difference, and

avoids ineffective under-prescribing in smaller children. Examples of drugs for which it should be used are most cancer chemotherapy agents, and corticosteroids.

Although there are several widely used formulae and nomograms that relate surface area to body weight and height, Boyd's self-adjusting power equation that relates it to body weight alone has been shown to be the most reliable method of estimation. A major advantage is that for any particular weight, it is merely necessary to read the surface area from a table (see Table 9.14). This is not only quicker, but it also reduces the risk of making an error almost to zero.

**TABLE 9.14** Surface area and weight

Weight (kg)	Surface area (m <sup>2</sup> )	Weight (kg)	Surface area (m <sup>2</sup> )	Weight (kg)	Surface area (m <sup>2</sup> )

FIGURE 9.11 Weight-for-length reference chart (87 cm or above). Based on World Health Organization data.

# Index

References to figures are in *italics*; references to tables and boxes in **bold**.

5HT3 antagonists 580

7-valent pneumococcal conjugate 95

8-aminoquinolines 745

AAFB (alcohol and acid-fast bacilli) 703–4

abacavir (ABC) 275, 698, 715, 717

ABC (Airway: Breathing and Circulation), in advanced life support 55; in anaesthesia 126; in APH 185; and inverted uterus 250; and meningococcal disease 651; and morphine 20; in pulmonary embolism 224; in shock 171, 545; in trauma 770–1, 778, 780

ABCD (Airway, Breathing, Circulation, Disability) 34–5, 97

abdomen: closing 317; opening 314–15  
abdominal distension: after shunting 620; and CNEP 847–8; and dehydration 545, 555; and ectopic pregnancy 178; and hepatoblastoma 585; and Hirschsprung's disease 560, 636; and intestinal obstruction 636; and meconium ileus 443; and NEC 377–8; and obstructed labour 214; and spinal cord injury 407; and uterine rupture 216; and vomiting 377; and Wilm's tumour 585  
abdominal examination: in antenatal care 137; and APH 185; detecting face presentation 239–40; and intussusception 635; in labour 146, 148; for multiple pregnancy 232; for new patients 30; in trauma 779

abdominal excursion 36, 772

abdominal malignancy 328

abdominal mass: and Cushing's syndrome 503; and gastrointestinal emergencies 43; and nausea 86; and TB 668

abdominal pain: and anthrax 678; and appendicitis 634; and ARF 482; causes of **158–9**, **161** 382–3; cramping 636; and DKA 262, 494; and dysentery 551; and ectopic pregnancy 177–8; and gastrointestinal emergencies 43; and HIV 705; and HSP 571; and hydatids 751; investigations in **382**; and jaundice 381; in late pregnancy **159–61**; and leptospirosis 647; and liver flukes 754; and malabsorption 566; in miscarriage 182; and mumps 721; and ovarian cysts 226; and peritonitis 305; and pneumonia 269, 437; and poliomyelitis 722; in pregnancy 144; recurrent 563, 617; and rheumatic disease 569; and SCD 534; and sexual abuse 821; and strongyloidiasis 759; and sulphasalazine 573; and TB 286; and tonsillitis 427; in triage 32–3; unexplained 782; and urinary stones 479; and uterine perforation 182; and VHF 726–7

abdominal palpation 147–8, 154, 312, 536

abdominal paracentesis 865

abdominal tenderness: and gastrointestinal emergencies 43; and puerperal sepsis 221

abdominal thrusts 53–4, 54

abdominal trauma: and amniotic fluid embolism 225; and APH 185; and Caesarean section 785; and Entonox 778

abdominal tuberculosis 561, 667

abdominal ultrasound 14, 228, 583, 782

abdominal wall, rigid 305

abdominal X-ray: and bladder stones 630; and cancer diagnosis 585; and intussusception 635; and urinary stones 479

abnormal postures 43, 266, 403, 595, 650

ABO incompatibility 23–5, 138, 368, 370–1, 383

abortion: complicated by infection *see* septic abortion; induced 162–3, 169, 171, 176, 179, 182; unsafe 94, 176, 183

abrasions 654, 725, 762–3, 779, 822

abscesses: formation of 221; incision and drainage of 14, 864–5

abuse: categories of 96; *see also* child abuse and exploitation; *see also* domestic violence

abusive injuries *see* non-accidental injuries

abusive relationships 112, 302

acceleration/deceleration injuries 782

accidental injuries 819, 824; sites for 819

ACE (angiotensin-converting-enzyme) inhibitors 175, 253–4, 474–5

acetazolamide, and headache 389

achondroplasia 406

aciclovir: in cancer treatment 580; and chickenpox 291, 680–1, 708; and eczema 627; and HSV 604, 705

acid-base disturbance 63, 487

acid-fast bacilli (AFB), and TB diagnosis 287, 665, 668

acid hydrolysis 690

acid regurgitation 121

acidaemia: and cardiac arrest 63; organic 499, 616

acidosis: and adrenal crisis 500; in cardiovascular collapse 451; and coma 593; and diarrhoea 557; and DKA 262–3, 494–5; and malaria 741; in obstetric haemorrhage 188, 195; and respiratory rate 38, 187; and shock 186; and tachypnoea 250; *see also* metabolic acidosis  
acidotic breathing: and DKA 262, 494; emergency treatment in 42; and malaria 279; and poisoning 811

ACS (acute chest syndrome): and blood transfusion 22–3; and SCD 174, 533, 536–7

ACT (artemisinin-combination therapy) 278–9, 281, 285, 736

actinomycin 577, 579, 585–7

active colitis 562

active labour: partography in 145; prolonged 153, 213; stages of 147–8; time elapsed since start of 147

acute appendicitis 285; and ectopic pregnancy 178; and gastroenteritis 271; and shock 166

acute flaccid paralysis 604, 614–15, **615**, 722

acute gastroenteritis 270–1, 545, 679, 747

acute glomerulonephritis 388, 474, 660, 756

acute haemolysis 22, 24–5, 166, 478, 540

acute hepatitis 95, 489, 686–7; causes of **686**

acute myeloid leukaemia *see* AML

acute renal failure (ARF): and burns 796; and encephalopathy 376; fluid depletion in 470; and leptospirosis 647; and malaria 283, 744; management of 483–4; and *Streptococcus* 659; types of 481–2

acute respiratory infection (ARI): assessment and treatment of 438; categories of 436; and *Chlamydia* 679; and HIV 701; and poor weight gain 528; and vitamin A deficiency 512

acute rheumatic fever 254, 452, 569–70, 659

acute sequestration events 536

acute stress disorder 509

acyclovir 43, 580, 680, 708

Addisonian crisis 257

Adelaide coma scale **594**, 739

adenitis, regional 642

adeno-lymphangitis 757

adenoidal hypertrophy 422

adenoma 502–3

adenosine 40, 456–7, 851

adenoviral infection 635

ADHD (attention deficit hyperactivity disorder) 404, 510–11

adjuvants 72, 81, 84

ADLA (acute dermatolympangoadenitis) 756

adnexal infections 221

adolescents: advocacy for 396; ARVs for 698; and cancer 576; cricothyroidotomy in 840; dying 80; HIV transmission among 688, 711; mediastinum of 791; nursing care for 395–7; psychiatric disorders of 396, 505–9; recovering from malnutrition 527; respiration rates for 131; STIs in 656, 658, 826; symptoms of sexual abuse in 821; TB in 666

adrenal carcinoma 503

adrenal crisis 500, 502–3

adrenaline: in airway resuscitation 35, 37; in anaesthesia 130; and anaphylaxis 258, 425–6; in asthma 256–7; in cardiac arrest 62–5; in cardiovascular collapse 451; in emergency room 110; and envenomation 816; in epiglottitis 424; equivalents in other drugs 881; excess 520; in high-dependency care 853; and local anaesthetic 126, 128; in neonates 336, 339–40; in obstetric haemorrhage 189, 200; in OT 14; in pain control 70; and shock 39, 171, 468; topical 88, 90; venous administration of 852

adrenaline toxicity 71

adriamycin 577, 583, 585, 587

advanced life support 55

*Aedes aegypti* 729

AEDs (automatic external defibrillators) 51–2, 51, 64–5, 69, 110, 863

*Aeromonas* 551

aerosols, substance abuse of 508, 814

AFL (acute filarial lymphangitis) 756

Africa: availability of morphine in 82;

Buruli ulcer in 642; LIP prevalence in 702; meningitis belt of 650, 653; post-natal care in 156

African Programme for Onchocerciasis Control 759

African trypanosomiasis 28, 381, 730, 734

African women, pelvis of 148

agammaglobulinaemia 659

agonal gasps 37, 45–7

AIDS (acquired immune deficiency syndrome) 687, 689–90, 705; *see also* HIV

AIDS support organizations 689

air-conditioning 4, 14–15

air cushions 417

air embolus: and amniotic fluid embolism 226; and exchange transfusion 23, 370; in IV administration 18, 851, 856

airway: secondary assessment of **41**; in shock 169

airway and breathing equipment 55

airway management, in trauma 771

airway obstruction: acute partial 427;

and neck extension 40; neonatal 365;

persistent 35; and sedation **77**; and trauma 771, 773, 780

airway-opening actions 35, 45–6, 58

airway patency 46, 284, 651, 770

airway resuscitation 35–6, 782–3

airway secretions: and death rattle 90; and dyspnoea 87; excess 845; and laryngeal spasm 125; and PPV 133

AL (artemether and lumefantrine) 279, 738

Alagille syndrome 490–1

alar flaring 36–7, 56, 772

albendazole: and anaemia 531; and encephalitis 606; and filariasis 756–7;

and hydatids 751; and malnutrition 523;

and strongyloidiasis 760; and worms 173, 748–50

ALCAPA (anomalous origin of the left coronary artery from the pulmonary artery) 455

alcohol: adolescent use of 507–8; as antiseptic 314; and ARIs 436; and coma 593; and drowning 797; exposure in utero 351; and sexual abuse 821

alcohol poisoning 814–15

alcohol swabs 17, 357, 773, 842, 854

Alder Hey Triage Pain Score 69, 78

ALF (acute liver failure) 381, 486–8, 490,

686–7; causes of **487**; clinical features of **486**

algid malaria 284, 743

alginate dressings 88, 90, 418

ALL (acute lymphoblastic leukaemia) 572,

576, 578–9, 581–3, 587

allergic reactions 24–5, 258, 385, 824

allergies, history of 43

Allis forceps 315

alloimmunisation 26

allopurinol 581–3

alopecia 579, 581, 608, 709

ALRI (acute lower respiratory infection)

436–8, **438**, 440, 654

ALSG (Advanced Life Support Group): and

BLS 44; training from 11, 109

ALT (alanine aminotransferase) 27, 686,

699, 717

ALTEs (apparent life-threatening events)

387

aluminium hydroxide 492

alveolitis 438, 796

amblyopia 592

ambulances 31, 97, 139, 787

American trypanosomiasis 732

Ametop 128

Amies medium 28

amikacin 287–8, 590, 642

aminoaciduria 814

aminoglycosides: and cancer treatment

580; and hearing loss 401; for infants

354; and peritonitis 637; and STIs 658;

and *Streptococcus* 660

aminophylline: and anaphylaxis 425–6;

and asthma 256, 433; in emergency

room 110; giving safely 257; in high-

dependency care 853; IV administration

of 852

aminosalicylates 561–2

aminosidine 733–5

amidarone 64–5, 110, 456–8

amitriptyline 84–5, 294

AML (acute myeloid leukaemia) 581–2

amniocentesis 225

amniotitis 215, 321

amniotic fluid embolism 66, 166, 186,

203, 225–6

amniotic fluid volume 231

amniotic hook 144, 151, 209

amniotomy 143, 242

amodiaquine 279, 740–1, 745–6

amoebiasis 172, 565, 637, 642, 747

amoxicillin: in ALF 488; and anthrax

679; and bladder damage 304; and

cancer 705; and cystitis 286; and

endocarditis 456; and gallstones

539; and *H. pylori* 564; and intracranial

abscesses 619; and leptospirosis 648;

and Lyme disease 649; and meningitis/

encephalitis 41; in neonates 357; oral

administration of 17; and otitis media

427; and peritonitis 222; and pneu-

monia 438–9; and PPRM 245, 331;

prophylactic **445**; routes of adminis-

tration 851; and salmonella 674; and

severe malnutrition 520–1; and typhoid

673; and urinary catheterisation 314;

and UTIs 473–4

amoxicillin/ampicillin 286, 673

amphetamines 508

amphotericin: in ALF 488; and encephali-

titis 605; and fungal infections 704, 707;

IV administration of 852; and leishma-

niasis 733–5

ampicillin: and appendicitis 285, 634; and

Caesarean section 316; and diarrhoea

557; and dog bites 794; in episiotomy

325; and headache 389; for infants

355, 440; and inverted uterus 250; in

labour 150–1; and lung abscess 442;

and meningococcal disease 651; and

NEC 377; in neonates 350, 352, 357; in

obstructed labour 214; oral administra-

tion of 17; and peritonitis 222, 286, 484;

in placenta removal 326; and pneumo-

nia 269, 439–40; in post-operative care

304–5; and PPH 198; and PPRM 245;

prophylactic **445**; and puerperal sepsis

221; and retropharyngeal abscess 428; routes of administration 851; and ruptured membranes 228; and SAM 521; and septic shock 171, 177; and septicaemia 354; and *Streptococcus* 660; and symphysiotomy 321; and typhoid 672; and uterine rupture 216

amputation: bleeding from 774; body parts from 784; and Buruli ulcer 642; and cancer 587; and detonation injuries 800; and septicaemia 653

anaemia: definition of 530; in adolescent girls 395; in antenatal care 136–7; and blood transfusion 21–2, 26; and cancer 576, 580–1; and cardiac failure 40; causes of 383, 530; and congenital syphilis 355; and CRF 485; and diarrhoea 380; and dyspnoea 87; and ectopic pregnancy 178; and FGC 300; fits and faints in 387; follow-up care for 746; and HIV 275, 694; and hyperemesis 251; investigations in **384**; and juvenile idiopathic arthritis 572; and lead poisoning 814; and learning difficulties 404; and leishmaniasis 734; and liver flukes 754; and malabsorption 566; and malaria 276, 280, 598, 710, 745; megaloblastic 515, 608; and multiple pregnancy 232–3; in neonates 332, 371; nutritional 27; in post-operative care 304; and pressure sores 416; prevention of 172–3; and prolonged labour 211; and SCD 176, 535; and scurvy 514; and severe malnutrition 516, 523; and shock 39, 166, 168; and skin colour 37; and trypanosomiasis 730; unexplained 369; *see also* haemolytic anaemia; severe anaemia

anaesthesia: in Caesarean section 253, 315–16; checking level of 75; in children 126, 628; for destructive procedures 321; essential equipment for 129; golden rules of 124, 126–7, 129; monitoring in 129–30; and obstetric haemorrhage 189, 199–200; and sedation 76, 127; and sedation **77**; toxic reaction to 226

anaesthetic assessment 176

anaesthetic machine 14

anaesthetists 15

anal fissures: bleeding from 565; and diarrhoea 380; and IBD 822; and toilet-habits 395

anal injuries 821–2, 824; differential diagnosis of **824**

anal intercourse 820

anal lesions 560

analgesia: and anaesthesia 127; inadequate provision of 576; for life-saving procedures 836–7; non-opioid 82; orally administered **72**; *see also* pain control

analgesic ladder **72**, **81**, 534

anaphylactic shock 38–9, 166, 226

anaphylaxis: and blood transfusion 24–5; and botulism 641; in children 425–6; emergency treatment for 35, 37, 42; and generalised oedema 388; and hydatids 751; and immunisation 93; pathway of care for 259–60, 425; and rabies vaccine 724; symptoms and signs 42, **258**, **426**; and upper airway obstruction 422; and VZIG 292

*Anaplasma phagocytophilum* 675

*Ancylostoma duodenale* 530, 567, 748, 750

anencephaly 620

angioneurotic oedema 166, 424

*Angiostrongylus cantonensis* 602

angiotensin-receptor blockers 175

Angola, leprosy in 645

anhedonia 294

ankylosis 642

Ann Arbor staging system 583

anorexia: in CLD 493; and jaundice 381; and leptospirosis 647; and malnutrition 525; and rheumatic disease 569

antacids: and anaesthesia 123; in Caesarean section 314; and oesophagitis 705; and portal hypertension 492

antenatal care: basic 136–7; effective system for 138–9; for HIV-positive mothers 275; investigations and interventions in 138; and malaria 277–8; opportunistic 136; and pre-eclampsia 211; routine visits in 143; and SCD 175; for twin pregnancy 233

antenatal clinics: for adolescents 396; and antimalarials 277; and domestic abuse 302; following up miscarriage 180; promoting attendance at 398

antepartum haemorrhage (APH): definition of 183; and anaesthesia 122, 124; causes of **184**; and cervix sweeping 150; and fetal distress 231; management of 185–9; pathway of care **188**; and PPH 189, 191; and pre-eclampsia 208; and Rh-D sensitisation 138

anterior episiotomy 153

anterior fontanelle, bulging 618

anthracylines 581–2

anthrax 678

anti-arrhythmic drugs 65, 455, 457, 797

anti-cholinergics 87, 90

anti-D immunoglobulin 182, 242

anti-embolism stockings: in coma 597; and hyperemesis 251; in post-operative care 304; and PPRM 245; and pre-eclampsia 211; and pulmonary embolism 223, 225; *see also* compression stockings

anti-emetics: and chemotherapy 580; not for children 544, 552; and hepatitis 686; and hyperemesis 251; and migraine 617; and morphine 76; and opioid therapy 86–7; routes of administration 90

anti-epileptic drugs 606–8, 610, 794; doses of **608**

anti-human globulin technique 23

anti-shock garment 169, 172, 187–8, 195, 214

anti-tetanus coverage, in post-operative care 303

anti-thrombotic stockings 176

anti-tuberculous drugs 287, 631, 633, **670–1**, 709

antibiotic-resistant microorganisms 7, 598, 659

antibiotics: and anaemia 383; and appendicitis 285; in asthma 552; and bacterial meningitis 598, **600–1**; for burns 809; and Buruli ulcer 642; and cancer treatment 576, 580; for cellulitis 333; and croup 423; and cystic fibrosis 444; and cystitis 286; and diarrhoea 551–2, 705; in emergency room 110; in EmONC 306; excess use of 357; and filariasis 757; and glandular fever 428; in HIV 696; and infective shock 171; and leptospirosis 648; and Lyme disease 649; in malaria 280, 282; in management of miscarriage 181–2; and meningococcal disease **651**; with multiple routes of administration 17, 851; and NEC 377; for neonates 351, 354–5, 358–9, **358–61**; and peritonitis 222; in pneumonia 269; and PPRM 245; for preterm babies 331; and puerperal sepsis 221; and relapsing fever 655; and respiratory distress 362; and seizures 372; in septic abortion 177; in septic shock 468; in septicaemia 354; side effects of 86; and *Staphylococcus* 679; storage of 19; for tetanus 661; and typhoid 673–4, **674**; and VHF 727; and wounds 763; *see also* broad-spectrum antibiotics; IV antibiotics; oral antibiotics

anticholinesterases 108, 815, 817

anticoagulants: in blood donor bags 179; and pulmonary embolism 37, 224–5

anticonvulsants: and anaemia 383; and drowning 797; as emergency treatment 43; in EmONC 306; and encephalitis 603; and fits 41; and malaria 280, 283, 741; and meningitis 599; in neonates 372; and nerve pain 84; post-delivery 210; prophylactic 207, 268, 280, 596, 599, 741

antidepressants: for adolescents 507; postnatal 294, 296; in pregnancy 293; side effects of 87; *see also* SSRIs; tricyclic antidepressants

antidiarrhoeal drugs 544, 552

antifolates 279

antifungal drugs 486, 606, 625, 627, 687, 709

anthelmintics 172–3, 516, 530–1, 751, 757

antihistamines: and allergic reactions 24; and anaphylaxis 258, 426; and chickenpox 680; and emergency treatment 42; and opioids 83; and rash 709

antihypertensive drugs: and EmONC 306; post-delivery 210; and pre-eclampsia 202; and severe hypertension 203; and volume expansion 208

antimalarial drugs: and anaemia 21, 173, 383; in children 738–9; effectiveness of 277–8; first-line 740–1; and G6PD deficiency 540; in pregnancy 279–81; and VHF 727

antimony 734–5

antipsychotic drugs 292, 294–5, 508

antipyretics: and encephalitis 603; for JHR 291; and meningococcal disease 652

antiretroviral prophylaxis 274–6

antispasmodics 662–3, 754

antivenom 815–18

anuria: and ARF 483; and malaria 283; and potassium 264

anxiety: and grief 113, 116; and pain 70; in palliative care 86–8; and sedation 76

anxiety disorders 295, 509, 821

anxiolytics 72, 81, 88, 90

aorta, coarctation of 450

aortic compression 169, 193, 199

aortic dissection 791

aortic regurgitation 254–5, 452–3, 570

aortic stenosis: and general anaesthesia 124; in heart failure 252–3; murmur in 451; and nifedipine 203; pulses in 450

aortocaval compression 52, 66, 121, 231–2, 314, 785–6

apathy, persistent 635

aphthous ulcers, idiopathic 705

apical impulse 254–5, 452–4

aplastic anaemia 445, 608, 686–7

aplastic crisis 22, 535–6, 540–1

APLS/ATLS system 762, 814

apnoea: and airway management 774; and ALRI 440; and anticonvulsants 791; and drowning 796; and encephalopathy 376; and ketamine 129; and morphine 72; in neonates 336, 345; and pertussis 654; post-operative 628; of prematurity 132, 365–6, 844; prolonged 346, 361; and RICP 618; in seizures 371; and septicaemia 352; terminal 340

APOD (acute papular onchodermatitis) 758

appendectomy 159, 161, 285, 628, 634

appendicitis: and abdominal pain 382; surgery for 633–4; and vomiting 384; *see also* acute appendicitis

appendix: changing position in pregnancy 285; perforated 634

APTT (activated partial thromboplastin time): and envenomation 816; in pre-eclampsia 209; in pulmonary embolism 224–5

aqueductal stenosis 721

aqueous benzylpenicillin 290

aqueous cream 709, 749

aqueous iodine oral solution 501

ARDS (acute respiratory distress syndrome) 25, 225–6, 279, 648, 700

ARM (artificial rupture of membranes) 151; and cord prolapse 247; in fetal death 228; in hypertension 209; in multiple pregnancy 233

arm recoil 343–4

aromatherapy 76, 90, 104

arsenic 106, 108, 508

artemether 279–81, 736, 739–40

artemisinins 279–80, 739–40

arterial oxygen saturation (SpO<sub>2</sub>): in anaesthesia 123, 126, 130; healthy levels of 59; normal **881**; and sleep-related upper airway obstruction 429–30

artery forceps 15, 109, 441, 842–3, 858

artesunate 279–81, 736, 739–40, 746

arthralgia: and iron dextran 173; and leptospirosis 647; and relapsing fever 655; treatment of 570; and VHF 727

arthritis: and chickenpox 680; and Lyme disease 649; and mumps 721; reactive 570, 572, 674, 759; and relapsing fever 655; and SLE 573; and *Streptococcus* 659

arthropathy 383, 445

arthrosis, secondary 624, 766

arthrotomy 622

ARVs (anti-retroviral drugs): for children 656, 690, 697–8, **714–16**, **718**; classes of 697, **698**; and co-trimoxazole 702; and diarrhoea 705; and failure to thrive 443; and malabsorption 566; and malnutrition 518, 524–5; monitoring response to 698–9, **712**; and phenytoin 84; post-partum 275; in pregnancy 273–4, **274**, 688, 695; prophylactic use of 695; side effects of **717**; and skin lesions 709; starting therapy 693, 698; and TB 703–4; third-line 700; treatment failure **699**

ascariasis 748–50

ascites: chylous 756; and CLD 490; drainage of 14; and generalised oedema 388; gross 87; and jaundice 381

ASD (atrial septal defect) 446, 451

Asherman chest seal 781

ASOM (acute suppurative otitis media) 427–8

asparaginase 576, 582

Asperger's syndrome 510

*Aspergillus* 704, 798

asphyxiation: and burns 807–8; and cricothyrotomy 772, 841

aspiration pneumonia: and meningitis 599; in neonates 364; risks of 440; and severe malaria 280

aspirin: and coma 593; and G6PD deficiency 540–1; and haemophilia 543; and heart failure 455; hypersensitivity to 73; and liver dysfunction 488, 492–3; in post-operative care 303; and pre-eclampsia 175; and rheumatic disease 570–1

asplenia, functional 534

asthma: acute 433; in children 431–3, 435; emergency treatment of 256–7; features of 255; and labetalol 203; life-threatening 37; pathway of care for 256, 434; and resuscitation 42; steroids for 500; with wheezing 430

asthmas, and NSAIDs 73

astrocytoma 406, 584, 593

asymptomatic cystitis 286

asymptomatic murmurs 446, 451

asymptomatic/placental malaria 277–8, 663

asystole: on ECG 62; management of 62–3

at-risk airway 35, 771

ataxia: and encephalitis 602; and headache 389; and poisoning 811; and tricyclic antidepressants 813; truncal 583; and trypanosomiasis 730; and Wernicke's encephalopathy 251

atelectasis, massive 257

atenolol 253, 457, 469

ATN (acute tubular necrosis) 376, 471, 481–2, 869

atonic uterus: and bleeding in C-section 318; NASG in 196; and PPH 189–92; preventing 154; and shock 169

atopic conditions 431, 590, 627, 709

atovaquone 702

atropine: in anaesthesia 130; in APH 188–9; and ARLs 436; and bradycardia 250; in cardiac arrest 63; in emergency room 110; and heart block 458; and ketamine 125; in OT 14; and poisoning 813

atropine and xerophthalmia 523

attachment 111–12, 117, 820

attention deficit disorder *see* ADHD

AURI (acute upper respiratory infection) 436

Australia, Buruli ulcer in 642

autism 403–4, 510, 820

auto-infection 759

Brazil: leishmaniasis 733; leprosy in 645  
breakthrough pain 82–4  
breast development 874–5  
breast milk: banking 347; best food for infants 16; blocked 222; expressed (EBM) 157, 344–5; and hypoglycaemia 374–5; vitamin A in 156  
breast milk substitutes 370, 524, 696  
breastfeeding: and anaemia 21; and burns 806; and diarrhoea 355, 394, 553–4, 558; for disabled children 399; establishing 348–9; and immunisation 93; and jaundice 367; and malnutrition 519, 525, 527; and mastitis 222–3; as pain relief 76; and pertussis 654; and preterm babies 246, 331; preventing HIV transmission in 273, 688, 690–3, 695–6; and psychiatric medicines 294–5; and rickets 514; and TB 288  
breath-holding episodes 387, 616–17  
breathing: adequacy of 46, 843; assessment of 772; equipment and skills for 58; in resuscitation 170; secondary assessment of 41–2; *see also* respiration  
breathing resuscitation 36–7  
breach delivery 241–4, 243; at Caesarean section 318; complicated 97; meconium passed in 232; and nerve palsies 351  
breach presentation 241–2; destructive procedures in 322; and hip impairments 399; reasons for death in 215, 321; and vacuum delivery 307  
bright torch light 29, 588  
Brill–Zinsser disease 675  
broad ligament haematoma 318  
broad-spectrum antibiotics: and cancer treatment 580; and convulsions 280; and diarrhoea 545; and intestinal obstruction 636; and intussusception 635; and kwashiorkor 523; in labour 176; and malaria 282, 284, 744; and meningococcal disease 651; and SAM 520–1; and septicaemia 355, 467, 488, 661; and shock 42, 355, 521, 580, 657, 674; for trauma 110, 781; and umbilical infection 375; and VHF 728; and vitamin K deficiency 515  
bronchial breathing 269, 437–8  
bronchiectasis: and asthma 431; in children 442; and cystic fibrosis 443, 445; and HIV 666, 704  
bronchiolitis: and ALRI 440; in children 430–1; and CNEP 846; and pneumonia 439; and resuscitation 35, 42  
bronchoconstriction 108, 850  
bronchodilation 125, 434  
bronchodilators 42, 430–3, 703–4, 850  
bronchopneumonia 680  
bronchorrhoea 813  
bronchospasm 24, 71–2, 129, 202–3, 808  
brow presentation 236–40  
Brownian motion 473, 868–9  
brucellosis 679, 734  
*Brugia* 755–6  
bruises: and child abuse 819, 821; and coma 267; documenting 30; and domestic violence 302; and leptospirosis 647; and neurological failure 777  
buccal midazolam: and bleeding 88; and CSE 610; and seizures 41, 89; and terminal restlessness 90  
Budd–Chiari syndrome 486–7, 492  
budesonide 423, 432, 720  
bulbar paralysis: and botulism 640; and diphtheria 645; and envenomation 815, 817; and poliomyelitis 722; and upper airway obstruction 422  
bulimia 384

- bupivacaine 71, 76, 123, 127–8, 130  
burettes: in high-dependency care 69; in IV infusions 17–18, 852; for oxytocin administration 752, 186, 215; for safe dosage 257  
burial of the dead 91, 119, 728; *see also* funerary procedures  
Burkitt's lymphoma 403, 575, 577, 582–3  
burn prevention 810  
burns: and anaemia 21; analgesia for 836; body proportion assessment for **806**, **807**; deliberate 96, 819, 823; depth of 807; electrical 795–6, 808–9; ingestion 803; inhalational injury due to 807–8; and intubation 839; pain relief for 70; and septicæmia 659; severe 769, 795, 805, 809; treatment of 804–6, 808–10; in triage 31–3  
burr-hole drainage 619, 779, 793–4  
Buruli ulcer 641–3  
butane gas 508, 814
- C-arm fluoroscopy unit 13  
Caesarean hysterectomy 214  
Caesarean section (CS): alternative to destructive operations 324; and amniotic fluid embolism 326; anaesthesia in 71, 121–2, 124–6; anticoagulation in 225; complications of 317–19; and cord prolapse 247; and diabetes 262; emergency 143; and EmONC 306; and fetal distress 232; and heart failure 253; and HIV 688; incision of placenta during 340; indications for 313; instruments for 15; and IUD 229; and malpresentation 239–44; and maternal SCD 174–6; method of 313–17; and misoprostol 228; in multiple pregnancy 234; and neonatal breathing 334; in obstructed labour 214–15; and oxytocin 151; perimortem 52, 66, 785–6; and placenta accreta 199; and placenta praevia 185, 189; post-operative care for 303–4; and PPH 190–1; in pre-eclampsia 209–10; previous history of 137, 174, 183, 231; and puerperal sepsis 220; and pulmonary embolism 223; and stillbirths 229; and transient tachypnoea of the newborn 364; and trauma 785; and uterine rupture 186, 215–16; and vasa praevia 186; wound infections following 142  
caffeine 357, 365–6, **366**, 433, 617  
CAH (congenital adrenal hyperplasia) 334, 500, 502–3  
calamine lotion 680, 709  
calcium: in CRF 485; intravenous 63; ionised 469; and lead poisoning 814; in neonates 346  
calcium carbonate 469, 482  
calcium chloride 110, 882  
calcium deficiency 514  
calcium gluconate: and magnesium toxicity 37, 63; and pre-eclampsia 208; in septic shock 469  
calcium sulphate 766  
caloric response 595  
Camper's fascia 317  
*Campylobacter* 565, 679, 705  
*Campylobacter jejuni* 551, 705  
cancer: and analgesia 81; in childhood 574–6, **575**; diagnosis of 578; epidemiology of 575; nausea and vomiting in 86; specialist centres for 577–8; surgery for 578  
cancer wasting 581  
cancerum oris 518, 705, 719  
*Candida*: and antibiotics 357; and APH 183; and cancer treatment 580; and lymphadenopathy 381; as STI 657  
*Candida albicans* 657, 719  
candidiasis: and antibiotics 696; and diarrhoea 380; oesophageal 688–9, 704; oral 517, 524, 528, 689, 704; oropharyngeal 626; superficial 357; *see also* thrush  
CAPD (chronic ambulatory peritoneal dialysis) 484  
capnography 35, 130, 772  
capreomycin 287–8, 670  
captopril 452–3, 455, 469, 474, 645  
caput, excessive 310  
caput succedaneum 351  
carbamazepine: and epilepsy 606; and liver dysfunction 488, 493; as mood stabiliser 293; and nerve pain 85; and seizures 84; side effects of 86  
carbimazole 501–2  
carbohydrate metabolism 374  
carbon dioxide retention 449, 616, 640, 848  
carbon monoxide poisoning 166, 459, 805, 807–8, 814  
carbon tetrachloride 488  
carboplatin 585  
cardiac arrest: and amniotic fluid embolism 225–6; and Caesarean section 52, 785–6; and chest compressions 38; child type of 55; and defibrillation 862–3; and drowning 797; drugs used in 65; and electrical injuries 795; initial approach to 67; and magnesium toxicity 207; management of 43–4, 62–3; in triage 31  
cardiac arrhythmias: in children 456; fits and faints in 387; and hypokalaemia 550; and Lyme disease 649; and phenytoin 207, 372; in pneumonia 269; in pre-eclampsia 208; and resuscitation 42; and TLS 581; and tricyclic antidepressants 813  
cardiac contusion 781  
cardiac failure: acute left 226; and anaemia 173–4, 383, 531, 743; and ARF 481; and beriberi 513; and blood transfusion 21–2; causes in pregnancy 252; in children 453–4; congestive 489, 522–3, 530–1; decompensated 252–3; and diarrhoea 545; and dyspnoea 87; and generalised oedema 388; and left-to-right shunting **454**; and LIP 702; and malnutrition 518; management of 253–4, 454–5; and nifedipine 245; and over-hydration 272, 466, 546; in pre-eclampsia 208; and respiratory distress 361; resuscitation for 39–40; right-sided 223; and shock 166–7, 466–7; and sleep-related upper airway obstruction 429; and *Streptococcus* 659; and thalassaemia 541; and transfusions 24–5; in triage 31–2; and trypanosomiasis 732; and volume expansion 208  
cardiac output: fixed 122, 124; in septic shock 167–8  
cardiac tamponade: and cardiac arrest 63; and pericardiocentesis 861–2; and shock 166, 459; in trauma 773, 776, 780  
cardiac ultrasound 791  
cardiogenic shock: and ARF 481; in heart failure 252; mechanism of 459; in pregnancy 166; in trauma 776  
cardiomegaly 455  
cardiomyopathy: and heart failure 454–5; hypertrophic (HCM) 252; and shock 40, 166–7  
cardiorespiratory arrest 37–8, 131, 777, 843  
cardiotocograph 230–1  
cardiovascular collapse 450, 797  
cardiovascular compromise 124, 364, 536, 603  
cardiovascular decompensation 782  
cardiovascular instability 189, 199  
cardiovascular system: examining 30; in neonatal examination 399  
cardioversion, DC 457, 795  
carditis 254, 452, 569–70, 644, 659  
carvedilol 455  
Cary-Blair medium 28  
Casal's necklace 513  
cat faeces 706, 747  
cataracts 107, 400–1, 488, 498, 585, 591–2  
caterers 5  
catheters, removal of 859  
cat scratch disease 675  
CATT (card agglutination test for trypanosomiasis) 730  
caustic ingestion burns 803  
caustic soda poisoning 563, 813  
cautery machine 15  
CD4 count: and HIV 493, 693–4, 698, 701, 709; postpartum 274; and pregnancy 273  
CDTI (Community-Directed Treatment with Ivermectin) 759  
cefalexin 304, 314  
cefazolin, and corneal ulcers 590  
cefixime 356, 657, 673–4  
CEFM (continuous electronic fetal monitoring) 175, 230  
cefotaxime: and Caesarean section 316; and DKA 262; and epiglottitis 424; and infective shock 171; and malaria 744; and meningitis/encephalitis 41, 352, 598; and meningococcal disease 651; in neonates 355–7; and osteomyelitis 621; in placenta removal 326; in pneumonia 439; and salmonella 675; and septicaemia 354; and *Streptococcus* 659, 794  
ceftazidime: and burns 809; and corneal ulcers 590; and cystic fibrosis 444–5; and meningitis 598; and otitis media 428; and peritonitis 484  
ceftriaxone: and conjunctivitis 590; and croup 423; and dysentery 551; and epiglottitis 424; and infective shock 171; and leptospirosis 648; and Lyme disease 649; and malaria 744; and mastoiditis 428; and meningitis 352, 598; for neonatal infection 354–7; and osteomyelitis 535; in pneumonia 439; and retropharyngeal abscess 428; and salmonella 674–5; and septic shock 468, 521; in severe malnutrition 521; and STIs 656–8; and *Streptococcus* 659; and syphilis 290  
cefuroxime: and appendicitis 634; and corneal ulcers 590; and croup 423; and epiglottitis 424; and intestinal obstruction 636; and intracranial abscesses 619; in obstructed labour 214; in pneumonia 269; and retropharyngeal abscess 428; and uterine rupture 216  
cellulitis: and Buruli ulcer 642; and chest drain insertion 843; neonatal 357; staphylococcal 333; and *Streptococcus* 658; treatment of 221  
Central African Republic 301, 645  
central blocks 128  
central venous catheters 109, 171, 579, 652, 852  
centrifuge, as essential equipment 27  
cephalexin: and cystitis 286; and UTIs 473  
cephalhaematoma 306, 311, 351, 383  
cephalic tetanus 660  
cephalo-pelvic disproportion (CPD) 212: and arrested labour 151; and Caesarean section 152; and fetal skull moulding 147; partograph indicators of 145  
cephalosporins: in ALF 488; and cystitis 286; first-generation 357, 709; and mastitis 222–3; and meningitis 267, 352; and septic shock 532; side effects of 709; *see also* third-generation cephalosporins  
cereals: and anaemia 532; and calcium 514; and constipation 83; and diarrhoea 551, 553; and zinc 515  
cerebellar ataxia 604, 741  
cerebral abscess 456, 593, 598, 600, 707  
cerebral concussion 779  
cerebral depression 132, 797  
cerebral haemorrhage: and adrenaline 71; and amniotic fluid embolism 226; and severe hypertension 203  
cerebral infarctions 371, 474  
cerebral malaria: and coma 596–7; and convulsions 283, 741; disorders associated with 282; and eye disorders 592; and headache 389; and hearing loss 401; neurological sequelae of 739; and RIPC 267; signs of 738; and VAD 513  
cerebral mass lesions **706**  
cerebral oedema: and coma 268; and dehydration 272; and DKA 262–3, 265, 494–6; and encephalitis 603; and fluid resuscitation 39, 170, 177; and poisoning 814; and pre-eclampsia 208–9; preventing 398; and trauma 793  
cerebral palsy: aids for children with 419; and GOR 564; and pathological jaundice 368; problems in **403**; signs of 402; and sleep-related upper airway obstruction 429; and visual impairment 400  
cerebral perfusion 64, 266–7, 466, 596, 775  
cerebral perfusion pressure (CPP) 265  
cerebrovascular accidents: and fits 207; and pre-eclampsia 136  
cervical carcinoma 183, 395  
cervical dilatation: arrested 212; assessing 146–8, 153, **148**, **153**; incomplete 241; over time 211  
cervical lesions 185  
cervical lymphadenopathy 427–8  
cervical smear 174  
cervical spine: immobilisation of 407, 771, 778, 783, 795, **864**; unstable 36, 130, 771, 839; X-rays of 784, 788–9, **789–90**  
cervical spine injury: and airway opening 46; clinical signs of 783; and drowning 796; haematoma due to 790; and head injury 779  
cervical tears, repairing 325  
cervical trauma 156, 196–7, 311, 325  
cervix: assessing 209; bleeding from 183; dilated 162, 179, 182–3, 215, 321–3; recording length of 146; stretching 150; visualising 181, 183  
Chad: FGC in 298, 301; guinea worms in 754  
Chagas disease 22, 732  
chancroid 656–7  
charcoal, activated 740, 810, 812–14  
charcoal dressings 90  
chart tables 69  
cheese 515, 617  
chelation therapy 26, 175  
chemoprophylaxis 277, 653, 660  
chemotherapy: anti-TB 288, 622, 624, 667–9; and body surface area 893; for cancer 576–8, 581–3, 585–7; induction 576; palliative 587; side effects of 86, 579–81  
chest compressions 47–8: and BLS 44; indications for starting 47; for neonates 338–9, 339; rate of 49; and shock 38; techniques for 47–8  
chest drains: in emergency room 110; insertion of 842–3; and lung abscess 442; and pneumothorax 61, 431; sites for **842**  
chest examination, in trauma 779  
chest expansion: and oxygenation 772; and respiratory difficulty 36  
chest infections: and antibiotics 88; recurrent 435, 443; and sickle-cell anaemia 174; and spinal cord injury 406  
chest pain: and anaphylaxis 24; and heart abnormalities 122; and leptospirosis 647; and pulmonary embolism 223; and SCD 534  
chest physiotherapy 268, 442–4, 597  
chest thrusts 53  
chest trauma 771, **773**, 780–1  
chest wall: indrawing 430, 437–40, 743; pain 87; recession 35–6, 252, 272, 429  
chest wounds, sucking 772, 780; *see also* open pneumothorax  
chest X-ray: and amniotic fluid embolism 225; and anthrax 678; and aspiration 208; and asthma 255; and cancer diagnosis 578, 582–3, 585, 587; and coma 596; and congenital malformations 365; for Down's syndrome 400; and dyspnoea 25; and empyema 441, 633; foreign bodies on 435; in heart defects 446, 448–9, 451–2; and heart failure 454; in hypercyanosis 450; for infants 351, 353, 364; and leptospirosis 648; and LIP 702–3, 702; and lymphadenopathy 631; and molar pregnancy 183; and over-hydration 272; pleural effusion on 441; in pneumonia 269, 440; and pulmonary embolism 224; in PUO 391; and rheumatic heart disease 254; and scrub typhus 677; in septicaemia 354; and TB 287, 666, 668; and TRALI 24; in trauma 780, 788, 790–1  
Cheyne–Stokes respiration 91, 266, 595  
chickenpox 680–1; in cancer treatment 580; and encephalitis 602; in HIV 708; management of 291–2; and rash 385; and septicaemia 659  
CHILD 2015 10, 12  
child abuse and exploitation: and burns 810; and coma 593; and domestic violence 302; and drowning 796; and failure to thrive 386; and fractures 765; and learning difficulties 404; and mental health problems 404; differential diagnosis of **824**; injuries from 770; investigation of 818; medical after-care following 828; recognition of 96, 818–19; reporting 100; *see also* sexual abuse, of children  
child-friendly environments 405  
child–parent interaction 468, 506, 823  
child protection procedures 812; examination under 828–34, **830–1**  
child soldiers 396, 818, 826  
child trafficking 826  
childbirth: in adolescents 395; checking for tears after 156; complications due to FGC 298, 300; convulsions following 203; patient safety checklist for 139; patient safety checklist for **140–2**; physical environment for 142–4; shock after 169; *see also* delivery  
childhood idiopathic inflammatory myopathies **574**  
children: airway clearance in 54; anaemia in 21; blood pressure in **38**; bowel evacuation in 404; burns in 803–4, 806, 810;

- children (*continued*) cardiac arrest in 44; circulation management in 805; competence of 100; developmental history of 43; drug administration for 81; dying 79–80, 90–1, 711; elimination habits of 394–5; estimating weight of 39; examination of 29; explosive injuries in 799; in eye examinations 589; and grief 114; of healthcare workers 3; HIV testing in 691, 693; holding for examinations 836; impact of war on 111; inserting airways in 56; and isolation techniques 9; keeping calm 35; morphine dosage for 20; and mother's mental health 296; normal values in 786; nursing sick 392–4; pain management for 80–1; palliative care for 79; personal hygiene of 393–4; preparation for procedures 836; respiration rates for 131; rights of 392, 398, 818; at risk of FGC 301; sedation of 76–8, 127; signs for urgent management 33; steroid usage in 85; supportive and distracting pain relief 70; surgery for 628; TB in 524, 666, 669–70; trafficked 827; tranexamic acid dose for 774; transition to adulthood 405; weighing 545; X-rays in 765–9, 783, 790
- Children's Coma Score 650, 792
- children's wards 6–7
- chin lift, in neonates 336, 337
- China, Guillain-Barré syndrome in 614
- chlamydia: and APH 183; and conjunctivitis 590; and ectopic pregnancy 177; as STI 655–6
- Chlamydia*: and HIV 704; and pneumonia 269; and puerperal sepsis 220
- Chlamydia pneumoniae* 679
- Chlamydia trachomatis*: and conjunctivitis 357; and miscarriage 182; sexually transmitted 656–7, 825; and trachoma 663, 679
- chloral hydrate 78, 127
- chlorambucil, in chemotherapy 577, 583
- chloramphenicol: and anaemia 383; and anthrax 679; and conjunctivitis 590; and corneal ulcers 590–1; and croup 423; and cystic fibrosis 445; and diarrhoea 551; and epiglottitis 424; in infants 440; and inhaled foreign bodies 435; and mastoiditis 428; and meningitis 41, 600; and meningococcal disease 650; and neonates 356–8; and plague 679; in pneumonia 439; and relapsing fever 655; and rickettsial disease 676–7; routes of administration 17, 851; and salmonella 674; in severe malnutrition 520–1; and typhoid 672–3; and VHS 726, 728; and xerophthalmia 523
- chloramphenicol resistance 598, 659
- chlorhexidine: in Caesarean section 314, 318; and evacuating products of conception 180; in hand washing 8; as mouthwash 580; and neonatal infection 354, 357; and umbilical stump 332, 350; and UVC 859
- chlorhexidine cream 151, 309, 327–8
- chlorine solutions 9
- chloroquine: as antimalarial 285, 739, 745–6; and G6PD deficiency 541; and pregnancy 278; and rabies 725; resistance to 279, 285
- chlorothiazide 469, 479
- chlorphenamine: and anaphylaxis 258, 426; and chickenpox 680; in epiglottitis 424; and pruritus 83; and rabies vaccine 724; and rash 709
- chlorproguanil 745
- chlorpromazine: as anti-emetic 580; as antipsychotics 295; route of administration 90; and schizophrenia 508–9
- choanal atresia 362, 422
- chocolate 482, 617
- choking, management of 35, 52–3, 53, 423, 435
- cholangitis 751–2, 754
- cholecystitis 539
- choledochal cysts 632
- cholera: and antibiotics 551; and dehydration 39, 463–4
- cholera epidemics 545, 548
- cholera vaccine 95
- cholestasis 346, 486, 489–91, 493
- cholestyramine 489, 491
- cholinesterase reactivator 813
- chordae 630
- chorea 570
- chorioamnionitis: and ARM 151; and fetal death 228; and fetal distress 232; and obstetric haemorrhage 182; and shock 169; and *Streptococcus* 659
- choriocarcinoma 183
- chorioretinitis 747, 758
- chronic cough 443, 517, 524, 688, 702
- chronic hepatitis 686–7
- chronic hypertension 201–2
- chronic inflammatory demyelinating polyradiculoneuropathy 614
- chronic lymphatic filariasis 756
- chronic osteomyelitis 621–2
- chronic pain 69, 73, 76, 300, 539
- chronic suppurative lung disease 689
- chylous diarrhoea 756
- ciclosporin, and IBDs 562
- cigarette burns 810, 819, 822
- cimetidine 86, 852
- cinchonism 740
- ciprofloxacin: and anthrax 678–9; and Buruli ulcer 642; and *Campylobacter* 679; and cystic fibrosis 444–5; during pregnancy 287; and dysentery 551; and meningococcal disease 653; oral administration of 17; and osteomyelitis 535, 621; and otitis media 427–8; and relapsing fever 655; and rickettsial disease 676; routes of administration 851; and salmonella 674–5; in severe malnutrition 520–1
- circulation: assessing and managing 47; equipment and skills for 62; in shock resuscitation 170; signs and symptoms 42; in trauma 774, 777
- circulation resuscitation 37–40
- circulatory access 854
- circulatory assessment 37, 774, 778
- circulatory collapse 279, 518, 520–1, 738, 812
- circulatory failure 38, 166–7, 495
- circulatory overload: and cardiac failure 252; and exchange transfusion 23; and spinal cord injury 407
- circulatory procedures 548, 850
- cisplatin 580, 586
- citrate 370, 519, 547–8
- clarithromycin: and Buruli ulcer 642; and *H. pylori* 564; and leptospirosis 648; and MAC 710
- clavicular fractures 351–2
- CLD (chronic liver disease) 381, 489–93, 514, 585, 686; clinical features of 489; laboratory features of 490
- cleaning 9
- cleaning fluids, ingestion of 811–14
- cleaning services 2, 4, 7, 15, 396
- cleft palate 77, 386, 404
- cleidotomy 323–4
- clindamycin: and anthrax 679; as anti-malarial 740; and osteomyelitis 535; and quinine 279; and retropharyngeal abscess 428; and skin infections 658; and STIs 658
- clinical chemistry tests 27–8
- clinical failure 699
- clinical observations chart 887
- clitoris, excision of 299
- clofazimine 287, 645–6
- clonazepam 84, 372
- clonidine 76, 617–18
- clonus 201, 203, 402, 408, 487, 595
- Clostridium* 220, 357; *botulinum* 640; *difficile* 552, 705; *tetani* 660–1, 794
- clotrimazole 591, 626–7, 657, 704
- cloxacillin: and abscess 305; and burns 809; for cellulitis 333; and eczema 627; and inhaled foreign bodies 435; and lung abscess 442; and mastitis 223; for neonatal infection 352, 355–6, 358; and pneumonia 439–40; and pressure sores 417; and skin infections 709; and wounds 763–4
- CMAM (community management of acute malnutrition) 516–17, 522, 527
- CMI (cell-mediated immune) response 666, 733
- CMT (Compliance with last Malarial Treatment) 737
- CNEP (continuous negative extrathoracic pressure) 67, 365, 431, 846–8
- CNS (central nervous system): and HIV 706; rapid assessment of 777; tumours 503, 583
- CNS (central nervous system) involvement 583, 685, 706, 730
- CNS-directed radiotherapy 582, 584, 586
- CNS disease 28, 582–3, 706, 710
- co-amoxiclav 763–4
- co-trimoxazole: and antimalarials 277, 741; and brucellosis 679; and cholera 551; and folic acid 745; and HIV 524; in infants 355; and otitis media 427; and PCP 689, 701–2; and pneumonia 580, 689; and rickettsial disease 676; routes of administration 17, 851; and salmonella 674–5; side effects of 709; and TB 670
- co-trimoxazole prophylaxis 274–6, 518, 701–2, 713
- coagulation disorders *see* blood clotting disorders
- coagulation factors 39, 486, 543, 652
- coagulopathy: in amniotic fluid embolism 225; and anaesthesia 121–2; and CLD 489–90; combating 39; and envenomation 816; and exchange transfusion 23; in hypertension 209–10; and liver failure 486; and lumbar puncture 650; and NEC 377; in obstetric haemorrhage 188, 194, 197–8, 200
- coal tar 709
- cobras 542, 815, 817
- Coca-Cola 617
- cocaine 71, 267, 508
- coccidiomycosis 705
- coconut fibre 416
- codeine: in analgesic ladder 71, 81; and ARIs 436; and post-operative care 303
- codeine linctus 88
- coeliac disease: and anaemia 383; and diabetes 498; diagnosis of 568–9, 568; and diarrhoea 380; and failure to thrive 386; features of 568; and folic acid 515; pathophysiology of 567; spectrum of 567
- coffee, and dehydration 552
- coffee-ground vomit 565, 634, 729
- cognitive impairment 510–11, 609, 615, 649, 688
- cold abscess 631
- cold chain 94, 154, 190, 576, 717
- cold extremities 167, 743–4
- cold packs 86, 456
- colectomy 562–3
- colic 87, 635, 754
- colicky abdominal pain 482, 635, 747
- coliforms 331, 597, 621–2
- colistin, and cystic fibrosis 444
- colitis, and gastroenteritis 271
- colloid fluids: in burns 806; commonly available 883; in emergency room 110; and shock 168–9
- collusion of silence 819
- colonoscopy 562–3, 565, 567
- colostomy 636
- colostrom 106, 332
- colpotomy 222
- coma: causes of 593; and diabetic ketoacidosis 39, 262, 494; and drowning 797–8; examination for 592–6; and lumbar puncture 865; management of 268, 596; and meningitis 353; pathway of care in 268; and poisoning 811; and severe malaria 279–80, 739, 741–2; and yellow fever 729
- coma scales 593–4, 739
- common mixing lesions 448–9
- communication aids 419
- communication disorders 404
- community health workers (CHWs): and disabled children 399; and IV morphine 79, 81, 83; in postnatal care 157, 330
- COMP (cyclophosphamide, vincristine, methotrexate, prednisolone) 577, 583
- compartment syndrome: and burns 806; and envenomation 817; and fractures 765, 784–5; and inter-osseous infusion 860
- compensated shock 167
- competence, and consent 100
- complete miscarriage 162, 179–80, 182
- complicated malaria 279, 738
- composite maintenance fluid 348
- compound fractures 763, 767, 787, 794
- compound presentations 240
- compression injuries 782
- compression stockings 175, 314, 539
- computed radiography (CR) 13
- computers 3–4, 10–11, 419
- condom catheter: in emergency room 109; and emergency transport 97; and shock 169; and spinal cord injury 414; and uterine tamponade 193–4, 197
- confidentiality 6, 100–1, 396, 506
- conflict: armed *see* war; impact on families 110–11; losses due to 111
- confusion: and cerebral oedema 265; and hypovolaemia 187; and magnesium toxicity 207; and opioids 83–4; and puerperal sepsis 221; and relapsing fever 655; and septic shock 167; and Wernicke's encephalopathy 251
- congenital abnormalities: and beta-blockers 253; of the bowel 384; of the brain 377; commonest 620; and diabetes 261; family history of 136; and multiple pregnancy 232; and respiratory distress 364–5; and stillbirth 229; and syphilis 290
- congenital cataracts 399–401, 591
- congenital haemolytic anaemias 21
- congenital heart disease: and cyanosis 365; and heart failure 453, 455; prevalence of 446; and respiratory distress 361–2
- congenital malaria 277, 284
- congenital muscular dystrophy 616
- congenital nephrotic syndrome 475
- congenital pneumonia 361
- congenital syphilis 289–90, 355–6, 361, 475, 655
- congenital TORCH infection 354
- congenital tuberculosis 288, 356, 667–8
- coning 266, 269
- conjunctival xerosis 512
- conjunctivitis: acute bacterial 590; acute viral 590; examinations for 590; phlyctenular 666; purulent 720; in rheumatic disease 571; and *Streptococcus* 659
- connective tissue disorders 385–6, 824
- consciousness: establishing level of 593; reduced level of 266, 428, 465, 549–50 (*see also* depressed conscious level)
- consent: ethics of 100; to research 102
- constipation: definition of 559; and abdominal pain 382; and anal injury 822; and antidepressants 294; and codeine 81; and dehydration 394; and hypothyroidism 501; and leptospirosis 647; management of 560–1; and nifedipine 203; and opioids 74, 83–4; in palliative care 87; and premature labour 244; and spinal cord injury 412; and tricyclics 85
- constipation cycle 559
- continuous electronic fetal monitoring (CEFM) 175, 230
- contraception: for disabled youths 415; emergency 396–7, 824–5, 827; and SCD 176
- contractures: and Buruli ulcer 642; in paraparesis 403; prevention of 418–19; and spinal cord injury 408–10, 412; *see also* uterine contractions
- control groups, level of care for 102
- controlled cord traction: after delivery 154–5, 155; in multiple pregnancy 234; and PPH 189–90; and retained placenta 197
- controlled delivery 143
- controlled drugs 20, 68–9
- controlled drugs records book 20
- conversion headache 389
- convulsions: and apnoea 365; and cerebral malaria 739, 741; differential diagnosis of 204–5; and eclampsia 203; and immunisation 93; and malnutrition 522; in meningitis 599; and meningococcal disease 650; multiple 279, 738; neonatal pathway of care 373; in palliative care 89; and pertussis 654; and poisoning 811; and pulmonary embolism 223; in severe malaria 280, 283, 742; and stroke 536–7
- convulsive status epilepticus (CSE) 403, 606, 610–11
- Coombs' test 25, 369, 371, 540, 542
- copper poisoning 488
- corneal culcers 107, 590
- corneal opacity (CO) 107, 664
- corneal scarring 512, 591, 663
- corneal ulceration 512, 517, 590–1, 710, 720
- corneal xerosis 512
- coronary artery aneurysms 571
- corrosive agents, poisoning with 813–14
- cortical blindness 592
- corticosteroid excess 503
- corticosteroids: and body surface area 893; and dyspnoea 88; and eczema 627; and headache 389; and IBD 562; and meningitis 598; and rheumatic disease 571–4; and spinal cord compression 89; and surfactant deficiency 245; and TB 667; and typhoid 674
- cortisol levels 85, 89, 499–500, 502–3, 596
- Corynebacterium diphtheriae* 643
- coryza 422, 424, 436, 438, 658, 719

- Côte d'Ivoire 301, 688, 727  
 cough: clearing airway obstruction 53; and HIV 701; in palliative care 88; and pulmonary embolism 223; and relapsing fever 655; and scrub typhus 677; and VHF 727; *see also* chronic cough  
 counterfeit medications 576  
 counting grid 870  
 Couvelaire uterus 317  
 cow dung 106–7, 633  
*Coxiella burnetii* 675  
 coxsackie 354, 574, 686, 721  
 CPAP (continuous positive airway pressure): and ACS 536; air flow in 133; in children 845–6; diagram of 846; in emergencies 37; and epiglottitis 424; in high-dependency care 67, 69; in infants 363; intubation in 864; nasal 362–3, 363, 366, 430–1, 846; in neonates 365  
 CPOD (chronic papular onychodermatitis) 758  
 CPR (cardio-pulmonary resuscitation): abandoning 52; and BLS 45; and Caesarean section 52; and cardiac arrest 63–5; continuing 49; and drowning 797–8; and electrical injuries 795; in pregnant women 66; and uterine rupture 216  
 cranial irradiation 582–3  
 cranial nerve palsies 389, 583, 595, 605, 667  
 cranial ultrasound 372  
 cranial X-ray 793  
 craniocentesis 322–3, 327  
 craniofacial syndrome 429  
 craniopharyngioma 389, 504, 584  
 craniosynostosis 501  
 craniotabes 491, 514  
 craniotomy: delivery after 239; and haematoma 793; procedure for 321  
 creatine kinase activity, elevated 616, 648, 707  
 creatine phosphokinase (CPK) 615, 644, 816  
 creatinine: and dehydration 471; in dialysis 484; normal plasma concentrations of 471  
 cretinism 501, 515  
 CRF (chronic renal failure) 480, 485–6, 514, 539, 659, 753  
 cricoid pressure: in airway management 35; in anaesthesia 121, 124, 126–7; and anaphylaxis 425; and intubation 130, 839  
 cricothyroidotomy: in children 840; complications of 841; equipment for 109, 124; and ingestion burns 803  
 cricothyrotomy 124, 422–3, 771–2  
 critical incident audit 144  
 Crohn's disease 380, 383, 386, 561–3, 561–2, 565–7, 636  
 cromoglycate 590  
 Crosby-Kugler capsule 568  
 cross-infection, minimising risks of 7–8, 10  
 croup: and airway obstruction 52, 422; disorders embraced by 422–3; emergency treatment of 35, 423; and epiglottitis 424; and measles 720; severity of 423  
 CRP (C-reactive protein): and IBD 561; for infants 351, 353; and PPRM 245–6  
 CRT (capillary refill time): and dehydration 271; normal 879; in obstructed labour 214; and septicæmia 352–3; in shock 38, 459, 466, 787  
 crude oil 106  
 crush injuries 766, 782, 784, 787  
 crutches 303, 408, 419  
 cryoprecipitate: after delivery 164; and amniotic fluid embolism 226; in obstetric haemorrhage 184, 188  
 cryptococcal meningitis 29, 697, 700  
 cryptococcosis 697, 707–8  
*Cryptococcus* 602–3, 605  
*Cryptococcus neoformans* 593, 598, 700, 704  
 cryptorchidism 500, 504, 629  
 cryptosporidiosis 556, 705, 747  
*Cryptosporidium*: and diarrhoea 546, 551; and HIV 493; and persistent diarrhoea 556  
 crystalloid fluid resuscitation 39, 170–1, 178–9, 194, 462, 806  
 crystalloid fluids: choice of 16–17, 169; commonly available 883; and dengue 685; and shock 168  
 crystalloid flush, in cardiac arrest 62  
 crystalloid infusions 14  
 crystals, in urine microscopy 869  
 CSF (cerebro-spinal fluid): bacteria in 355; clinical chemistry tests 28; draining 321, 323; in hydrocephalus 619; leakage 123, 779, 794; and meningitis 355, 597, 598, 651, 667; microscopy of 26, 28, 354, 603, 866; in poliomyelitis 722; in spinal anaesthesia 123  
 CSF examination 389, 586, 603  
 CSF protein levels 355, 614, 722, 731  
 CSOM (chronic suppurative otitis media) 428  
 CT scan: and amoebiasis 747; for cancer 577–8, 583, 585–7; and coma 268, 596; and headache 389; and hydrocephalus 619; and retropharyngeal abscess 429; in trauma 779, 783–4  
 CT scanners 13, 783  
 CTC (community-based therapeutic care) 516, 527  
 CUC (cow's urine concoction) 106  
 CUD (chronic ulcerative dermatitis) 178, 222, 305  
*Culex* mosquitoes 604  
 cultural bereavement 114  
 cultural differences: abusive 96; and death 91; and employment discrimination 10; ethics of 101–2; in pain experience 70, 80  
 cupping 515, 819  
 cure4kids 576, 587  
 curettage, evacuation by 180  
 curved-blade laryngoscope 131, 838, 839

 Cushing's response 40, 780  
 Cushing's syndrome 503–4, 574  
 Cushing's triad 266  
 cushions 417  
 cutaneous larva migrans 749–50  
 cutaneous shunts 489–90  
 CVP (central venous pressure): in ALF 488; insertion of line 188, 206; measuring 252; monitoring 69, 170, 208, 250, 464, 549; optimising 171, 179; and shock 459, 464–5  
 CVS (congenital varicella syndrome) 291, 644, 680  
 cyanide 805, 808  
 cyanosis: and ALRIs 437; and amniotic fluid embolism 225; and anthrax 678; and chest trauma 781; in examination 30; and heart failure 40, 522; and hepatopulmonary syndrome 490; and LIP 703; and malaria 743; and measles 720; in older infants 449; oxygen treatment for 58; and PCP 701; peripheral 271, 463; and pertussis 654; and pneumonia 439; and pulmonary contusion 781; and pulmonary embolism 223; in RDS 363; respiratory and cardiac 446; and respiratory distress 37, 361; and septicæmia 352; and tetanus 375; in triage 31; and heart defects *see* cyanotic congenital heart defects  
 cyanotic breath-holding 387, 616  
 cyanotic congenital heart disease 40, 339, 446–51, 448–9, 454  
 cyclizine 75, 86–7, 90, 251  
 cyclopentolate 588  
 cyclophosphamide: in chemotherapy 577, 581–3, 585–7; and nephrotic syndrome 476; and SLE 573  
 cycloserine 287–8, 670  
 cyclosporine 476, 744  
 cystic fibrosis 442–5; and asthma 431; and diarrhoea 380; and portal hypertension 491  
 cystic hygroma 630, 632  
 cystitis 286, 472, 478, 480, 586  
 cytomegalovirus (CMV) 687; and anaemia 530; and bilirubin levels 368; and exchange transfusion 370; and HIV 493, 704–5  
 cytosine 582  
 cytotoxic drugs 383, 488, 578, 580–1  
 danthron 89  
 dapsone 541, 645–6, 701–2, 709, 817  
 daunorubicin 582  
 day/night cycle 76  
 DBS (dried blood spots) 444, 688, 693  
 DDAVP 504, 543  
 DDT 278, 655  
 de-infublation 300  
 De Leers incision 315  
 dead bodies, refrigeration of 10  
 dead fetus, retained 186  
 dead space, in IV administration 17–18  
 dead tissue 417, 641, 794, 802, 809  
 deafness: conductive 401; and cretinism 515; facilities for 405; and jaundice 368, 399; and meningitis 599, 653; and syphilis 290  
 death: and attachment behaviour 112; and children's understanding of 114–15, 117  
 death of patient: infection control after 9–10; preparation for 91  
 death rattle 90–1  
 DEBONEL (Dermacentor-borne-necrosis-escharlymphadenopathy) 675  
 debridement: of fractures 765; of gunshot wounds 802  
 debris, in urine microscopy 869  
 DEC (diethylcarbamazine citrate) 757–8  
 decapitation 234, 323–4  
 decerebrate attacks 618–19  
 decerebrate posture 40, 595, 741  
 decision making: information for 100; in triage 30  
 decorticate posture 595, 741; and neurological assessment 40  
 decortication 633  
 Deferasirox/Deferiprone 532, 538, 542  
 defibrillation 862; and heart failure 40; protocol for 64, 862–3; *see also* AEDs  
 deflexion 240  
 degenerative conditions 89  
 degree of dehydration: and diarrhoea 545; in DKA 262–3, 494; estimating 547; in gastroenteritis 271  
 dehydration: and body weight 545; in children 394, 399; classification of 270–1, 463 (*see also* degree of dehydration); and constipation 87; and dengue 684; in diabetes 261; and DKA 39, 262, 494; ECF volume deficit in 470; emergency treatment for 271–2; home therapy for 552–3; and hypercalcaemia 407; and hyperemesis 138; and hypovolaemia 470; and intestinal obstruction 636; and intussusception 635; and malaria 283–4; and malnutrition 517; and NSALDs 73; ORS for 553–4; and pertussis 654; and pulmonary embolism 223; respiratory rate in 437; and SCD 174, 533–4; in triage 32; and urinary stones 479  
 delayed puberty: and anaemia 530; causes of 503; and hypothyroidism 501; and juvenile idiopathic arthritis 572; and malabsorption 566; and SCD 538; and thalassaemia 541  
 delirium, febrile 609  
 delivery: and APH 189; blood loss in 172; in Caesarean section 316; estimated date of (EDD) 137–8; for HIV-positive mothers 274–5; life-threatening complications of 166; in mothers with diabetes 262; normal process of 154, 298, 300, 322, 332; in pre-eclampsia 209; timing of 175; vaginal bleeding after 164  
 delusions: and schizophrenia 508; somatoform 649  
 Democratic Republic of Congo 645, 727, 827  
 dengue 681–5; degrees of severity 681; management of 684  
 dengue fever 385, 593, 647–8, 682–3  
 dengue haemorrhagic fever *see* DHF  
 dental infections 721  
 dentition, delayed 514  
 departmental meetings 10–11  
 depressed conscious level: and asthma 257; and heart failure 252; and inverted uterus 250; in PPH 192; and pulmonary embolism 224; in resuscitation 178, 187; and seizures 43; and upper airway obstruction 422  
 depression: and abuse 820; antenatal 293; in children 404; and grief 112–13, 116; and hyperemesis 251; postnatal 96, 157, 210, 292–4, 297, 507  
 depressive delusions 294  
 depressive illness 293, 298, 505–7, 810  
 dermatitis: and schistosomiasis 752; seborrhoeic 709  
 dermatomyositis 571–3  
 dermatosis 93, 513, 523–4  
 dermoid cysts 866  
 desferrioxamine: and diarrhoea 535; in iron chelation 26, 535, 537–8, 542; and iron poisoning 812; and pregnancy 175  
 desmopressin 89, 543  
 desquamation 385, 517, 523, 571, 658, 804  
 destructive procedures 241, 244, 248, 321–3  
 detonation injuries 799  
 developmental aids 419  
 developmental assessment 402  
 developmental coordination disorder 404

- diethylcarbazine 750, 756  
diffuse lymphadenopathy 666, 710  
dignity: of adolescents 396; of children 89, 393; adying with 101; in vaginal examination 328  
digoxin 40, 252–4, 357, 452, 455  
dihydroartemisinin (DHA) 279, 740  
dioxanide 747  
diphenhydramine hydrochloride 709  
diphtheria 643–5; clinical features of **643**; complications of **644**; cutaneous 642; immunisation against 92, 95; as neuropathy 614; and stridor 422, 425; and tonsillitis 427  
diplegia, spastic 403  
disability: secondary 418; and trauma 770; young people with 396  
disabled children 397–402, 404–5, 418; abuse of 819; aids for 418; equipment for assessment **418**  
disaccharide intolerance 380  
disasters 110–11, 114, 117–18, 543, 769  
discharge information 29–30  
discharge planning, inadequate 529  
disinfectant cream 144, 147–8, 312, 350  
disinfectants: preparation of 8–9; supply of 4; use of 7–8  
disinfection 6–9, 728, 842  
disseminated tuberculosis 93, 666, 734  
dissociative shock 166, 459  
distal humeral fractures 768  
distal intestinal obstruction syndrome 443, 636  
distal radial fractures 769  
distraction techniques 70, 837  
distributive shock 166, 459  
diuretics, and heart disease 254  
diversional therapy 86  
Djibouti, FGC in 299, 301  
DKA (diabetic ketoacidosis) 262–5; and acidotic breathing 42; in children 494–7; and coma 593; and dehydration 270–1; pathway of care for **264**; risks of developing 261; and shock 39, 167, 463; and vomiting 384  
dobutamine: and dengue 685; and heart failure 455; in high-dependency care 853; in septicemia 354; and shock 171  
dog bites 723, 794  
dog faeces 749, 751  
doll's head manoeuvre 595  
domestic violence: and child abuse 819; and hyperemesis 252; observing 96; and pregnancy 301–2, 785–6; and pregnant mothers 96; and uterine rupture 215  
domperidone **75**, 86–7, 564, 684  
dopamine: in cardiovascular collapse 451; and dengue 685; and heart failure 455; in high-dependency care 853; in septicemia 354; and shock 171, 468; surges of 851; venous administration of 852  
Doppler ultrasound 14  
DOT (directly observed therapy) 277, 704  
DOTS (directly observed treatment: short-course) 288–9, 669  
double mucus trap 335  
double vision: and anti-epileptics 608; and botulism 640; and cancers 586; and magnesium toxicity 207; and migraine 617; and RICP 618; and squint 592; and Wernicke–Korsakoff syndrome 251  
douche system, sterile 249  
Down's syndrome: and autism 510; and duodenal atresia 377; and Hirschsprung's disease 636; and intubation 130, 839; and learning difficulties 404; protocol for 400; and sedatives 78; and sleep-related upper airway obstruction 387, 429; and spinal cord injury 406  
doxorubicin 582–3, 586–7  
doxycycline: and cholera 551; and filariasis 756; and leptospirosis 648; and Lyme disease 649; and onchocerciasis 758; and quinine 740; and relapsing fever 655; and rickettsial disease 676–7; and STIs 657–8  
DPL (diagnostic peritoneal lavage) 782  
DPT (diphtheria, pertussis and tetanus) 93–4  
dreams 112, 115, 117, 440, 509  
dressing changes: in burns 808–9; in fungating wounds 90  
drinking water: filtration of 755; in labour 143  
drowning 796–8; and cardiac arrest 44, 55; and hypothermia 63; in low-income countries 769–70  
drowsiness: and DKA 262; and hypotension 38; and hypoxia 37; and opioids 83–4; in shock 787  
drug abuse 365, 387, 506–8, 810  
drug doses, measuring 17, 19  
drug errors, minimising 17–18, 850–3  
drug eruptions 709–10  
drug ingestion, accidental 384  
drug interactions: and anti-epileptics 608; and ARVs 699; and erythromycin 357; iron and methyllopa 202; and traditional medicine 105  
drug overdose, intentional 63, 810  
drug side effects, in HIV 709  
drug storage 19, 69  
drug withdrawal 377  
DSD (disorders of sexual development) 502–3  
DTIC 586  
DTP vaccine 425, 654  
Duchenne muscular dystrophy **613**, 615–16  
duodeno-jejunal biopsies 568  
dulcolax 83, 411–12  
duodenal atresia 377  
duodenal ulcer 564  
DVT (deep vein thrombosis): in coma 268, 597; and endometritis 304; and hyperemesis 251; and PPROM 245; and pre-eclampsia 211; and puerperal sepsis 221; and pulmonary embolism 223; treatment of 225  
dying patients, attempting to prolong life of 101  
dysentery: amoebic 546, 551–2; and antibiotics 544, 551; classification of 545; and gastroenteritis 382; and HUS 478; in infants 355; and malaria 284; in neonates 355; and re-feeding 526  
dysmenorrhoea 383  
dysmorphism 399  
dyspepsia 403, 563  
dysphagia: and morphine administration 83; and relapsing fever 655  
dysphasia 604, 619  
dysplasia 333, 364, 485, 572, 629  
dyspnoea: and amniotic fluid embolism 225; and anaemia 383; and anaphylaxis 24–5; and anthrax 678; and asthma 431; and chest trauma 781; exertional 490; and FBAO 53; and heart disease 122, 255; and heart failure 531; and HIV 701; and mitral regurgitation 452; and oedema 388; in palliative care 87–8; paroxysmal nocturnal 254–5, 452; and pulmonary contusion 781; and pulmonary embolism 223–4; and relapsing fever 655  
dysreflexia 411, 415  
dystonia 75, 402, 509  
dysuria: and cystitis 286; and leptospirosis 647; and schistosomiasis 753; and sexual abuse 821; and STIs 657  
earache, referred 427  
early pregnancy: abdominal pain in **158**; dating 137; diabetes in 261; and ectopic pregnancy 178; ketamine in 125; nausea and vomiting in 138; shock in 169; vaginal bleeding in **162–3**  
Eastern Cape 107  
eating and drinking aids 419  
eating disorders 396, 821  
Ebola 487, 686, 727–8  
EBV (Epstein–Barr virus) 687; and glandular fever 428; and leukoplakia 705; and LIP 702; and lymphoma 575  
eczymoses 385, 514, 571, 705, 719  
ECF (extracellular fluid) 470–1  
ECG (electrocardiogram): and amniotic fluid embolism 225; in anaesthesia 130; in arrhythmias 456, 458; and cardiac arrest 62; cardiomyopathy on 455; and diphtheria 644–5; and DKA 263; for Down's syndrome 400; and Guillain–Barré syndrome 615; heart defects on 448, 450–3; and heart failure 453–4; in needle pericarditis 862; and pheynitoin 611; and pulmonary embolism 224; and rheumatic heart disease 254; and tachycardia 40  
ECG monitors: in emergency room 110; in high-dependency care 69  
Echinococcus 750–1  
echocardiography: and aortic regurgitation 255; and diphtheria 644; and disabled children 400; and endocarditis 456; and heart defects 447, 449, 451–2; and heart failure 455; and rheumatic disease 571; and SCD 174  
eclampsia: in adolescent girls 395; and amniotic fluid embolism 226; and anaesthesia 121, 124; and APH 186; and convulsions 203, 205; emergency box for **210**; emergency drug treatment of 206–7; and ergometrine 154, 190; impending 32, 161, 203, 207; and ketamine 125; and magnesium sulphate 63; and pre-eclampsia 201; respiratory difficulties in 37; and RICP 265, 267; and severe malaria 280, 283  
eclamptic fits 266  
econazole 591  
ecthyma 626  
ectopic pregnancy: and antenatal care 137–8; blood loss due to 171; causes of 177; and endometritis 220; implantation of 177–8; and IUCDs 304; and miscarriage 181; ruptured 32; shock due to 166, 178–9; symptoms and signs of 178  
ectropions 183  
EDTA (edetate calcium) 22, 814  
EEG (electroencephalogram): and coma 596; and CSE 612; and encephalopathy 602–4; and meningitis 596; and neonatal seizures 372; and seizures 606  
efavirenz (EFV): for children 697; dosage for children 715; and malaria 741, 745; and MDR-TB 670; for pregnant women 274–5, 695  
effacement 146, 148, 150–1, 159  
effusion, and dyspnoea 87  
eflornithine 730–1  
EgAr device 193, 310–11, 310  
egg allergy 93  
Egypt, FGC in 299, 301  
Ehrlichia 675  
ehrlichiosis 648, 675–6

ethionamide 287–8, 670  
Ethiopia: EPDS in 294; FGC in 299, 301; guinea worms in 754; *Leishmania* in 733  
etomidate 200  
etoposide 580–2, 585  
Eustachian tube obstruction 427  
euthanasia 101  
evacuation 323  
Ewing's sarcoma 586–7  
examination: basic equipment for 29; conduct of 29–30; recording findings of 30  
examination light, portable 69  
exchange transfusion: complications from 859; and jaundice 370–1; and resuscitation 39–40; and SCD 173, 536–7, 539; uses of 23  
exhaustion, and respiratory failure 36, 131  
exophthalmos 502, 582  
expiratory noises 36, 131, 843  
extensor spasms 487, 606–7  
external jugular veins *856*: access to 178, 194; cannulation of 776, 856  
extra digits 333, 352  
extradural haematoma 788, 793  
extradural haemorrhage, acute 779  
extrapulmonary tuberculosis 287–8, **666**, 697  
extravasation: and cannulation 858; and gunshot wounds 801–2; and IV fluids 375, 458, 661, 731, 852  
extreme-drug-resistant TB (XDR-TB) 670  
extremity injuries 784  
eye contact 402–3, 510  
eye disease, and onchocerciasis 758  
eye drops 19, 128, 358, 572, 589–92  
eye examination 572, 588–90, *588*  
eye infections 401  
eye medications, traditional 107  
eye movements, conjugate 741  
eye padding 268, 523, 597, 720–1  
eye pointing 419  
eyelid drooping 251  
eyelid oedema 357, 744  
eyelid retraction 520  
eyes: enucleation of 107, 577, 585, 592; signs of VAD in **512**  
EZ-IO drill 548, *861*  
F-75 520, 524–6, **525**; homemade **526**  
F-100 407, 522, 526–7, 529; homemade **526**  
fabricated illness see *Fill*  
face masks: in emergency room 109; in high-dependency care 69; in ventilation 58–60  
face presentation 239–40, 307, 312  
facial burns 808  
facial nerve paralysis 351, 428, 649, 680  
facial nerves, injury to 313  
faecal clinical chemistry tests 28  
faecal discharge 163, 633  
faecal impaction 560  
faecal soiling *560*  
failure to thrive: and abuse 820; and cystic fibrosis 443; differential diagnosis of 443; and heart failure 454; and HIV 700; and malabsorption 566; mechanisms of **386**; and rheumatic disease 569; and thalassaemia 541  
faints: in children 387; investigations in **387**  
falciparum malaria 276, 278–80, 728, 739–41, 745  
Fallopian tube: implantation in 177; ruptured 177  
falls, in pregnancy 786  
false localising sign 389, 650, 793  
families: in care of children 392; caring for patients 6; of dead patients 9–10; and dying children 79–80, 90–1; estimating pain in child 70; ill treatment and abuse in 96; intensive care facilities for 68; living with HIV 711; and mental health disorders 505; of preterm infants 340–1; supporting grief in **116**, 117, 120; violence in see domestic violence  
family counselling 268, 597  
family history: in antenatal care 136; recording 29; in resuscitation 43  
Fanconi's nephropathy 488  
fans, portable 69  
fascioliasis 754  
fasciotomy 785, 795, 817  
fast breathing, definitions of 36  
fat malabsorption 390, 515  
fatigue, and respiratory failure 36, 131  
fatty acids, polyunsaturated 493  
favism 540–1  
favus 627  
FBAO (foreign body airway obstruction) 31, 35, 42, 52–4, 422–3  
FDCs (fixed-dose combinations) 279, 287, 697, 739  
FE (fractional excretion) 471  
febrile convulsions: and crude oil 106; fits and faints in 387; and tonsillitis 427  
febrile illness: and headache 389; and malaria 278  
febrile non-haemolytic reactions 24–5  
febrile seizures 608–10, 719  
feeding, uncoordinated 349  
feeding difficulties 348, 394, 399, 401, 403, 419  
feet, tiptoeing of 410  
female genitalia: examination of 831–2; normal external *306*; see also FGC  
femoral block 128  
femoral cannulation 857–8, *857*  
femoral fractures 767, 774  
femoral pulses, examining 30  
ferrous fumarate 172, 282, 531, **745**  
ferrous sulphate: and anaemia 172–3; and severe malnutrition 523  
FES (*Fasciola* excretory-secretory) antigen 754  
fetal alcohol syndrome 404, 510–11  
fetal asphyxia 209, 227–8  
fetal assessment, in obstetric haemorrhage 189  
fetal blood sampling 230–1, 240  
fetal compromise 38, 147, 232  
fetal condition 147, 209, 230  
fetal death: and blunt trauma 785; destructive procedures relevant to **324**; and domestic violence 302; in obstructed labour 215, 321; ultrasound finding of 182; in utero (IUFD) 228–9; and vasa praevia 186  
fetal descent *149*: in face presentation 240; in normal labour 148–9, 153; obstruction of *211*  
fetal distress: and assisted delivery 154, 307; and blunt trauma 785; and Caesarean section 313; during labour 230; and episiotomy 153; managing 232; and maternal SCD 174; and maternal shock 167; in multiple pregnancy 234; and nifedipine 246; and pre-eclampsia 209; and prolonged pregnancy 150; signs of 212  
fetal haemoglobin 366, 538  
fetal head: arrested 241; hyper-extension of 242, 244; malpositions of 237–8  
fetal heart: auscultation of 137, 143, 185, 188–9, 227, 247; and resuscitation 30, 124  
fetal heart monitor: as basic equipment 144; in high-dependency care 69  
fetal heart rate: absent 160, 163, 184, 228; accelerating 230–1; falling 212, 231; in induction of labour 152; in malpresentation 238, 240, 242; and maternal blood pressure 208; monitoring 147, 227, 230, 235, 785; normal 147, 230; recording 146  
fetal hypoxaemia 228  
fetal injury, and domestic violence 302  
fetal movements: reduced 144, 163, 227, 231, 242; reduced **227**  
fetal neck 239, 243–4, 323  
fetal oxygen delivery 187  
fetal position, assessing 150, 235–6  
fetal scalp: bleeding *311*; pH assessment 231  
fetal skull *235*: incision 322; moulding of bones *147*, *212*  
fetal viability 179–80, 247–8  
fetal well-being, monitoring 230–1  
feto-maternal haemorrhage 21, 138, 340, 366, 786  
feto-maternal transfusion 371, 383  
feto-pelvic disproportion 241–2  
fever: and pneumonia 439–40; relapsing 654–5, 675, 734; of unknown origin see PLO; see also pyrexia  
FFP (fresh frozen plasma) 22, 652, 684, 726  
FGC (female genital cutting) 298–301, 299; as abuse 96, 823; campaigning against 397;  
fibrinogen 226, 543  
fibroids 137, 241, 317  
field block 128  
Field's stain 28  
'fiftths' *148*  
Fill (fabricated or induced illness) 96, 387, 478, 818, 823–4, 828  
filariae 515–6  
fine-particle masks 703  
finger clubbing 30, 380, 442, 561, 667, 702, 749  
finger intubation *839*  
fingers, damage to nerves 784  
firearms see gunshot wounds  
fish, venomous 817  
fits: in children 387; fabricated 823; investigations in **387**  
fixation tape 129, 210, *840*  
flaccid bladder 413–14  
flaccid bowel 411–12  
flail chest 36, 772–3, 780  
flat affect 508  
flecaicaine 457  
flucloxacillin: and burns 809; for cellulitis 333; and cystic fibrosis 444; and eczema 627; and empyema 633; and encephalitis 605; and fungal infections 705; and inhaled foreign bodies 435; and lung abscess 442; and mastitis 222; for neonatal infection 352, 356–8; and osteomyelitis 535, 622; and peritonitis 305, 484; and pleural effusion 442; in pneumonia 269, 440; and pressure sores 417; prophylactic **445**; and pyomyositis 621; and retropharyngeal abscess 428; routes of administration 17, 851; and septic shock 468, 532; and skin infections 658; and wound abscess 305  
fluconazole 488, 580, 704, 707, 709, 851  
flucytosine 605, 708  
fluid administration: minimising errors in 850–1; rate of 17  
fluid balance: in malaria 283; monitoring 189  
fluid balance charts: and eclampsia 207; and gastroenteritis 271; and IV fluids 17, 175; and malaria 282; and oxytocin infusion 152, 253; post-operative 304  
fluid deficit, estimating 547  
fluid extravasation 375, 860  
fluid loss, and shock 39, 166  
fluid maintenance, in bronchiolitis 431  
fluid overload: and amniotic fluid embolism 226; and ARF 482–3; and blood transfusion 24–5; and dehydration 465, 468; and heart failure 453; and malaria 281–3, 738, 742–4; and malnutrition 529; and pre-eclampsia 208; and rehydration 519; and shock 38, 545, 547, 549  
fluid replacement, and antimalarials 282–4  
fluid requirements: in children **465**, **470**, **495**, **546**; and dehydration 271; in diarrhoea 546; and DKA 263, 495; for neonates 345, 347; normal **882**, **882–3**; in rehydration phase 549  
fluid restriction, in pneumonia 269  
fluid resuscitation: and gunshot wounds 801; and peritonitis 637; and PPH 194–5; pressure bags in *170*; response to 171; and trauma 774–5, 777  
fluid retention 192, 475, 483, 493  
flukes 748, 752  
flumazenil 813  
fluoroquinolones 287, 670, 676  
flouxetine 293, 504, 507  
flupenthixol 504, 509  
flushing: and iron dextran 173; of IV lines 17–18, 283, 373, 852, 859  
FNAC (fine-needle aspiration cytology) 631  
focal segmental glomerulosclerosis (FSGS) 475–6  
focal seizures 372, 604, 777  
folate, and malaria 279  
Foley catheter 228; and cord prolapse 247; ripening cervix with 228; in urethral catheterisation 306, 413–14  
folic acid: and anaemia 21, 172–3, 383, 515, 523, 531; and diabetes 261; and diarrhoea 559; and enzyme deficiency 541; and malaria 739, 745; and neurosurgical disorders 620; preventing stillbirth 229, 398; and SCD 174; and spherocytosis 540  
folic acid deficiency 383, 515  
folic acid 706, 747  
fontanelle: bulging 371, 597, 650; delayed closure of 514; sunken 394, 463, 545  
food: healthcare workers growing 3; high-energy **408**, 527, 558; see also RUTF  
food deprivation 557  
food intake chart *885*  
food intolerance 380, 383  
foot drop 419  
forceps: in assisted delivery 154; in Caesarean section *313*; trial of 313, 318  
forceps delivery 220, 239–40, 247, 311–13, 351  
forearm fractures 768–9  
foreign body: in the airway see FBAO; in the eye 589; inhaled 35, 390, 423, 435, 438, 442; in oesophagus 563; suspicion of 61; in wounds 762–4, 787; on X-ray 791  
forensic sampling 822, 824–5

- foul-smelling lochia 160, 164, 191, 198  
 foul-smelling vaginal discharge: antibiotics for 228; as emergency sign 157; and endometritis 220; and PPRM 245; and retained placenta 197; and septic abortion 176  
 fractures: in children 764–9; fixation of 767–8; in infants 359–9; non-accidental 96; splinting *see* splintage  
 fragile X syndrome 404, 511  
 frenulum, torn 819, 822  
 frontal bossing 381, 541  
 frozen watchfulness 404, 819  
 fruit juices 394, 415, 496, 532, 552–3, 684  
 FTC (emtricitabine) 274, 695, 698, 700  
 full blood count (FBC): in antenatal care 138; and anthrax 678; and blood transfusion reactions 25; in septic shock 469  
 fumigation machine 14  
 fundal height, measuring 137, 13  
 fundoscopy 30, 384, 400, 498  
 fundus, supporting 326  
 funerary procedures 10, 91, 112–15, 117–18, 229  
 fungal corneal ulcers 591  
 fungal infections: and headache 598; in HIV 704, 708–9; smears of 29; superficial 626–7; systemic 488, 580  
 fungal peritonitis 484–5  
 fungal sepsis 350, 353, 580  
 fungating tumours 86, 88  
 fungating wounds 90  
 furosemide: and ARF 481–2, 744; and dengue 684; in emergency room 110; and fluid overload 25, 743; and glomerulonephritis 477; and heart failure 455, 522, 531; and hypercalcaemia 407; and metabolic acidosis 284; in pre-eclampsia 208; and pulmonary oedema 40, 252–3, 451, 455, 465–6; and RICP 652; and urine output 283  
 fusidic acid 679  
 futile treatments 101  
 G6PD deficiency 540–1; and anaemia 21–2, 530; and co-trimoxazole 702; and haemolysis 368–9, 383, 478; and jaundice 399; and primaquine 738; and quinine 281  
 gabapentin 84  
 gag reflex, inoperative 40  
 galactosaemia 368–9, 374, 487–8, 503  
 Galeazzi fracture 769  
 gallop rhythm: and anaemia 383; and heart failure 40, 252, 272, 453–4, 546; and malaria 742–3  
 gallstones 539–40  
 Gambia, hospital workers in 3  
 Gambian trypanosomiasis 28, 730–1

 gravidity 136  
 greenstick 765, 768–9  
 grey baby syndrome 440  
 grief: abnormal reaction to 509; and attachment 110–11; children's responses to 116–19; effect on health 113; stages of 112; waves of 116  
 griseofulvin 627, 709  
 group A *Streptococcus* 220, 658–9  
 group B *Streptococcus* (GBS) 658–9; and neonatal sepsis 350, 353, 597, 621; and PPRM 244  
 growth failure: and CRF 485–6; and HIV 688; and IBD 563; and juvenile idiopathic arthritis 572; and radiotherapy 584; and SCD 538  
 growth monitoring 276, 557, 873  
 growth recovery chart 528  
 grunting: in ALRIs 437, 440; expiratory 361; and pneumonia 438–9; and respiratory distress 36, 361  
 Guedel airway 55–6, 210, 837  
 guided imagery 86  
 Guillain-Barré syndrome 604–5, 613–15, 640–1, 680  
 guilt 113–14, 294, 296, 506, 810  
 Guinea, FGC in 301  
 gunshot wounds 762, 782, 786, 794, 800–2  
 Gustilo classification 765  
 H<sub>2</sub>-blockers 407  
 H<sub>2</sub>-receptor antagonists 86, 121, 124, 492, 564, 729  
 HAART (highly active antiretroviral therapy) 688, 693, 708, 711, 735  
 Haemacel 208, 806, 883  
 haemangiomas 422, 631–2  
 haematemesis 383, 563–5, 635, 753  
 haematinics 21, 530, 734, 738–9  
 haematocolpos 300  
 haematocrit: in APH 189; and ARVs 699; and burns 806; and dengue 683–4  
 haematological investigations 27  
 haematoma: and Buruli ulcer 642; and cricthyrotomy 772; in episiotomy 325; and upper airway obstruction 422  
 haematuria: and anaemia 383; and bladder stones 479, 630; and cephalopathy 376; and filariasis 756; and glomerulonephritis 477–8; and haemophilia 544; and HSP 571; and leptospirosis 647; and NEC 377; and nephrotic syndrome 476; in SCD 539; and uterine rupture 214; *see also* microscopic haematuria  
 haemocytometer 27  
 haemodialysis, peritoneal 813  
 haemodynamic instability 775, 797, 865  
 haemoglobin, glycosylated 498  
 haemoglobin colour scale 27, 173  
 haemoglobin concentration, normal **530**, **879**  
 haemoglobin defects 539, 541  
 haemoglobin electrophoresis: and ALTEs 387; and anaemia 384, 530; and jaundice 381; and respiratory distress 390; and SCD 174, 533; and thalassaemia 541  
 haemoglobin levels: in labour 147; optimal 127; in septic shock 469  
 haemoglobin measurement 27, 138, 172–3, 459, 616, 736  
 haemoglobinaemia 24–5  
 haemoglobinopathy 174–5, 383, 530, 572, 585  
 haemoglobinuria 24–6, 540, 738, 804  
 haemolysis: and anaemia 371, 383; chronic 532, 541; and jaundice 368–9, 380; in malaria 741; presentation of 173; *see also* acute haemolysis  
 haemolytic anaemia: acquired 539, 542; and blood transfusion 23; clinical features of 539; congenital and acquired **539**; and folic acid 515; hereditary 540–2; and HUS 478; severe 540, 743; and severe malaria 282  
 haemolytic disease, and bilirubin levels 368  
 haemolytic disease of the newborn: and antibodies 138; and blood transfusion 22–3, 26  
 haemolytic reactions 24–5  
 haemolytic-uraemic syndrome 481, 540, 552  
 haemoperitoneum 213, 782  
 haemophilia 383, 543–4, 572  
*Haemophilus*, and SCD 535  
*Haemophilus ducreyi* 657  
*Haemophilus influenzae* 679; antibiotic resistance of 598; and croup 422–3; and cystic fibrosis 444–5; and epiglottitis 424; and HIV 701; immunisation against 599; and meningitis 597–8; and otitis media 427; and pneumonia 436; prophylaxis against 601; and SCD 538; and septic arthritis 622; and tonsillitis 426  
*Haemophilus parainfluenzae* 428  
*Haemophilus pneumoniae* 268  
 haemopneumothorax 166, 843  
 haemoptysis: and bronchiectasis 704; and chest trauma 781; and cystic fibrosis 445; and leptospirosis 647; and lung abscess 442; and mitral stenosis 452; and pulmonary embolism 223; and rheumatic heart disease 254  
 haemorrhage: control of 770; in labour 147; life-threatening 298, 778; in the neonate 366; in pregnancy 144; spontaneous 209, 514, 543; in triage 32  
 haemorrhagic disease of the newborn 342  
 haemorrhagic necrosis 604  
 haemorrhagic shock 683, 775, 780  
 haemorrhoids 412, 491  
 haemostatic dressings 88  
 haemothorax: and respiratory distress 36, 780; and shock 166; traumatic 772–3, 778, 781; and ventilation 61  
 hairworm 750  
 hairy leukoplakia 696, 705  
 Haiti 114  
 hallucinations: and ketamine 129; and opioids 84; and schizophrenia 508; and substance abuse 814; and Wernicke's encephalopathy 251  
 halofantrine 281  
 haloperidol 84, 86–7, 295, 569–70  
 halothane: in anaesthesia 14, 129, 257; and inverted uterus 250  
 halothane poisoning 488  
 hand-foot syndrome 534  
 hand-washing: effective 8; and handling neonates 333, 350; and infection control 8, 142; room for 14  
 hand-washing facilities 69, 728, 810  
 handicap, use of term 397  
 hanging groin appearance 758  
 hantavirus 648  
 hard cervical collars 110, 407  
 hard palate: defects of 290; erythema of 573  
 hare lip 404  
 Harrison's sulci 432, 514, 705  
 Hartmann's solution: and blood transfusion 25; in dehydration 272; and drug IVs 16–18; in emergency room 110; in shock 16, 169–70; soaking dressings in 90  
 Hashimoto's thyroiditis 502  
 HATI (human anti-tetanus immunoglobulin) 762–3  
 HbAS (sickle-cell trait) 533, 535

- HbIG (hepatitis B immunoglobulin) 95, 358
- HbS solubility filtration test 27
- HBSAg (hepatitis B surface antigen) 26–7, 95
- HbSS (homozygous sickle-cell disease) 23, 530, 532–3, 535–7
- HBV (hepatitis B virus) 686–7; chronic 492; and liver failure 486; and liver tumours 585; and needlestick injuries 764; for neonates 358; and nephrotic syndrome 476; and SCD 536; and sexual abuse 824; staff exposure to 6; vaccination against 92–5, 175, 492, 538, 656
- HCC *see* hepatocellular carcinoma
- HCV (hepatitis C virus) 492–3; chronic 492–3; exposure to 6; and HIV 712; and iron chelation 542; mechanisms of spread 687; staff exposure to 6; testing for 22; and thalassaemia 542
- head bobbing 37, 58, 217
- head circumference: and anaemia 371; and failure to thrive 386; and hydrocephalus 599; measuring 823, 874; in meningitis 353; recording 334, 384
- head examination, in trauma 778
- head injury: and airway management 35, 77–1; anaesthesia in 788; analgesia for 74–5, 778; and brain injury 792–3; and drowning 797; intubation in 864; and meningitis 269; non-accidental 819; and RICE 265; and seizures 203; in trauma 13, 775, 777, 779–80
- head nurses 2
- head tilt/chin lift 45: in airway opening 35, 45–6, 48; readjusting 47, 61
- headache: and cancer 587; and cerebral oedema 265; in children 389; and circulation problems 32; and depression 506; and leptospirosis 647; and meningitis 269; in pregnancy 144; and relapsing fever 655; and rheumatic disease 569; and spinal anaesthesia 123; in triage 32; and VHF 727; *see also* migraine
- healers, traditional 104–8, 376
- health education: and childbirth 139, 144; ethical commitment to 102
- health information, availability of 6
- healthcare professionals: continuing education for 10–11; as court witnesses 828; and cross-infection 10; employment issues for 5; financial incentives for 2; immunisation of 95; protection from VHF 728; relationship with patients 102–3; and society 103
- hearing, in neonatal examination 400

- hypofibrinogenaemia 816
- hypoglycaemia: definition of 884; and adrenal crisis 500; and antimalarials 740; and APH 189; and ARF 483; and cardiac arrest 65; in children 498–500;

- and coma 593, 596; in dehydration 272, 549; in diabetes 261, 496–7; in diarrhoea 550; emergency treatment for 40, 43, 372, 521–2; and encephalopathy 377; and epilepsy 606; and exchange transfusion 23; fits and faints in 387; and fluid resuscitation 16, 805; and galactosaemia 488; and GHD 503; and hepatitis 686; and hypothermia 799; and liver failure 487, 490; and malaria 280–3, 738–9, 741–2, 744–5; and poisoning 811; and polycythaemia 360; rebound 340, 610; and respiratory distress 365; and seizures 371–2; and severe malnutrition 516–17; and shock 465–6, 521; symptoms and signs of **499**; and traditional medicine 106–8; in trauma 770, 780; and trypanosomiasis 731; and yellow fever 729
- hypogonadism 503–4
- hypokalaemia: and ALF 487; and cardiac arrest 63; and dehydration 272; in diarrhoea 550–1, 557; and DKA 262, 494; equipment for detecting 27; and furosemide 455; and hyperemesis 251; and salbutamol 433; and severe malnutrition 516
- hypomagnesaemia 376, 516
- hypomania 295, 506
- hyponatremia: definition of 470; and adrenal crisis 500; and dextrose 171; in diarrhoea 550; and encephalitis 603; and encephalopathy 376; equipment for detecting 27; and fluid resuscitation 268, 272, 596, 611; and hyperemesis 251; and IV feeding 16; and leptospiriosis 648; and meningitis 599; and ORS 547; and oxytocin infusion 152; and quinine 281; and seizures 371, 375; and shock 460
- hypoparathyroidism 503, 542, 567
- hypophosphataemia 516, 651
- hypopigmentation 627
- hypopituitarism 499–500, 503–4
- hypoproteinaemia, and severe malnutrition 516
- hypospadias 630
- hypotension: and abdominal trauma 782; and adrenal crisis 500; and amniotic fluid embolism 225; and antipsychotics 509; and blood transfusion 24–5; caused by morphine 72; in diabetes 261; and drowning 797; and ectopic pregnancy 178; in head injuries 779; and hypopituitarism 504; and hypovolaemia 187; and iron dextran 173; and metabolic acidosis 284; and phenytoin 372; and poisoning 811; in pregnant women or children 32; and puerperal sepsis 221; and pulmonary embolism 223; and SCD 533; and shock 24, 38, 168, 787; and spinal anaesthesia 123–4, 189; and spinal injury 406–7, 783; and transfusion 22; and uterotonics 192
- hypotensive drugs, for children **474**
- hypothermia: and ALRI 440; and cardiac arrest 63; in children 787–8; and diarrhoea 549; and drowning 796–8; and hypoglycaemia 373; and hypopituitarism 504; and inverted uterus 250; and malnutrition 517; and medical procedures 836; in neonates 246, 331, 344–5, 349; and obstetric haemorrhage 188, 195; and poisoning 267; prevention and treatment 344, 349, 398, 521, 776, 799, 848; and respiratory distress 361–2, 365; and septicemia 352, 354; and severe malnutrition 517; and shock 465, 521; and spinal cord injury 407; in trauma 770
- hypothyroidism: acquired 501; and ADHD 511; and autism 510; and bilirubin levels 368; and coeliac disease 567; congenital 368, 501; and constipation 560; and DSD 503–4; and jaundice 368; and learning difficulties 404; maternal 515; and radiotherapy 584
- hypotonia: and aspiration pneumonia 364; and benzodiazepines 296; and coma 595; in legs 406; and malaria 741; and neurological assessment 40
- hypotonic solutions 126, 263, 376
- hypoventilation: and anticonvulsants 794; nocturnal 613, 616
- hypovolaemia: and ARF 481; and cardiac arrest 63; and dehydration 470; and drowning 796; and fetal distress 232; and furosemide 477; and hypothermia 797; intravascular 208, 475; and intussusception 635; and malaria 284, 744; and morphine 72; in neonates 340; and nephrotic syndrome 475–6; and obstetric anaesthesia 121–2; in obstructed labour 214; signs of 187; and trauma 770, 774–5, 785
- hypovolaemic shock: and dehydration 271, 463; fluid resuscitation in 39, 42; mechanism of 459; in neonates 21; in pregnancy 166, 168; and ruptured ectopic pregnancy 178; and trauma 775; and uterine rupture 216
- hypoxaemia: adverse effects of 430; and ALRI 440; and amniotic fluid embolism 225–6; and asthma 255, 433; and botulism 640; in bronchiolitis 430; and croup 422–3; and heart failure 455, 522; and intubation 37; and malaria 743; in neonates 338; and obstetric anaesthesia 121, 129; and pertussis 654; and pneumonia 439; in pregnancy 266; and pulmonary contusion 781; and respiratory distress 390; and SCD 176; signs of 36; and upper airway obstruction 422
- hypoxia: and airway management 771; and BLS 44; and cardiac arrest 63; and CSE 610; and drowning 796–7; in head injuries 779; and heart rate 37; intrapartum 365, 376–7; and PCP 701; and resuscitation 42; and SCD 174, 176; and seizures 371; and spinal cord injury 407; in trauma 770
- hypoxic-ischaemic cerebral injury 398–9, 404, 798
- hysterectomy: and obstetric haemorrhage 189, 198–9; in post-operative care 304; and puerperal sepsis 221; and retained placenta 197; and ruptured uterus 216; and septic abortion 177; subtotal 216, 326
- hysterical conversion disorders 507
- IBD *see* inflammatory bowel disease
- ibuprofen: and arthritis 573; and liver dysfunction 488, 492–3; and migraine 617; as pain relief 72–3, 82; in palliative care 81
- ICD (International Classification of Diseases) 29, 113, 229
- ICF (International Classification of Functioning, Disability and Health) 397–8, 470
- ICN (International Council of Nurses) 98–9
- icterometer 367
- IED (improvised explosive devices) 799–800
- ifosfamide 579, 586
- IgA nephropathy 476–8
- IGRA (interferon gamma release assay) 287–8, 668
- ILCOR (International Liaison Committee on Resuscitation) 335–6, 342
- ileostomy 563
- ileus: and DKA 263, 495; and puerperal sepsis 221; *see also* meconium ileus; paralytic ileus
- imaging facilities, essential 12–14
- Imaging the World 13
- Imbelekisane 107
- IMCI (integrated management of childhood illness) 276
- imidazole cream 627
- impipenem 535, 673, 678–9
- imipramine 294
- immediate-release morphine 82
- immunisation: and antenatal care 138; for healthcare workers 5–6; and HIV 710–11; hospital issues regarding 92–5; for measles 721; in pregnancy 144; and preventing disability 398; and SCD 174–5
- immunisation information 29
- immunisation instruments 94
- immunocompromised children 93–4, 551, 605, 680–1, 721
- immunoglobulin therapy 580
- immunological failure 699
- IMNCI (Integrated Management of Neonatal and Childhood Illnesses) 109
- impairment: prevention of 398; use of term 397
- impetigo 625–6; and burns 819; in HIV 709; and rash 385; and *Staphylococcus* 679; and *Streptococcus* 658; treatment of **626**
- impulsivity 404, 510–11
- inattention 510–11, 820
- incarcerated hernia 628–9, 636
- incinerator 4, 8, 142
- incisions: care for 763–4; use of term 762; in wound debridement 802
- incomplete miscarriage 179–81
- incontinence: in palliative care 89; and spinal cord problems 403–4
- increased respiratory rate **437**: and dehydration 394; and puerperal sepsis 221; and pulmonary oedema 208; and shock 38
- incubators: in OT 14; and oxygenation 362; and preterm infants 14, 345, 349; temperatures for **350**
- India: cancers in 575; child abuse in 821; leprosy in 645; malaria in 285; thalassaemia in 541
- India ink stain 29
- Indonesia, 2004 tsunami in *see* South-East Asian tsunami of 2004
- induction of labour: and APH 189; and dating of pregnancy 137; and diabetes 262; and fetal death 228; and maternal SCD 174; and PPRM 246; in pre-eclampsia 209–10; procedures for 150–3; routine 229
- induction training 5
- indwelling catheters 89, 412, 652, 859
- Inembe 107
- inevitable miscarriage 162, 179–80, 182
- infant botulism 640–1
- infant brain 14
- infants: anaesthesia for 127; chest compressions in 47–8; clearing airway in 53; eye examinations for 589; face masks on 60; heart failure in 454; identifying pulse of 47; IM injections in 18; laboratory evaluation of unwell 350–1, 353; need for resuscitation in **31**; newborn *see* neonates; respiratory distress in 37; respiratory rates of 36, 131; RIPC in 794; signs for urgent management **33**
- infection: after childbirth **219–20**; and apnoea 365; asymptomatic 245, 331, 729; and cancer 579–80; in post-operative care 304; and PPRM 246; preventing spread of 103; in SAM 520; and SCD 534–6; and miscarriage *see* septic abortion
- infection control: audit of 4; in bronchiolitis 431; in cancer treatment 579, 588; and child–parent contact 9; in childbirth 139, 142; and death of patients 9–10; in OT 15; and VHF 727–8
- infective shock 24, 171
- inferior vena cava, occlusion of 50, 144, 187, 211
- infertility, and chemotherapy 579, 581, 583
- infubulation 298–300
- inflammatory bowel disease: and abdominal pain 382; and anal injury 822; and arthritis 572; and diarrhoea 546, 556; and gastroenteritis 271; investigations for 561–3
- inflation breaths 337, 341
- infiximab 563, 573
- influenza 175, 574, 648, 721, 747
- information: children's needs for 393; disclosure of 100–1
- information technology 3
- informed consent 6, 100, 313, 689

- intracranial imaging 372
- intracranial pressure: controlling 496; monitoring 603; raised *see* RIPC
- intracranial spread 123
- intra-dermal injections 724–5, **854**
- intramuscular gas 377
- intramuscular (IM) injections: of adrenaline 433; antihypertensive 205–6; avoiding in pain 69, 76, 81, 173; avoiding in polio 722; of metastatic infections 674; of penicillin prophylaxis 570; precautions for 851; procedure for 18–19, 853; of varicella vaccine 681; of vitamin A 558
- intraosseous cannulation 62, 856
- intraosseous infusion 464, 548, 774, 856, 860–1
- intraosseous needles 109, 465, 549–50, 742, 860–1
- intrapartum fever, maternal 659
- intrapartum pneumonia 339
- intrapertoneal haemorrhage 784
- intrauterine death 32
- intrauterine growth retardation (IUGR): and beta-blockers 253; and fundal height 138; and hypoglycaemia 375; and malaria 276; and multiple pregnancy 232; and pre-eclampsia 201, 205, 209; preventing 398; and stillbirth 229; use of term 342
- intrauterine infection: and fetal death 215, 321; and hearing loss 401; and sepsis 122
- intravascular lines 851
- intravenous *see* IV
- intravenous urogram (IVU) 472, 585
- intraventricular haemorrhage 355, 365, 371, 374, 376
- intubation: in anaesthesia 127, 130–1; in asthma 434–5; for children 423, 787, 838–9; in children 423, 787; and croup 423; and epiglottitis 424; failed 124; and high-dependency care 67; in resuscitation 34–5, 37, 42, 169; in trauma 771
- intussusception: and abdominal pain 382; and diarrhoea 545, 548; and shock 463–4; surgery for 635; and vomiting 377, 384
- inverted uterus 248–50; and bleeding 171, 191, 199; pathway of care for 249; in placenta removal 326
- involuntary movements 371, 402
- iodine: and rehydration 520; tincture of 314
- iodine deficiency 501–2, 515
- iodophor, in Caesarean section 314
- ipecaacuanha 812
- IPPV (intermittent positive pressure ventilation): air flow in 133; and high-dependency care 67; indications for

- 845; in resuscitation 177; and trauma 773  
 IPT (intermittent preventive treatment): antimalaria 173, 746; for pregnant women 398  
 IPTp (intermittent presumptive treatment) 276–8  
 IPV (inactivated poliovirus vaccine) 92–3, 763  
 IRIS (immune reconstitution inflammatory syndrome) 699–700  
 iritis 589, 591, 655, 758  
 iron: and liver dysfunction 493; parenteral 172–3  
 iron chelation therapy 174, 532, 538–9, **538**, 541–2  
 iron deficiency anaemia: clinical features of 530; and HIV 275; and hyperemesis 252; management of 530–1; in pregnancy 172, 398; preventing 532  
 iron dextran 173  
 iron overload 26, 174, 485, 537, 542  
 iron poisoning 488, 745, 812, 815  
 iron sucrose 173  
 iron supplements: and anaemia 172–3, 175, 275, **531**; and pressure sores 416–17; for preterm infants 346; in severe malnutrition 523  
 irreversible shock 167  
 irritable behaviour 271, 463  
 irritable bowel syndrome: and abdominal pain 382; and diarrhoea 380  
 IRS (indoor residual spraying) 277–8, 284, 736  
 ischaemic stroke 536–7, 707  
 ischial spines 149, 309–10, 327–8  
 Isihlambezo 107  
 isolation, for specific infections 9  
 isoniazid: and liver dysfunction 488, 493; routes of administration 851; and TB 287–8, 666–7, 669, 671  
 isoniazid preventive therapy 356, 666, 671, 703  
 isoprenaline 450, 458  
 isopropyl alcohol 351, 353  
 itching: and blood transfusion 24; *see also* pruritus  
 ITNs (insecticide-treated bednets) 157, 229, 276–8, 736  
 ITP (idiopathic thrombocytopenic purpura) 543–4  
 itraconazole 709  
 IUCD (intrauterine contraceptive device) 177, 304  
 IV administration: drugs available by 90; through cannula 855  
 IV administration sets 129  
 IV antibiotics: and appendicitis 634; and diarrhoea 557; as emergency treatment 42; and intussusception 635; in labour 150; and uterine perforation 182; and UTIs 473  
 IV drip stands 69  
 IV fluids: administration of 16–17; in anaesthesia 129–30; compared to human serum **460**; comparison of **16**; complications of 18; and dehydration 272, 549; excessive 454; in labour 175; post-operative 127; recording chart for **886**; in shock 459–60  
 IV/IA (intravenous/intra-arterial) access 852  
 IV infusions: antibacterial 679; and convulsions 108; and dehydration 555–6; of desmopressin 543; diazepam 661; drip rates for 883–4; in high-dependency care 853; line flow rates **775**; in malnutrition 518; methylprednisolone 573; minimising errors in 852; of morphine 74; prednisolone 570; procedures for 17–18  
 IV lines 18  
 IV rehydration 550, 555–7  
 ivermectin 625, 748–50, 755–60  
 IVIG (intravenous immunoglobulin) 604, 658–9  
 IVRA (intravenous regional anaesthetic) 128  
 jaundice: and anaemia 383; and blood transfusion 26; brain damage due to 376; in children 380–1; and CLD 489; documenting 30; and enzyme deficiency 540–1; and haemolysis 173; and hepatitis 686; and hydatids 751; and hypothyroidism 501; investigations in **381**; and leptospirosis 647; and malaria 279, 283, 738; and mumps 721; in neonates 333, 353, 355, 366–70, 399, 401; obstructive 83, 368, 567, 632, 710; and polycythaemia 360; and pre-eclampsia 209; prolonged 368, 472, 501; and septicaemia 352; and TB chemotherapy 669; and toxoplasmosis 747; and yellow fever 729  
 jaw thrust 46, 67; in airway opening 35, 46, 48; in neonates 336–7; in trauma 771

 laryngeal oedema 24, 208, 210, 424  
 laryngeal/pharyngeal lesions 130, 839  
 laryngeal spasm 125, 662, 796  
 laryngeal trauma 422  
 laryngoscopes: in advanced life support 55; in anaesthesia 124; designs of 56; in emergency room 109; in high-dependency care 69; and intubation 130–1, 838–9, 839; in neonatal resuscitation 330, 335, 339  
 laryngoscopy 42, 57, 423–4  
 laryngospasm, in neonates 336  
 laryngotracheitis 679  
 laryngotracheobronchitis 422  
 larynx, anatomy of 840  
 Lassa fever 487, 686, 726, 728  
 last menstrual period (LMP), date of 136  
 late miscarriage 182  
 late pregnancy: abdominal muscles in 52; abdominal pain in **159–61**; cardiac arrest in 65; diaphragm in 269; morphine in 72; shock in 169; vaginal bleeding in **163–4**  
 lateral tilt: in Caesarean section 66; in induction of labour 152; in resuscitation 38, 170, 187; wedges for 68  
 laundry service 4, 8  
 laws: concerning death 91; controlling drugs 19; and ethics 98  
 laxatives: in bowel training 412; in constipation 560; prophylactic 83–4, 87  
 LBRF (louse-borne relapsing fever) 654–5  
 LBW (low birth weight) babies: and breastfeeding 347; categories of 344; and chickenpox 291; and CNEP 847; discharge and follow-up of 345–6; and domestic violence 302; emergency problems for 348; iron supplementation for 398, 532; and malaria 276–7; and maternal depression 292; mortality of 330; neonatal sepsis in 156; post-natal care for 156–7; and prematurity 342; and syphilis 289; and TB 275, 286  
 LCD (liquid crystal display) 13  
 lead poisoning 383, 508, 814  
 learning difficulties 404–5; and abuse 96; and cerebral palsy 403; and expression of pain 70; facilities for children with 418; and hearing impairment 401  
 left heart obstruction 252, 450–1, **450**, 453, 455  
 left-to-right shunting cardiac defects 451, 453–4, **454**  
 left ventricular dysfunction 254–5, 452–3  
 left ventricular hypertrophy (LVH) 254–5, 451–2, 644  
 leg amputation 799–800  
 leg pain 223–4, 735  
 leg separators 419  
 leg tremor 251  
 leg ulcers 106, 539  
*Legionella* 7, 602, 704  
 legs: elevating 170, 177, 187, 194, 549; extended 40, 237, 243; in symphysiotomy 319–20  
*Leishmania amastigotes* 27  
 leishmaniasis 28, 626, 642, 733–5  
 lemon juice 106; *see also* fruit juices  
 leprosy 645–6; and Buruli ulcer 642; immunisation against 93; investigations for 28; and nephrotic syndrome 476; smears for 27  
 leptospirosis: and ALF 487; and coma 593; and encephalitis 602; and rickettsial disease 676–7  
 leucocytosis 263, 495, 658, 673, 749  
 leucopenia: and measles 719; and SLE 573; and trypanosomiasis 732; and typhoid 673; and yellow fever 729  
 leukaemia: and anaemia 383, 530; bleeding in 88; lumbar puncture in 579, 865; and lymphadenopathy 381, 631; palliative care in 91; *see also* ALL; AML  
 leukocytosis 570, 631, 635  
 leukodystrophies 614  
 leukoencephalopathy 706  
 leukotriene antagonists 432  
 levamisole 173, 469, 476, 750  
 levofloxacin 287, 670  
 LGA (large for gestational age) 342  
 lichen sclerosis 822  
 lidocaine: accidental injection into fetus 377; and arrhythmias 813; in bowel training 412; in Caesarean section 126; and cardiac arrest 65; during surgery 76; in general anaesthesia 124; and inter-osseous infusion 860; as pain control 70–1; in pudendal block 327–8; and spinal anaesthesia 123; and vacuum delivery 308  
 lidocaine toxicity **71**  
 life skills training 509  
 light bleeding, definition of 163  
 light sources, LED 27  
 lignocaine: and cannulation 857–8; in chest drain insertion 843; in culdocentesis 222; and envenomation 817; as local anaesthetic 110, 127–8, 130; and lumbar puncture 866; and magnesium sulphate 206; and management of miscarriage 180–1; in OT 14; in symphysiotomy 319; uses in labour 300  
 limb fractures 784–5  
 limb girdle muscular dystrophies 616  
 limb weakness 706, 777, 816  
 limb wounds 802  
 linctus 88  
 LIP (lymphoid interstitial pneumonitis) 666, 689, 702–3, 702  
 lip smacking 371, 607  
 lipodystrophy 699, 717  
 lipoid pneumonia 812–13  
 lipoma 406, 642  
 liquor: bloodstained 231; chronic loss of 364; foul smelling 151; meconium-stained 147, 227, 337; recording state of 146–7  
 Lisinopril 253  
*Listeria* 355, 600  
*Listeria monocytogenes* 350, 353, 597, 600  
 lithium 293  
 lithotomy position: and Caesarean section 316; fetal scalp assessment in 231; on OT tables 14; repairing tears in 196; for vacuum delivery 308  
 liver: enlarged *see* enlarged liver; trauma to 782–3  
 liver abscesses, amoebic 747  
 liver cirrhosis 386  
 liver disease: basic investigations in **491**; and bleeding 88  
 liver dysfunction: and drugs 493; and magnesium 207  
 liver failure: and NSAIDs 73; and pre-eclampsia 209; and yellow fever 729  
 liver flukes 754

- liver function tests: and anthrax 678; and SCD 174; and shock 171; and traditional medicine 108
- liver palms 381, 490
- liver transaminases 108, 381, 669, 734
- liver tumours 491, 585–6
- LLINs (long-lasting insecticidal nets) 277–8, 284, 736, 739, 745
- LMAs (laryngeal mask airways) 55
- LMWH (low-molecular-weight heparin) 42, 175–6, 211, 224–5
- Loa loa 756–8
- local anaesthetic: and abdominal paracentesis 865; in Caesarean section 122; and cannulation 75, 856–8; and chest drain 842; and de-infibulation 300; dosage and application of 127–8; in emergency room 110; in eye drops 589; and lumbar puncture 866; as pain control 70–1, 76–7
- local anaesthetic toxicity 66, 203
- local lymphadenopathy 381, 678
- localised tetanus 660
- lockjaw 660–1
- LOD (lichenified onychodermatitis) 758
- LODOX Statscan 13
- log-rolling 774, 778, 780, 783, 864; position of staff for 864

- meningeal arteries, bleeding 793
- meningism 647, 655, 677, 707
- meningitis: and ADHD 511; antibiotics for 357; aseptic 604–5, 677; and botulism 640; and coma 267–8, 596; complications of 653; and CSE 610; and CSF leakage 794; diagnosis of 269; and eye disorders 591–2; and febrile seizures 609; and headache 389; and hearing loss 401; immunisation against 93, 398, 436, 539, 599; investigations for 29, 355; and Lyme disease 649; malignant 579; and mastoiditis 428; and relapsing fever 655; and resuscitation 41; and RICP 265; and salmonella 674; and SCD 535–6; and seizures 203, 207, 371; signs of 40; and *Streptococcus* 659; and strongyloidiasis 759; and TB 666–7; and visual impairment 400; and vomiting 384
- meningococcaemia, purpura of 593
- meningococcal disease 649–53; antibiotic doses in 651; epidemics of 649, 653; immunisation against 95; investigations in 651; monitoring of 599; and rash 385; and septic shock 41
- meningococcal infections 42, 171, 385, 598, 676
- meningococcal meningitis 597–8, 650; signs and symptoms of 650
- meningococcal septicaemia 388, 593, 596, 650, 653, 655
- Meningococcus*: and BLS 50; and SCD 538; and septic shock 466, 468
- meningoencephalitis 601–2, 605–6, 655, 675, 677, 721
- menorrhagia 544
- mental health problems: and abuse 820; in children 404, 504–5; for mothers 292–3, 296; postpartum-onset 293
- mental impairment 402, 501, 819; *see also* cognitive impairment
- mental retardation *see* developmental delay
- mental status: altered 40, 678, 706–7, 808; and breathing 36–7; and circulatory failure 38; improving 171; and respiratory support 131–2
- mento-anterior position 240
- mento-posterior (MP) position 237, 240
- mercaptopurine 582
- mercury poisoning 106, 508
- meropenem 355, 535, 600–1, 659, 678–9
- mesalazine 562–3
- metabolic acidosis: and ARF 482–3; and iron poisoning 812; in malaria 280, 283–4, 743; and meningococcal disease 652; and persistent fetal circulation 364; and respiratory rates 36; in salicylate poisoning 812; and seizures 376; and septicaemia 352
- metabolic alkalosis 486–7, 634–5
- metabolic bone disease 346, 491
- metabolic derangements 581, 596
- metabolic disorders: and autism 510; and convulsions 89; and hypoglycaemia 375, 498–9; and neurological failure 268; and opioids 84
- metabolic encephalopathies 592, 602, 741
- metabolic liver diseases 493
- metabolism, inborn error of 362, 368, 371, 376, 593, 602
- metastases, and dyspnoea 87

- metastatic disease 584, 586–7  
metastatic infections 674  
metformin 261  
methadone 76, 508, 811  
methaemoglobinemia 808  
methionine 812  
methotrexate 493, 572–4, 577, 582–3, 586  
methyl benzethonium 733–4  
methyldopa 200, 202  
methylene blue 28, 632  
methylphenidate 404, 511  
methylprednisolone 561–2, 573–4  
methylxanthines 256, 365, 432  
metoclopramide 86–7, 251, 580, 617  
metronidazole: and appendicitis 285, 634; and botulism 641; for children 358; crushed 88, 90; and diarrhoea 552; in emergency room 110; in episiotomy 325; and fetal death 228; and gallstones 539; and giardiasis 523–4; and *H. pylori* 564; and IBD 563; and intestinal obstruction 636; and intracranial abscesses 619; and intussusception 635; and inverted uterus 250; and malaria 743; and measles 720; and NEC 377; in obstructed labour 214; and peritonitis 222, 637; in placenta removal 326; in post-operative care 304–5; and PPH 198; and PPRM 245; and protozoal infection 747; and puerperal sepsis 221; and retropharyngeal abscess 428; routes of administration 17, 851; and septic shock 171, 177, 468, 532; in severe malnutrition 521; and STIs 657–8; and symphysiotomy 321; and tetanus 661; and tropical ulcer 626; and uterine rupture 216; and wound infections 221  
MIBG (metaiodobenzylguanidine) scan 578, 585  
miconazole: and candidiasis 704; and eczema 627; and impetigo 626; for infants 358; and STIs 657  
microcel rubber 417  
microcephaly, acquired 706  
microfilariae 28, 755–9  
microhaematocrit centrifugation 27, 730  
micronutrient deficiencies 402, 522, 556  
micronutrient supplementation 395, 558, 700  
micropenis 500, 503–4  
microphthalmia 747  
microscope, as basic equipment 27, 29  
microscopic haematuria: and endocarditis 456; and glomerulonephritis 478; and leptospirosis 648; and scurvy 514  
microscopy: and cystitis 286; for malaria 278  
microsporidia 705  
microsporidiosis 705  
*Microrhizium* 626  
mid-trimester miscarriage 180, 182, 228  
midazolam: in anaesthesia 130; for children 41; and CSE 610–11; in emergency room 110; in high-dependency care 853; and morphine toxicity 84; in neonates 354, 372; and permanent anaesthesia 89; and rabies 723; as sedative 90, 127; storage of 19; see also buccal midazolam  
midwifery: compassion in 142–3; universal requirements for 139  
midwives: in antenatal care 136, 143; giving health advice 144; on-call 97; suction devices for 109  
MIF (microimmunofluorescent) antibody test 676  
mifipristone 182, 228  
migraine 203, 382, 384, 389, 617–18  
military tuberculosis 666–8, 702–3  
milk: diluted 806; therapeutic 521, 523, 526, 529  
milk protein intolerance 380, 383, 386, 565, 569  
milrinone 455  
miltfosine 735  
Minerva cast 407  
minor surgery, minimum instruments for 15  
minor wounds 662, 762–3  
miscarriage: blood loss due to 171; and domestic violence 302; and malaria 276; management of 180–3, 228; and multiple pregnancy 232; types of 179–82  
misoprostol: and asthma 255; and atonic uterus 318; in emergency room 110; and emergency transport 97; and EmONC 306; and fetal distress 232; and induction of labour 152–3, 209–10; and inverted uterus 250; and IUD 228–9; in management of miscarriage 180, 182–3; and oxytocin 151; and PPH 190, 192, 304, 319  
missed miscarriage 179  
missile injuries 662, 794, 800  
mites 432, 625, 675–7, 710  
mitral commissurotomy 254, 452  
mitral regurgitation 254, 452, 455, 570  
mitral stenosis 252–4, 452, 570  
MMR (measles-mumps-rubella) vaccine 93, 95, 681, 711, 721  
mobile screens 69  
Modified Children's Coma Score 650  
molar pregnancy: blood loss due to 169, 171; and hyperemesis 138, 251; and hypertension 202; management of 183; and pre-eclampsia 202  
molluscum contagiosum 657, 689, 708–9  
monoamine oxidase inhibitors 507  
monoarthritis 666, 668, 756  
monocytic leukaemia 582  
mononucleosis, infectious 381, 427–8  
Monteggia fracture 768  
Moro reflex 351  
morphine: in anaesthesia 130; and appendicitis 285; BNF advice on 73; for children 77, 79, 81–4; in emergency room 110; and heart failure 40, 253; in high-dependency care 68, 853; and hypercyanotic spells 450; IV dosage of 74; in labour 150; and neonatal apnoea 365; non-oral administration of 83; in OT 14; as pain relief 72–4, 76; parental anxiety about 91; in placenta removal 326; in pregnancy 175–6; prevention of nausea and vomiting due to 75; and rabies 723; and respiration 88; safe use of 19–20; and tetanus 662; in trauma 777–8; WHO advice on 73; see also oral morphine  
morphine toxicity 84  
mortuary department 10  
mosquitoes: and dengue fever 681; and filariasis 755, 757; killing 278; in malaria 736–7; preventing breeding 142, 685; and VHFs 726; and yellow fever 729  
mother and baby, emergencies for 157  
mothers: advice card for 892; discharge from hospital 156; mental health of 292–3  
motor development, delayed 514, 613  
motor difficulties 401, 663  
motor function, testing 595  
motor system, examination of 30  
motor tone 376  
mourning 110–11, 113–17, 119–20, 711  
mouth lesions 518, 566  
mouth-to-mouth breaths 46  
mouth-to-mouth resuscitation 48; for adults 37, 46, 48; and electrical injuries 795; for infants 60, 338–9  
mouth-to-nose ventilation 797  
mouth ulcers 71, 517, 604, 608, 720  
movement disorders 289, 570, 602, 604  
moving needle technique 71  
moxifloxacin 670  
Mozambique 587, 645  
MRCP (magnetic resonance cholangiopancreatography) 567  
MRI (magnetic resonance imaging): and cancer 227, 578; cardiac 174; and coma 596; and encephalitis 606; and hypopituitarism 504; and spinal injury 784  
MSU (midstream urine) 28, 221, 245  
MTCT (mother-to-child transmission of HIV) 98, 273–5, 687, 694–5; prevention of see PMTCT  
MUAC (mid upper arm circumference): and malnutrition 516–17; and nutritional status 462, 464, 467, 493, 873  
mucopolysaccharidoses 839  
mucositis 571, 580–1, 717  
mucous membranes, dry 138, 262, 271, 463, 494  
multi-drug resistance (MDR), and antibiotic overuse 357  
multi-drug-resistant (MDR) TB 288, 356, 665, 668–70  
multi-drug-resistant (MDR) typhoid 672–4  
multi-organ failure 68, 167, 487–8, 647–8, 659  
multibacillary leprosy 645–6  
multidisciplinary team meetings 578  
multigravida 136, 147–8, 152–4  
multiparity, grand 186, 191  
multiparous women: cervical dilation in 148, 311; forceps delivery in 247; manual rotation in 239; oxytocics in 215; and transfusions 24; use of term 136; uterine rupture in 151, 186, 216; vaginal delivery in 238  
multiple birth: and polycythaemia 360; postpartum management of 234; as single parity 136  
multiple personality disorder 820  
multiple pregnancy: antenatal monitoring in 233; and cord prolapse 246; dating of 137; and fetal distress 231; and hyperemesis 251; risks of 232; terminologies for 136  
multivitamin supplements 346, 444, 522, 558, 705  
mumps 602, 686, 721  
murine typhus 675–6  
muscle, dead 802  
muscle guarding 178  
muscle relaxants: in anaesthesia 124, 127; and intubation 130; and magnesium 207; and pain relief 76; uterine 152  
muscle spasms: and palliative care 89; and spinal cord injury 406, 408, 410–11; and tetanus 661  
muscle strength 411, 616  
muscle weakness: and botulism 640; and Cushing's syndrome 503; and hypokalaemia 550; and rheumatic disease 569, 574  
muscular dystrophies 574, 613, 615–16  
musculoskeletal pain 85, 244, 569  
mushroom poisoning 488  
MV (minute ventilation) 36, 131  
MVA (manual vacuum aspiration) 158, 162–3, 177, 180–3, 181, 306  
MVPP (mustine, vinblastine, procarbazine, prednisolone) 577, 583  
myalgia: and iron dextran 173; and leptospirosis 647; and mastitis 222; and relapsing fever 655; and scrub typhus 677; and VHFs 727  
myasthenia gravis 207, 574, 615  
*Mycobacterium avium* complex (MAC) 705, 710  
*Mycobacterium leprae* 645–6  
*Mycobacterium tuberculosis* 633, 665, 669, 699, 701  
*Mycobacterium ulcerans* 641  
*Mycoplasma*: and anaemia 383; and encephalitis 602–3, 605; and HIV 704; and puerperal sepsis 220  
*Mycoplasma pneumoniae* 269, 440, 602, 701  
mydriatics 30, 569, 572, 588, 591  
myelitis 602, 604  
myeloblastic leukaemia 582  
myelomeningocele 620  
myelopathy 706–8, 753  
myelosuppression 582  
myocardial contusion 776, 781  
myocardial infarction 226, 455, 776, 781  
myocardial ischaemia 255  
myocarditis: and chickenpox 680; and heart failure 454–5; and leptospirosis 648; and mumps 721; and relapsing fever 655; in rheumatic disease 570–1; and rickettsial disease 675; and scrub typhus 677; and trypanosomiasis 730  
myoclonic jerks 84, 604–5, 720  
myoglobinuria 796, 816  
myomectomy, and uterine rupture 186  
myopathy 77, 422, 574, 706–8  
myositis 658, 680  
myotoxicity 815  
N-acetylcysteine 486, 488, 810, 812, 814–15, 814  
NAIP (neuronal apoptosis inhibitory protein) 613  
nalidixic acid 389, 480, 544, 551  
naloxone: in anaesthesia 124; as emergency treatment 43, 110; and morphine 20, 73–4; for neonates 330, 335, 340, 365; and overdose 811; and respiratory depression 208  
nappy rash 820  
naproxen 570, 573  
narcotics 19, 73, 351, 365, 812  
nasal cannulae 59; clean 142; and CPAP 845, 846; in emergency room 109; in high-dependency care 69; and oxygenation 59, 362, 439  
nasal flaring 58, 361, 430, 438  
nasal intubation 131, 787, 839  
nasal mask, in high-dependency care 67  
nasal PEEP 339  
nasal septum erosion/necrosis 845  
NASG (non-pneumatic anti-shock garment) 170, 178, 195–6, 195, 199, 249–50  
nasogastric feeding: in ALF 488; in bronchiolitis 431; and burns 806; and cancer treatment 581; in diarrhoea 558; in heart failure 455; in malnutrition 518, 525  
nasogastric suction 222, 305  
nasogastric tube: in coma 268; for decompression 636; in diaphragmatic hernia 365; for disabled children 401; drugs via 17; in emergency room 110; for gastric lavage 812; and ileus 263; inserting 863–4, 863; in meningitis 599; and neonatal emergencies 349; in palliative care 86–7; procedures for use 16; in rehydration 556; and renal failure 482; in severe malaria 280; and tetanus 375, 661; and trauma 779; and ventilation 61  
nasopharyngeal airway, use of 56–7  
nasopharyngeal aspirate 668–9, 701  
nasopharyngeal lesions 586  
nasopharyngeal tube 56, 132, 424, 430, 844  
nasopharynx, ulcerations of 678  
natamycin, for corneal ulcers 591  
national immunisation days (NIDs) 92  
nausea, and anaphylaxis 24  
nausea and vomiting: and chemotherapy 580; and dehydration 394; and diabetes 261; and encephalitis 602; and headache 389; and migraine 617; and mumps 721; and opioids 72, 75, 83; and peritonitis 305; and poliomyelitis 722; and relapsing fever 655; in palliative care 86; in pregnancy 138, 251  
nebulised adrenaline: and anaphylaxis 258, 425; and group C23; in emergencies 35, 42; and measles 720  
nebulised salbutamol: and anaphylaxis 258, 425; and asthma 256; and dyspnoea 88; in emergencies 37  
nebulised saline 88  
nebuliser, in emergency room 110  
NEC (necrotising enterocolitis) 344, 347, 371, 376–8, 565, 859  
*Necator americanus* 748, 750  
neck: anatomy of 772; broken 241; care of in CNEP 848; reduced mobility of 130, 839; severe extension of 40  
neck bruit 451  
neck examination, in trauma 779  
neck flexion 487, 793, 845, 866  
neck pain 428, 618–19, 783  
neck protector 847  
neck seal 847–8, 847  
neck stiffness: and encephalitis 602; and meningitis 267, 269, 597–8; and meningococcal disease 650; and pneumonia 269, 437  
neck swellings 333, 630, 632, 644  
neck veins, distended 781, 861  
neck X-ray 429  
necrotising fasciitis 221, 305, 642, 658, 660  
necrotising retinochoroiditis 747  
NECT (nifurtimox-efornithine combination treatment) 731  
needle criothyrotomy 840–1  
needle pericardiocentesis 62, 773, 861–2, 862  
needle thoracocentesis 842; and bronchiolitis 431; and tension pneumothorax 37, 364, 773, 841–2  
needles: care with 8; unsterilised 688  
needlestick injuries 5–6, 275, 314, 762, 764  
negative pressure system 847  
neglect, as abuse 96, 402, 796, 818–20  
*Neisseria*, and APH 183  
*Neisseria gonorrhoeae*: and conjunctivitis 356; as STI 656–8, 825  
*Neisseria meningitidis* 268, 593, 597, 599–601, 649  
nelfinavir 715–16  
nematodes 748, 755–6  
neomycin 93, 356  
neonatal care, basic aspects of 330  
neonatal care chart 889  
neonatal chickenpox 291  
neonatal conjunctivitis 350, 353, 356–7, 590  
neonatal deaths: and multiple pregnancy 232; and vasa praevia 186  
neonatal emergencies, drugs for 348  
neonatal examination 333–4, 399–400

- neonatal hepatitis 368, 632  
 neonatal hypoglycaemia 351, 354, 373–5, 500  
 neonatal hypothermia 207  
 neonatal infections: antibiotics for 357–8; danger signs for **345**; deaths due to 330; preterm 331; preventing 350; recognising and treating 352–3  
 neonatal jaundice 138, 380  
 Neonatal Life Support (NLS) 335  
 neonatal meningitis 352–5, 597  
 neonatal mortality: estimations of 330; and prolonged pregnancy 150  
 neonatal nephrotic syndrome 475  
 neonatal osteomyelitis 621  
 neonatal resuscitation 306; air or oxygen in 338; algorithms for **341**; and anticonvulsants 207; capacity for 143; drugs in 339–40; environment and family in 340; equipment for 331–2, 335–6; in normal labour 154; poor response to 341–2; quality of 398; sequence of actions 336–9; and vacuum delivery 307  
 neonatal sclerosing cholangitis 491  
 neonatal sepsis: antibiotics for 355; and bilirubin levels 368; as cause of death 156; and diarrhoea 545; infections causing 106; origins of 350  
 neonatal tetanus: and immunisation 93, 95, 333; infection with 660–1; and muscle spasms 375; prognosis for 663; and umbilical discharge 357, 633  
 neonatal thyrotoxicosis 501  
 neonatal treatment chart **890**  
 neonates: acidosis in 340; acute blood loss in 340; anaemia in 21; anaesthesia for 127; cardiac failure in 453–4; cyanosis in 335, 338, 353, 446–7; danger signs after discharge **346**; feeding volumes for **345**; fluid requirements for 347–8, 882; immunisation of 95; intubation of 337, 839–40, **839**; keeping warm 336; management of healthy 332; neutral position of head and neck **336**; normal temperatures for 349–50; pain in 76; premature *see* preterm neonates; preparation and care for 330; respiration of 37, 131, 334–5; screening for SCD 533; and traditional practices 106; transfusions to 22  
 Nepal 645, 733  
 nephritis: appearance of symptoms 476; and generalised oedema 388; and mumps 721; and relapsing fever 655; reversible 753; on ultrasound 472; and VAD 513  
 nephrocalcinosis 472, 479  
 nephropathy: membranous 476; and schistosomiasis 753  
 nephrotic syndrome: and ARF 481; in children 475; fluid depletion in 470; and generalised oedema 388; and SCD 539; and SLE 573; steroid-sensitive and steroid-resistant **475**; and *Streptococcus* 659  
 nephrotoxicity 108, 288, 292, 731  
 nerve blocks 70, 84, 128, 181  
 nerve compression 84–6, 266, 587  
 nerve pain 80, 84–5  
 nerve palsies 351, 389, 617, 791  
 nerve transection 776, 858  
 neural tube defects 401–2, 515  
 neuroblastoma 406, 572, 575, 577–9, 584–5, 587  
 neurocysticercosis 389, 750  
 neurodegenerative disease 89, 91, 402–3  
 neurofibromatosis 475, 510

 neuroleptic malignant syndrome 509  
 neuroleptics 508  
 neurological deterioration 406, 652, 667  
 neurological disease 93, 660  
 neurological examination 30, 208, 268, 387, 402, 593, 779, 797  
 neurological failure: emergency treatment for 43; resuscitation in 40–1; in RICP 267; signs and symptoms **43**; in trauma 777  
 neurological impairment 607, 667, 688–9, 798  
 neurological state: abnormal 376, 534; measuring 884  
 neuromuscular disorders 131, 402, 595, 843  
 neuropathic pain *see* nerve pain  
 neuropathies, common 613  
 neurosurgery 583  
 neurosurgical disorders 618  
 neurotoxicity 493, 579, 706, 815–16  
 neutropenia: and cancer 579–80; cyclic 380; and folic acid 515; and HIV 698  
 nevirapine (NVP): and breastfeeding 274–5; drug interactions of 699; in HIV-exposed children 694; for infants 698; and liver enzymes 712; in pregnancy 695; side effects of 709; in South Africa 98; and syphilis 358; and TB 704  
 NGOs (non-governmental organisations) 11, 117, 120, 576  
 nicotine poisoning 814  
 nicotinic acid 513  
 nifedipine: and hypertension 203; and premature contractions 330; as tocolytic 245–6; as vasodilator 208, 253  
 nifurtimox 730–2  
 Niger, FGC in 301  
 Nigeria: FGC in 301; hypocalcaemia in 514; traditional medicine in 104–7  
 night blindness 512, 591  
 nightmares: and grief 115, 118; and opioids 84; and sexual abuse 821  
 nipples, supernumerary 352  
 Nissen fundoplication 564  
 nitazoxanide 754  
 nitric oxide dysregulation 533  
 nitrofurantoin: and bladder damage 304; and G6PD deficiency 540–1; and urinary catheterisation 314; and UTIs 473; and VUR 480  
 nitrogen mustard 583  
 nitrous oxide 14, 75, 150, 778  
 NNRTIs (non-nucleoside reverse transcriptase inhibitors) 275, 697–8, 700, 704, 715, 717  
 nodulectomy 758–9  
 noma *see* cancrum oris  
 non-accidental injuries 96, 572, 770, 808, 819; sites for **819**  
 non-Hodgkin's lymphoma 381, 582–3, 705, 710  
 non-maleficence 98  
 non-rebreathing valve 129  
 non-shockable cardiac rhythms 62–4, 62  
 non-verbal communication 393, 403  
 normal saline: in emergency room 110; in fluid administration 16; and shock 169, 460  
 Norwegian scabies 708, 710  
 nose breaths 46  
 nosocomial infection *see* hospital-acquired infection  
 NRTIs (nucleoside reverse transcriptase inhibitor): as backbone of therapy 697–8; for HIV-positive mothers 275; as second-line treatment 700; side effects of 709, 717  
 NSAIDs (non-steroidal anti-inflammatory drugs): and anaesthesia 127; and dengue 684; and G6PD deficiency 540; and haemophilia 543; and headache 389; and leprosy 646; as pain relief 72, 82, 85; and paracetamol 71, 81; in post-operative care 303; postpartum 176; in pregnancy 175; and rheumatic fever 570, 573; side effects of 86  
 NTS (non-typhoidal salmonella) 524, 551, 598  
 nuclear imaging 578  
 nurse attendants 3  
 nursing: for burns 810; and cancer treatment 575; of children 392–3; high-dependency 77, 487  
 nursing staff: code of ethics for 98–9; in intensive care 68; in operating theatre 15  
 nutrition: and ARF 482; and pressure sores 416–17  
 nutritional assessment 30, 174, 581, 871–3  
 nutritional management: in antenatal care 175; and cancer treatment 581; and CLD 491, 493; and HIV 700–1, 705, 713; and malnutrition 517  
 nutritional status: and ALTEs 387; documenting 30; and heart failure 253; and lymphadenopathy 381; and malaria 280; and oedema 388; and shock 462, 464, 467; and vomiting 384  
 nuts: allergies to 258, 425; fibre in 411; folic acid in 515; and migraine 617; vitamin B1 in 513  
 nystagmus: and cataracts 591; and convulsions 280, 741; as drug side effect 608; and ketamine 125; and Wernicke–Korsakoff syndrome 251  
 nystatin: and candidiasis 357, 657, 704; and dermatosis 523; and measles 720; prophylactic 488  
 O-negative blood 169, 194, 250  
 obesity: and assessing gestational age 137; and diabetes 261; and pulmonary embolism 223  
 obsessional behaviours 294–6, 404  
 obsessive-compulsive disorders 293, 295, 509  
 obstetric anaesthesia 121  
 obstetric emergencies 21, 42–3, 75, 97, 171  
 obstetric haemorrhage: and Caesarean section 313; massive 226; and shock 39, 170; and transport 97  
 obstetric history 136, 232, 246, 334  
 obstructed labour: in adolescents 395; Bandl's ring in 215; and Caesarean section 313–14; and delays 153; diagnostic issues in 213; emergency treatment for 214; fetal death in 215, 231, 321; and fetal distress 231–2; and oxytocin 151; and pain 69; partogram in 212; pathway of care in 214; prolonged 186, 216, 228; and puerperal sepsis 220; recognition of 211; transport for 97; and uterine rupture 186, 215  
 obstructive shock 166, 459  
 occiput-anterior (OA), position 149, 238–9, 312  
 occiput-posterior position 238–9 deflexion in 240; management of 238; rotation to 236; vacuum delivery in 310  
 oedema: and pre-eclampsia 201; *see also* generalised oedema

- pelvic X-rays 788, 791–2, 791
- pelvis: anatomy of 144; contracted 235, 247
- penetrating injuries: abdominal 781–2, 786, 802; to chest 781; in children 770; haemodynamic instability after 865; to the head 794; minor 641; and oxygenation 772; and pericardial effusion 861; and resuscitation 39, 461–2, 775; and RPA 428; and shock 39; and stab wounds 764
- penicillamine 493
- penicillin: in ALF 488; and anthrax 679; and botulism 641; and cholestasis 493; in emergency room 110; in episiotomy 325; and glomerulonephritis 477; in lymphadenitis 631; and malaria 744; and mastoiditis 428; and measles 720; and meningitis/encephalitis 41; and neonatal infection 352, 355–7; and nephrotic syndrome 476; and PPRM 245; and pressure sores 417; and relapsing fever 655; and SCD 174; and septic shock 468, 532; side effects of 709; and *Streptococcus* 658–9; and syphilis 289–90, 356; and tonsillitis 427; and wound abscess 305; see also oral penicillin
- penicillin allergy 93, 258, 648
- penicillin resistance 626, 651
- Penicillium maffei* 689
- pentamidine 701–2, 730–1, 734–5
- PEP (post-exposure prophylaxis): for HIV 275, 396, 824; for STIs 656
- peptic ulcer 382, 563
- percussion, as diagnostic tool 772
- percutaneous nephrostomy 479, 482
- pericardial effusion 791, 861
- pericardial tamponade 62–3, 777, 781
- pericarditis: and chickenpox 680; constrictive 454, 492; and generalised oedema 388; in pneumonia 269; in rheumatic disease 571; and TB 667, 669
- perimeter fence 3–4
- perinatal infection 291, 331, 696
- perinatal mortality 144, 261, 276, 286
- perinatal TB 288
- perineal oedema 314
- perineal tears, repairing 196
- perineal trauma 71, 143, 153, 196, 238, 240
- perineum, local anaesthesia to 324
- periodontal disease 705
- peripheral artery lines 852
- peripheral blood smear 369, 533
- peripheral lymph node TB 669
- peripheral neuritis 287, 513
- peripheral neuropathy: causes of 613–14; and chemotherapy 579; and HIV 706, 708; and lead poisoning 814; and trypanosomiasis 731; and vitamin E deficiency 491
- peripheral perfusion, in obstetric haemorrhage 188, 195
- peripheral vasodilatation: and overheating 194, 250; in salicylate poisoning 812; and shock 167, 465
- peripheral veins, dilated 406
- peritoneal dialysis 283, 483–4, 744, 868, 870
- peritoneal lavage 222, 782
- peritonitis: and amoebiasis 747; and appendicitis 285, 634; and dialysis 484; and ectopic pregnancy 177–8; and gastroenteritis 271; generalised 215, 285, 378; pelvic 304, 314, 658; perforative 637; in post-operative care 305; and puerperal sepsis 221; and rectal reduction 635; and shock 166, 464; and *Streptococcus* 659; treatment of 222; and typhoid 672, 674; and urinary catheterisation 304
- permethrin 625, 655, 729, 735
- peroneal muscular atrophy 613
- persistent diarrhoea: and HIV 689, 705; and Kaposi's sarcoma 710; and malabsorption 566; and malnutrition treatment 526; management of 557–8, 557, 566; nutrition for 558–9, 558; risk factors for 556–7; use of term 545
- persistent fetal circulation 339, 364
- persistent pulmonary hypertension of the newborn 362, 446
- persistent vomiting: in palliative care 83, 87; and upper gastrointestinal disorders 563; and vitamin A deficiency 513
- personal hygiene 4, 300, 393
- Pertussis disease 623–4
- pertussis 653–4; health burden of 67; immunisation against 92; and pneumonia 436–8, 440; and vomiting 384
- pessaries 192, 326
- pesticides 278, 812
- petechiae: and anaemia 386; in dengue 683; and endocarditis 453; and haemophilia 544; and leptospirosis 647; and measles 719; and relapsing fever 655; and scurvy 514; and septicemia 352; and sexual abuse 822; and toxoplasmosis 747
- petechial rash 597–8, 683
- pethidine 150, 176, 365, 534
- petrol, ingestion of 812–13
- Pflanzenstiel incision 314–15
- PFIC (progressive familial intrahepatic cholestasis) 491
- pGALS approach 569
- PGL (persistent generalised lymphadenopathy) 696
- phaeoerythrocytoma 202
- pharyngeal airways 55
- pharyngeal ulcers 726
- pharyngitis 436, 570, 615, 647, 658–9
- phenacetin 540–1
- phenobarbital 280, 372–3, 376, 612, 741
- phenobarbitone: and CSE 611; in emergency room 110; and epilepsy 606–7; maternal 341; in neonates 354, 372; and tetanus 662; withdrawal of 610
- phenobarbitone poisoning 488
- phenoxymethylpenicillin 357, 375
- phenylketonuria 404, 510
- phenytoin: and arrhythmias 813; and CSE 611; and eclampsia 207; in emergency room 110; and epilepsy 606, 795; and folic acid 515; IV administration of 18, 852; in neonates 372; and nerve pain 84–5; in severe malaria 280, 283
- phenytoin poisoning 488
- phimosis 630
- phlebitis 611, 731, 776, 858
- phosphate, and lead poisoning 814
- phosphate enemas 459–60
- phosphate retention 485
- phosphorus supplements 346
- photo-colposcopy 822
- photophobia: and eye disorders 590–1; and meningitis 269; and vitamin A deficiency 517, 523
- phototherapy 360, 367, 369–70
- Phthirus pubis* 654
- physeal fracture 769
- physical abuse of children 818–19, 821, 826
- physical stimulation 517, 528
- physiological jaundice 367, 369
- physiotherapy: and amputation 800; and bleeding 89; and botulism 641; and bronchiectasis 704; and cerebral palsy 401, 403; and coma 268; and cystic fibrosis 444; post-delivery 321; and rheumatic disease 572, 574; and spinal cord compression 89; and suppurative lung disease 848–50
- PICUs (paediatric intensive care units) 466–7, 469
- PID (pelvic inflammatory disease): and abdominal pain 158, 383; and epididymitis 658; and infertility 395; and obstetric haemorrhage 177–9; and post-operative care 304; and TB 286
- Pierre-Robin syndrome 77, 130, 429, 839
- Pinard's stethoscope: in antenatal care 137; as basic equipment 29, 230; in labour 143; and viability of pregnancy 180
- pinworms 749–50, 822
- piperacillin, and burns 809
- piperacillin-tazobactam 355
- piperazine (PQP) 279, 740, 746
- piperazine 750
- PIs (protease inhibitors) 697–8, 700, 715–17
- PISCES trial 539
- PITC (provider-initiated testing and counselling) 690
- pituitary adenoma 503
- pityriasis alba 646
- pityriasis versicolor 627, 646, 709

- pizotifen 617–18  
 placenta: accidental incision of 340, 366; aiding separation of 190; delivery of 155; examining 155–6, 156; low implanted 185; manual removal of 197–8, 306, 326–7, 326; in miscarriage 183  
 placenta accreta 197–9, 317–18, 326  
 placenta praevia: and anaesthesia 122; and APH 183, 185; and ARM 151; and Caesarean section 174, 313, 315–18; and cervix sweeping 150; and cord prolapse 247; and malpresentation 241; and retained placenta 197; and trauma 785; and vaginal bleeding 232  
 placental abruption: and abdominal tenderness 231; and anaemia 371; and APH 183, 185–6; and Caesarean section 785; and domestic violence 302; and induced labour 150; and pre-eclampsia 201–2, 209; in SCD 175; and trauma 786  
 placental failure 228  
 placental perfusion 121, 254, 342  
 placental separation: and blunt trauma 785; premature 21; signs of 155, 190  
 plaque 671, 678–9, 728  
 plants, poisonous 814  
 plasma, freeze-dried 22, 160, 162–3, 184, 188  
 plasma expanders 335, 462, 684, 775  
 Plasma-Lyte 261–3, 265, 494–6  
 plasmapheresis 476–7, 614  
*Plasmodium falciparum* 26–7, 276, 279, 736–9  
*Plasmodium knowlesi* 736  
*Plasmodium malariae* 276, 284–5, 736, 745  
*Plasmodium ovale* 276, 284–5, 736–7, 745  
*Plasmodium vivax* 276, 284–5, 736–8, 745–6  
 plaster of Paris 764, 766, 854  
 plastic aprons 9, 142, 728, 808, 810  
 plastic wrap, and heat loss 330, 332, 335, 347, 848  
 platelet count, normal **879**  
 platelet transfusion: and dengue 684; preparation for 22; prophylactic 580; reactions to 24  
 play, in children's wards 6–7  
 play therapy 120  
 pLDH tests 284–5, 737, 745  
 PLEDs (periodic lateralising epileptic discharges) 604  
 pleocytosis 355, 598, 603–4, 647, 707  
 pleural effusions: and anthrax 678; and dengue 684; diagnostic tests for 843–4; drainage of 14; infected 632; and pneumonia 269, 440; and scrub typhus 677; in TB 667–9; treatment of 441–2  
 pleural infection 773, 842–3  
 pleural inflammation 269  
 pleuritic chest pain: and anthrax 678; and empyema 633; and hydatids 751; and pneumonia 269, 437; and pulmonary embolism 223  
 plunger withdrawal technique 71  
 PMTCT (prevention of mother-to-child transmission of HIV) 273–5, 398, 524, 694–6, 701  
 pneumatoceles 440, 633  
 pneumatoxis intestinalis 377–8  
 pneumococcal vaccination 539, 544, 658, 660  
*Pneumococcus*: antibiotic resistance in 598; and HIV 701; and SCD 535, 538; vaccination against 175  
 pneumocystis pneumonia *see* PCP  
 pneumocystis prophylaxis 670  
 pneumonia: antibiotics for 282, 551; and ARI 436–7; on chest X-ray 437; in children 437–40; chlamydia 590; and diarrhoea 551, 557; emergency treatment of 269; and febrile seizures 609; and heart failure 522; and HIV 688, 701; hypostatic 268, 597; immunisation against 436; inhalational 494; and malaria 284, 743; and measles 719; and mumps 721; in neonates 339; and pertussis 654; and plague 679; and poisoning 813; and relapsing fever 655; and salmonella 674; and *Staphylococcus* 679; and *Streptococcus* 659–60; with wheezing 430  
 pneumonitis: chemical 106, 364; and chickenpox 291; hemorrhagic 647; and scrub typhus 677; and strongyloidiasis 759  
 pneumothorax: and asthma 61, 255, 257, 434; and bronchiolitis 431; and cannulation 858; and chest drain 843; and CPAP 845; and cystic fibrosis 445; in neonates 339, 341, 361–2, 364; and oxygenation 772; and thoracocentesis 842; in trauma 780–1; on X-ray 791  
 Pneumovax 174, 532, 538  
 PNS (peripheral nervous system), and HIV 706  
 pocket mask 60  
 pocketbooks 10–11  
 PODC (Paediatric Oncology in Developing Countries) 578, 587  
 podophyllin 657–8  
 poisoning: and botulism 640–1; in children 384; deliberate 810, 812, 819, 823; laboratory explorations in 814–15; management of 811–12; and RICP 267–8; and shock 167; symptoms and signs of 810–11; and traditional medicine 104; types of 810  
 poliomyelitis 722; and botulism 640–1; and breathing difficulties 37; and CNEP 846; immunisation against 92, 95, 398, 711  
 political violence 118  
 polyarthritis 108, 570, 572–3, 659  
 polycystic kidney disease 478  
 polycythaemia: and bilirubin levels 368; and blood transfusion 23; and diabetes 351; and hypoglycaemia 373; neonatal 332, 360–1; and seizures 371  
 polydipsia: and diabetes 504; and DKA 262, 494; and hypercalcaemia 407  
 polyglycolic acid suture 317, 324  
 polyhydramnios: and ARM 151; and cord prolapse 246; in diabetes 261–2; examination of 231; and multiple pregnancy 232; and oesophageal atresia 377; and PPRM 244  
 polymeric diet 561, 563  
 polyps, cervical 183  
 polysaccharide vaccines 653, 660, 674  
 polyuria: and diabetes 261, 504; and DKA 262, 494; and hypercalcaemia 407; and shock 167  
 POND4kids 576–7, 587  
 Ponseti management 623  
 popliteal angle 343–4  
 pornography, of children 820  
 porphyria 383, 478, 593  
 portal hypertension: and ALF 486; and CLD 489–92; and cystic fibrosis 445; and haemetemesis 563; and hepatitis 686; and schistosomiasis 753; and umbilical discharge 633  
 portal thrombosis 633  
 portal vein thrombosis 490–1, 859  
 porters 2, 5, 196, 396  
 positive pressure ventilation: in anaesthesia 127, 131; face masks for 60, and respiratory distress 361; in septic shock 468; use of 133, 257, 845  
 possetting 384  
 post-eclampsia 210  
 post-mortem examination 10, 91  
 post-operative adhesions 636  
 post-operative care 303–5  
 post-operative pain, managing 76  
 post-operative shock 215  
 post-scarlet fever rash 385  
 post-streptococcal glomerulonephritis 476–8, 626  
 posterior arm, delivery of 218  
 posterior urethral valves 472–3, 481, 485, 633  
 postgraduate education centres 10–11  
 postnatal care: for disabled children 399; for HIV-positive mothers 275; routine **157**; traditional birth attendants in 105  
 postnatal care programmes 144, 156–7  
 postpartum haemorrhage (PPH): definition of 189; and anaemia 21, 136; and anaesthesia 199; and APH 189; and asthma 255; causes of **191**; emergency treatment for 43; and inverted uterus 248; management of 191–6; and multiple pregnancy 232, 234; pathway of care for **199**; and pituitary infarction 200; and placenta praevia 318; and post-operative care 304; and pre-eclampsia 208; prevention of 154, 174, 189–90; and resuscitation 35–6; and retained placenta 197–8; and shock 169; and shoulder dystocia 217, 219  
 postural drainage 407, 444, 704, 848–50, *849*  
 postural hypotension: and antidepressants 294; and antipsychotics 508; and botulism 640; in CRF 485; and Methyldopa 202; post-operative 305; and spinal cord injury 407  
 posture, and neurological assessment 40  
 potassium: adding to IV fluids 18, 272, 852; in ARF 482; in diarrhoea 550–1; and DKA 263–5, 495–6; and furosemide 455; in rehydration 39  
 potassium chloride: and dehydration 272, 549; and diabetes 262; in DKA 265  
 potassium iodide 501, 520, 522  
 potassium permanganate 626  
 potassium replacement: in asthma 256; in hyperemesis 251; for neonates 348  
 Pott's disease 622, 624  
 pouch of Douglas 178, 305  
 poverty: and cancer 575; and sexual exploitation 395; and stillbirths 229; and traditional medicine 104; and VAD 512  
 povidone iodine 8, 351, 353, 626, 723  
 PPRM (pre-term pre-labour rupture of membranes) 231, 244–6, 331  
 PPV (patent processus vaginalis) 628–9  
 Prader-Willi syndrome 429, 503  
 pralidoxime 810, 813  
 praziquantel 751–4  
 prazosin 815, 817  
 pre-eclampsia: in adolescent girls 395; and anaesthesia 121, 124; antenatal care for 136–7; and APH 186; complications of 208–9; and diabetes 261–2; and ergometrine 154, 190; and fetal distress 231; and heart failure 252; and hypertension 201–2; management of 202; and nifedipine 246; and pulmonary embolism 223; and RICP 265; and SCD 175; severe 207–8, 210–11; signs of 137, 144, 147; and stillbirth 229; in triage 32; and urinary catheterisation 304; volume expansion in 208  
 pre-operative management 75–6  
 pre-renal failure 471, 481–2, 550, 651  
 pre-verbal children, and pain 70  
 prednisolone: and adrenal crisis 500; and airway resuscitation 35; and asthma 432–3; in cancer treatment 576–7, 580, 582; and diphtheria 645; and encephalitis 606; equivalents in other drugs 881; and haemangiomas 632; and haemolytic anaemia 542; and IBD 563; and iritis 591; and leprosy 646; and nephrotic syndrome 475–6; and PCP 701; and rheumatic disease 570–1; and sleep-related upper airway obstruction 430; and trypanosomiasis 731; *see also* oral prednisolone  
 pregnancy: accurate dating of 137; in adolescents 395; anaemia in 21; assessing viability of 180; attempted termination of 176; blood loss in 166–71; blood loss in **774**; breathing difficulties in **165–6**; burns in 803–6, 808; circulation management in 32, 805; complications due to FGC 300; diagnosis of complications of 158; emergencies in 97, 109; exaggerated signs of 183; fits in 41; fluid requirements in **883**; fluid resuscitation in 38, 168, 775; and folic acid 515; and high-dependency care 67; hypertension in 40, 200–1; and immunisation 94–5; improving outcomes in 398; ketamine in 125; life-threatening complications of 166; malaria in 276–8, 398; and mortality 139, 395; mumps during 721; prolonged 150, 217, 231; radial pulse in 39; and respiratory rates 36; and SCD 174; sedation in 76, 127; severe malaria in 280; and sexual abuse 821–2; shock in 167–71, 172, 186, 216; sonography in 14; thrombogenesis in 223; traditional medicine in 107–8; trauma in 785–6; unintended 275, 695; vitamin A in 156; *see also* early pregnancy; ectopic pregnancy; late pregnancy; molar pregnancy; multiple pregnancy  
 pregnancy-related events 136  
 pregnant women: abuse and exploitation of 96; anaesthesia for 121–2; ARV therapy for 695; blood pressure in 38; blood transfusions for 21; cardiac arrest in 52, 55, 65–6; chest compressions in 48; circulation actions for 49; diazepam for 811; drug-dependent 351, 377; heart rates in 37, 192; inserting airways in 56–7; LTBI in 288; malaria prevention in 746; morphine dosage for 20; need for resuscitation **31**; need for urgent management **32**; NSAIDs and 72–3, 76; respiratory failure in 131; respiratory rates in 187; resuscitation of 782; risk of infection 7; shock in 166; syphilis in 289–90, 356; tetanus vaccine for 663; tranaxemic acid dose for 774; transport plans for 97; varicella in 291  
 premature delivery: and jaundice 368; and malaria 276; and multiple pregnancy 232; and pre-eclampsia 209; reducing risks of 21  
 premature labour: and blunt trauma 785; in diabetes 261; and domestic violence 302; and early-onset sepsis 350; and fetal deaths 228; and MTCT 695; and multiple pregnancy 232–3; and PPRM 244–5; preventing 245, 330; signs of 32; and syphilis 228; in triage 32  
 prematurity: defining 330; fits and faints in 387; and immunisation 93; and maternal SCD 174; and *Streptococcus* 659; *see also* preterm neonates  
 presbydermia 758  
 prescribing practice 17  
 prescription charts 18–19, 852, *884*  
 prescriptions, writing 17, 852–3  
 pressure bags 170, 188, *194*  
 pressure bandage 816  
 pressure sores 417; and coma 597; likely sites for *416*; in paraparesis 403; in post-operative care 303; prevention of 418, 420; and spinal cord injuries 406–10, 415–17; treatment of 417–18  
 presumed consent 100  
 preterm neonates: airway size for 57, 130; apnoea in 365; death of 156; endotracheal intubation of 339; heat loss in 332; iron supplementation for 531; and PPRM 244; problems associated with 246, 331; and respiratory distress 362; use of term 342; and vitamin D 346  
 priapism 22, 538–9, 784, 817  
 primaquine 284–5, 541, 736, 738–9, 745–6  
 primary assessment: ABC approach to 34–7; neurological 40  
 primary tuberculosis 666  
 primigravida: effacement in 148; and malaria 277; oxytocin infusion for 152; pain control for 150; stages of labour in 147; time of delivery in 153; use of term 136  
 privacy, for adolescents 396  
 procaine benzylpenicillin 290, 358, 644  
 procarbazine 577, 583  
 prochlorperazine 90, 251, 580, 617–18  
 products of conception: evacuation of 180; partial expulsion of 179; retained 191, 197–8, 220–1, 306  
 professional bodies, publications of 12  
 professional registration system 5  
 progressive encephalopathy 707–8  
 progrenil 745

 prolonged grief disorder 113  
 prolonged labour: and PPH 191; prevention of 145, 211; and puerperal sepsis 220  
 prolonged rupture of membranes: and fetal death 215, 321; and induction of labour 150; and PPH 198; and sepsis 122, 220, 350; and *Streptococcus* 659  
 promethazine 78  
 promyelocytic leukaemia 582  
 prophylactic antibiotics: and Caesarean section 314, 316, 318; and cystic fibrosis 444; and drowning 798; in induction of labour 151; and inter-osseous infusion 860; and inverted uterus 250; for mediastinitis 812; for neonates 331, 350; in placenta removal 198–9, 326; and PPRM 245; and puerperal sepsis 212; and relapsing fever 655; and rheumatic fever 452; and ruptured membranes 228; and SCD 176; and STIs 656; and uterine rupture 186, 216; and UTIs 473–4; and VUR 480  
 prophylactic antipsychotic drugs 295  
 prophylactic antiretrovirals 6, 273–4  
 prophylactic chloramphenicol 358  
 prophylactic penicillin 475, 538, 540, 544  
 propranolol 450, 457, 469, 492, 501, 617–18  
 proptosis 584, 586  
 prostaglandin E 446, 448–9  
 prostaglandin E1 448, 451  
 prostaglandin E2 40, 448  
 prostaglandins: and heart failure 454; and oxytocin 151  
 prosthesis 279, 738  
 protective clothing 4, 6, 9–10, 142

- protein-losing enteropathy 386, 475, 546  
protein malabsorption 493  
protein malnutrition 475  
proteinuria: and filariasis 756; and HSP 571; in IgA nephropathy 477; and leptospirosis 647–8; measurement of 472; and nephrotic syndrome 475–6; and pre-eclampsia 136, 164, 201, 203; and SCD 174–5, 539; testing for 201; and yellow fever 729  
*Proteus* 580  
proteus urinary tract infections 479  
prothionamide 670  
prothrombin time (PT) 486, 491, 566, 682, 686, 816  
proton pump inhibitors 403, 564  
protozoal infection 487, 686, 705, 733, 747  
provider paralysis 44, 55  
proxymetacaine 589  
pruritus: and cholestasis 491; and CLD 490; and jaundice 381; and opioids 83; and STIs 657  
pseudo-paralysis 514  
pseudo-seizures 507  
pseudoephedrine 539  
pseudomembranous colitis 552  
pseudomembranous group 422  
*Pseudomonas*: and cancer 580; colonisation of 350; neonatal infection with 355, 358, 598; and otitis media 428  
*Pseudomonas aeruginosa*: and burns 809; and cystic fibrosis 444–5; in HIV 704; water containing 798  
psoriasis 572, 574, 642, 646, 657, 709  
psoriatic arthritis 572  
psychiatric emergencies 293  
psychiatrists, traditional 105  
psychological abuse 819–20  
psychological damage 300, 503, 821  
psychological support 89–90, 406, 573, 579  
psychopathic personality disorder 96  
psychosis: and hypercalcaemia 407; and Lyme disease 649; and SLE 573  
ptosis 815–16  
PTSD (post-traumatic stress disorder) 111–14, 121, 300, 509  
pubertal development 501, 503, 874–5  
puberty: and depression 506; precocious 503, 824; *see also* delayed puberty  
pubic hair 314, 503, 875  
pudendal block 312, 327–8  
puerperal infection 333  
puerperal psychosis 292–5  
puerperal sepsis: and Caesarean section 314; and endometritis 220; and maternal death 156; in placenta removal 326; preventing 221; and *Streptococcus* 659; treatment of 221; and urinary catheterisation 304  
puerperium: anti-thrombosis during 176; iron supplementation during 174; severe infection in 219; shock in 172; uterus during 190  
pulmonary aspiration 743  
pulmonary atresia 447–9  
pulmonary barotrauma 841  
pulmonary capillary vasodilation 490  
pulmonary contusion 780–1  
pulmonary disease, and blood transfusion 22  
pulmonary embolectomy 224  
pulmonary embolism 66, 223–6, 303–4; minimum standards for 223; signs and symptoms of 223  
pulmonary embolus: and amniotic fluid embolism 225–6; and dyspnoea 87; and puerperal sepsis 221; in resuscitation 37, 42; and shock 459  
pulmonary fibrosis 87  
pulmonary flow murmur 451  
pulmonary haemorrhage 362, 647–8, 791  
pulmonary hypertension: on echocardiogram 174; and mitral regurgitation 452; and NSAIDs 72; and rheumatic heart disease 254; and *Salmonella* 753; and upper airway obstruction 429–30  
pulmonary hypoplasia 244, 339, 362, 364–5  
pulmonary irritation 807–8  
pulmonary oedema: and amniotic fluid embolism 225–6; and anaemia 383; and drowning 796–7; and eclampsia 203; and envenomation 817; and fluid resuscitation 464–5, 468, 549; and heart defects 252, 254, 452; and heart failure 455; and leptospirosis 647; and malaria 279–80, 283–4, 738, 743; and meningococcal disease 652; and naxolone 74; and overhydration 466; and poisoning 813; and pre-eclampsia 201–2, 208; and septic shock 467; and severe hypertension 203; and spinal cord injury 407  
pulmonary parenchymal disease 365  
pulmonary sepsis 632  
pulmonary stenosis 446, 448, 451  
pulmonary tuberculosis: chemotherapy for 667; and cystic fibrosis 443; features suggesting 668; global incidence of 665; and HIV 703; and malnutrition 524; and measles 720; in pregnancy 288; treatment of 669  
pulmonary valve stenosis 449  
pulmonary vascular markings, increased 448–9, 452, 454  
pulse, slow 47, 186, 263, 266, 495  
pulse oximeter: in anaesthesia 127; in emergency room 110; in high-dependency care 69  
pulse oximetry: and assessment of respiratory failure 844; and asthma 255; in neonates 335, 362, 365–6; and oxygenation 58–9, 845; in pneumonia 269; and tetanus 663  
pulse rate: and heart failure 521–2; in labour 145, 147  
pulse volume, weak 38, 158, 547  
pulses, collapsing 255, 453  
punctate keratitis 758  
PUO (pyrexia of unknown origin) 391, 710  
pupillary dilatation: and eye disorders 588; and head injury 780, 793; and meningococcal disease 650; and neurological disorders 267, 619; and poisoning 811, 813; and uncus syndrome 266  
pupillary function, changes in 267  
pupillary responses: and coma 594–5; in emergencies 211; and red reflex 400; and RICEP 266  
pupils: pinpoint 43, 84; unequal 389, 793, 865  
purpura: and chickenpox 680; and haemophilia 544; and lymphadenopathy 381; and shock 39, 42  
purpuric rash 42, 171, 383, 468, 571  
pushing positions 145  
pVT (pulseless ventricular tachycardia) 44, 61–5, 862  
pyelonephritis: acute 286; and PPRM 244; and shock 169; and VUR 480  
pyloric stenosis 377, 384–6, 634–5, 812  
pyoderma 625–6, 658, 660  
pyogenic infections 625, 787  
pyogenic meningitis 619  
pyomyositis 620–1, 679, 697  
pyrantel 173, 530, 750  
pyrazinamide 287–8, 667, 669–71  
pyrexia: and endocarditis 456; and iron dextran 173; and mastitis 222; and tonsillitis 426; *see also* fever  
pyridoxine (vitamin B<sub>6</sub>) 251, 288, 376, 523  
pyrimethamine 706, 708, 710, 745–7, 851; *see also* SP  
pyruvate kinase deficiency 383, 539, 541  
pyuria 647–8
- Q fever 675–6  
QBC (quantitative buffy coat) 655, 730  
QT prolongation 740  
quadriplegia 407–8, 614; spastic 403–4  
Quiet Houses 120  
quinine: as antimalarial 279–81, 739–40, 746; in emergency room 110; fetal levels of 284; and G6PD deficiency 540; and hypoglycaemia 281–2  
quinine dihydrochloride 281, 740  
quinine sulphate 281  
quinolones: and G6PD deficiency 541; and otitis media 427; and typhoid 672  
quinsy 427
- rabies 605, 723–5; post-exposure treatment for 725  
rabies vaccine regimens 725  
raccoon eyes 779  
radial pulse: and organ perfusion 39; palpable 39, 775  
radiant warmers 14, 347  
radiation, from X-ray units 13  
radiculoneuritis 649  
radiological clearance 783–4  
radiotherapy: for cancer 577, 579, 583–4, 586; palliative 84–7, 89, 587  
raised intracranial pressure (RICP): and coma 268, 593, 596; and CSE 611; and encephalitis 602–3, 605; and envenomation 817; and headache 389; and hypopituitarism 504; and lead poisoning 814; and lumbar puncture 865; and meningitis 598; and meningococcal disease 651–2; and morphine 72; nausea due to 86; pathophysiology of 265–6; and respiratory rates 36–7; and resuscitation 41; signs and symptoms of 40, 266–7, 595, 618–19; suspected 124, 652, 740–1; in trauma 43, 777, 793–4; and vomiting 384  
Ramstedt's pyloromyotomy 635  
range-of-motion exercises 409–10  
ranitidine: in ALF 488; and anaesthesia 124; and GOR 564; IV administration of 852; in meningitis 599; and nausea 86; and oesophagitis 705  
rape 302, 395, 821, 827  
rapid initial assessment 30  
rapid sequence induction of anaesthesia 189, 199–200, 652  
Rapid Syphilis Test 290, 355  
Rapyd Leishman's test 28  
rashes: causes of 385; investigations in 385; pruritic papular 709; in rheumatic disease 570–1, 574; in stronglyloidiasis 759  
rats, and VHF 726  
RDS (respiratory distress syndrome) 283, 361–4, 677, 796, 845  
RDTs (rapid diagnostic tests): and malaria 28, 276, 278–80, 737–8, 746; and PUO 391  
rebound tenderness 178, 182, 221, 285, 304  
recovery position 205, 216, 266: in airway opening 45; and febrile seizures 609; placing patient in 50, 51; in RICEP 266  
recovery room 15, 77  
rectal artesunate 281, 736, 739  
rectal biopsy 636, 753  
rectal bleeding, and gastrointestinal emergencies 43  
rectal diazepam: and bleeding 88; and convulsions 742; and eclampsia 207; in emergency room 110; and epilepsy 608; and febrile seizures 609; and morphine toxicity 84; and seizures 41, 89  
rectal examination: and constipation 559; explaining 30; and forceps birth 313; in trauma 779, 782  
rectal morphine 83  
rectal pain 158, 162, 178  
rectal paraldehyde 41, 207, 373, 612  
rectal prolapse: and cystic fibrosis 443; and diarrhoea 551; treatment of 552  
rectal reduction 635  
rectal route: absorption by 17; acceptability for children 83; and loss of oral route 90  
rectovaginal fistula 215  
rectus sheath 221, 317, 484  
red blood cells (RBC): and bilirubin 366–7; in CSF 604; glomerular 869; and malaria 276, 285, 736–7, 743; on microscopy 286, 472, 868; perfusion of 166; reduced lifespan of 539; separating from plasma 171, 253, 282; in stool 28; transfusion of 25, 39, 467; in urine 782  
red cell antibodies 174, 369  
red reflex 400, 588  
reduced consciousness: and airway obstruction 35; and hypoglycaemia 40  
reflexology 86, 104  
reflex nephropathy 403, 475, 480  
refractive error 592  
refrigerators: care of 94; in high-dependency care 69; storage of drugs in 19  
regressive behaviour 113, 115, 118  
regurgitation, in neonates 349  
rehydration 557; completion of 519; and diarrhoea 544–7, 549–50, 555; and fluid overload 744–5; fluids for 481, 550; and gastroenteritis 16; inappropriate 522; normal requirements for 882; and ORS 553–4, 557; and sodium levels 271; and stroke 537  
rejection, as child abuse 820  
relaxation, progressive 86  
renal disease: and magnesium 207; and pre-eclampsia 202  
renal failure: and crude oil 106; and leptospirosis 647–8; and malaria 738; and NSAIDs 73; oliguric 485, 488, 581; in palliative care 84; and paracetamol 812; polyuric 485; and pre-eclampsia 208; and UTIs 472; *see also* ARF; CRF  
renal impairment 73–4, 84, 175, 204, 208, 253, 287, 292, 358–9, 534, 550, 677, 729, 735; and antivirals 292; and hypokalaemia 550; and opioids 74, 84; and paracetamol 73; in pre-eclampsia 208; and SCD 175; and yellow fever 729  
renal scarring 472, 474, 480  
renal transplantation 486  
renal tubular acidosis 560  
renal tubular defects 539  
renal ultrasound 286, 478  
rescue breaths: in airway management 35; in BLS 44–7; techniques for 48, 49  
research ethics 102  
reservoir bag 58: in emergency room 109; in high-dependency care 69; in oxygenation 37–8, 60  
ReSoMal: and diarrhoea 547, 550; and heart failure 522; and malnutrition 270, 463–4, 519; and other ORS 519  
respiratory acidosis 362, 434, 652  
respiratory alkalosis 812  
respiratory arrest: and amniotic fluid embolism 225; and electrical injuries 795; and magnesium toxicity 207  
respiratory depressants, overdose of 33  
respiratory depression: and anticonvulsants 125, 207, 603, 794, 811; and magnesium toxicity 207; and opioids 72, 83–4, 778; and sedation 77  
respiratory disorders: distress due to 361; and HIV 666, 701  
respiratory distress: causes of 390; and congenital syphilis 355; and CPAP 845; and cystic hygroma 632; and dengue 684; and heart failure 522; in heart failure 252; and hypoglycaemia 373; intubation in 864; investigations in 390; and leptospirosis 647; in malaria 279, 282–3, 738, 743–4; neonatal 361–5; and over-hydration 272; oxygen treatment for 58; and poisoning 810; signs of 36–7; in trauma 780; in triage 32–3; *see also* ARDS; RDS  
respiratory failure: and airway resistance 61; and anthrax 678; assessment of 55, 844; development of 131–2; and heat stroke 798; in infants and children 843; and leptospirosis 647  
respiratory infections: fits and faints in 387; in neonates 440; recurrent 566  
respiratory paralysis 614, 722, 815  
respiratory pattern, and coma 595  
respiratory problems: and fever 437; and gastric reflux 57; and pneumonia 269; in pregnancy 165–6  
respiratory rate: of children 21; monitoring of 20, 23, 25, 30, 377, 845; and oxygenation 772; at rest 36; and septicaemia 345, 352–4; *see also* increased respiratory rate  
respiratory support: modes of 132, 844; and neonatal seizures 372–3; non-invasive 131, 431, 843  
respiratory system: and circulatory failure 38; examining 30; and spinal cord injury 407  
respiratory tuberculosis 666–7  
responsiveness, assessing 45  
restoration orientation 112  
restraining children 837, 853, 856, 866  
resuscitation: in anaphylaxis 426; and APH 186–8; Caesarean section in 52; in children 31, 66, 787; for disabled children 399; in DKA 262; in eclampsia 205–6; in emergencies 34–6; exhaled air 46–7; preferred equipment for 129; in pulmonary embolism 224; in RICEP 266–7; and shock 38, 169–70, 177–9, 464, 546–9; stopping 66, 342, 798; and triage 30–1; in uterine rupture 216  
resuscitation equipment 34, 109, 122, 327, 331  
resuscitation trolley 55, 69  
retained placenta: and placenta accreta 199; and PPH 191, 197; preventing 108; and shock 169  
retained placental fragments 171, 198, 221, 304, 316  
retinal degeneration 400  
retinal haemorrhages 43, 268, 593, 595, 819, 823  
retinal screening 174  
retinitis, and cytomegalovirus 704, 710  
retinitis pigmentosa 591  
retinoblastoma: and eye disorders 591; incidence of 575; and red reflex 400; treatment of 577, 585  
retinopathy, proliferative 174  
retinopathy of prematurity (ROP) 344, 591  
retrieval service, in intensive care 68  
retroperitoneal haemorrhage 784

- retropharyngeal abscess 422, 426, 428–9, 658
- Reye's syndrome 593, 602, 640, 680, 684
- rhabdomyolysis 648, 815
- rhabdomyosarcoma 577, 586
- Rhesus incompatibility 138, 371
- rheumatic arthritis 500, 570–2
- rheumatic disease, in children 569
- rheumatic fever: and AURI 436; diagnosis of **570**; and heart failure 454; long-term consequences of 452; and rash 385; *see also* acute rheumatic fever
- rheumatic heart disease: in pregnancy 254; and shock 40; and *Streptococcus* 659
- rhinitis 258, 425, 432
- Rhodesian trypanosomiasis 730
- rib fractures 128, 772, 780–1, 790–1, 819
- ribavirin 542, 687, 726
- riboflavin 251, 513, 523
- ricketts: and cholestasis 491; and developmental delay 402; and short stature 504; treatment of 514–15
- rickettsia, distribution of **676**
- rickettsial infections 602, 648, 675–6
- rickettsial pox 675–6
- ricketty rosary 491, 514
- rifampicin: and anthrax 679; and ARVs 697; and Buruli ulcer 642; and cholestasis 493; and leprosy 646; and meningitis prophylaxis 601; and meningococcal disease 653; and rickettsial disease 676–7; routes of administration 851; and TB 287, 667, 669, 671
- rifampin 287–8
- Rift Valley fever 686, 726
- RIG (rabies immunoglobulin) 723–5
- right upper quadrant tenderness 203, 683
- right ventricular strain pattern 224–5
- rigors, febrile 609
- Ringer-lactate solution: and blood transfusion 23–5; in dehydration 272; and drug IVs 16–18; in emergency room 110; in shock 16, 169–70; soaking dressings in 90
- risperidone 295, 508, 510
- ritonavir 698, 705, 716–17
- ritual punishments 96
- ritual sexual initiation 397
- ritualistic behaviour 403, 510
- rizatriptan 618
- road traffic accidents 67, 770–1, 785–6
- Rocky Mountain spotted fever (RMSF) 675–6
- rod-shaped bacteria 868–70, 868
- rodents 647–8, 677, 726, 733
- ROSC (return of spontaneous circulation) 62–5
- Ross procedure 255, 453
- rotavirus 545, 551, 705
- rotavirus vaccines 93, 95
- roundworms 567, 636–7, 748, 750
- routes of administration: abbreviations for 17, 853; appropriate 86; and choosing antibiotics 521, 598; of maternal drugs 334
- RPR (rapid plasmin reagent) 290, 355–6, 656
- RSV (respiratory syncytial virus) 362, 430, 701
- rubella: and anaemia 530; and bilirubin levels 368; and encephalitis 602; in infants 354
- rubella vaccine 95
- Rubin's manoeuvre 218
- rupture of membranes: artificial *see* ARM; and breech delivery 241–2; and cervix stretching 150; and misoprostol 182–3; and preterm 159–60, 245, 331; and prolapsed cord 32; *see also* PPRM
- ruptured ectopic pregnancy 177; emergency treatment of 179; surgical intervention for 169; in triage 32–3
- ruptured uterus: and APH 186; and Caesarean section 314, 785; and fetal death 321; and herbal medicines 107; managing 153, 216; and obstructed labour 213–15; and oxytocin 151, 212; and PPH 191; risk factors for 215–16; symptoms and signs of 216; and trauma 785–6; and urinary catheterisation 304; and vaginal bleeding 232
- Rusch balloon 193
- RUTF (ready-to-use therapeutic food) 516–17, 522–3, 527, 558
- RVH (right ventricular hypertrophy) 449, 451–2
- Rwanda, military rape in 827
- saber shins 678
- sadistic injuries 96
- sadness 111–12, 115, 120, 506–7, 509
- safer sex 273–5
- sagittal suture 212, 312–13
- salbutamol: and anaphylaxis 426; and asthma 432–3; in emergency room 110; in high-dependency care 853; and hyperkalaemia 483; inhaled 42, 255–8, 433, 435; and LIP 703; and suppurative lung disease 850; *see also* nebulised salbutamol
- salicylate poisoning 267, 499, 812–13
- salicylates: and coma 593, 596; in dengue 684
- salicylic acid 646, 709
- saline, soaking dressings in 90
- saline drops 356, 720
- saline flushes 18, 65
- saliva: aspiration of 88; transmission of viruses by 6, 50
- salivary glands, swelling 630–1, 721
- Salmonella*: and diarrhoea 551; non-typhoidal 674–5, 696; and SCD 535; and schistosomiasis 753
- Salmonella paratyphi* 621, 672
- Salmonella typhi* 28, 672–4, **674**, 753
- Salmonella typhimurium* 486
- salpingectomy 158, 179, 303–4
- salpingitis 177, 590
- salt, iodination of 397–8, 501
- salt loss 471, 500, 502
- Salter–Harris classification 765–6, 769, 784
- sandbags: in emergency room 110; in resuscitation 36
- sandflies 733
- Sandifer–Sutcliffe syndrome 564
- sanitary towels 221, 244, 825
- sarcoglycans 616
- sarcoidosis 386
- Sarcoptes scabiei* 625, 710
- Sarnat's clinical grading system **376**
- Save the Children 12
- scabies 385, 625–6, 645, 710; topical treatment of **625**
- scalded skin syndrome 357, 385
- scalds 807, 810, 819, 824
- scalp abrasions 311
- scalp drips 856
- scalp ringworm 626–7
- scalp vein needles 855, 861
- scalp veins 354, 618, 854–6, 861
- scarf sign 343–4
- scarlet fever 658, 660
- Schistosoma mansoni* 28, 476, 478
- schistosomiasis 752–4; and anaemia 173; and blood in urine 201; clinical features of **753**; geographical areas for **752**; and *Salmonella* 551; and typhoid 672
- schizophrenia 396, 508–9, 649
- SCIWORA (spinal cord injury without radiological abnormality) 783, 788–9
- scoliosis 419, 613, 615–16, 624
- scorpion sting 815, **817**
- scrotum, hypoplastic 629
- scrub typhus 648, 675–7, 682
- scurvy 383, 513–14
- sea snakes 815
- seat-belt injuries 782, 786
- seated posture 590
- second tumours 581
- secondary assessment: of circulation 42; in emergencies 34, 41; of neurological failure 43
- secondary bacterial infection: and bronchiolitis 430; and chickenpox 680; and eczema 627; and pneumonia 439; of scabies 625; in wounds 764
- secondary PPH 191, 198
- security: in education centres 11; in hospitals 3
- sedation: clinical procedures requiring 75; and fundoscopy 30; and head injury 780; and life-saving procedures 836; minimum information for 77; for neonates and infants 127; and psychiatric drugs 294–5; risk of respiratory problems from **77**, 133
- sedatives **78**: dosage for children 77; storage of 19, 88
- seizure diary 608
- seizures: and brain sonography 14; and brain tumours 583; in coma 593, 595–7; eclamptic 203, 205, 209; emergency management of 89; and encephalitis 603; in encephalopathy 376; and HIV 706, 708; and jitteriness **371**; in neonates 371–2, 375–7; and pertussis 654; repeated 268, 596; and resuscitation 40; and severe malaria 742
- Seldinger technique 57, 776, 856–7
- selenium 520, 522, 709
- selenium sulphide shampoo 627, 646
- self-determination 100
- self-harm 101, 396, 505–6, 803, 821
- self-inflating bags 60: for anaesthesia 129; in emergency room 109; in neonatal resuscitation 335, 338; and tracheal tubes 57; and ventilation 58
- Senegal, FGC in 301
- senior doctors 2, 68
- senna 83, 87, 412, 559–60
- sensory block 123
- sensory impairments 70, 400, 415
- sensory stimulation 6
- sepsis: and anaesthesia 122; and anthrax 678; and coma 593; dangerous 33; and dysentery 545; and exchange transfusion 23; and fetal distress 232; and fever 267; and intracranial abscesses 619; in labour 147; in neonates 350, 353; in obstructed labour 214; pathogens causing 220; and respiratory distress 365; and seizures 371; and spinal cord injury 406; and *Streptococcus* 659
- septic abortion 158, 169, 176–7, 179, 183, 659
- septic arthritis 570, 572, 621–2, 674, 857
- septic screen 486, 865
- septic shock: and amniotic fluid embolism 226; and anaemia 531; and ARF 481; in children 466–9; and dexamethasone 41; and endometritis 304; in infants 354; and obstetric emergencies 43; physiology of 167–8; and PPH 198; in severe malnutrition 520–1; signs and symptoms of 176; and uterine perforation 182
- septicaemia: antibiotics for 282, 551, 580; and APH 186; and cannulation 855, 858; and chickenpox 680; and diarrhoea 548; and jaundice 368; lumbar puncture in 650; and malaria 744; and malnutrition 521; and meningococcal disease **650**, 653; neonatal 352–4; and plague 679; and pressure sores 415; and puerperal sepsis 221; and shock 39, 166, 171, 284, 463–4; and *Streptococcus* 659; and tetanus 661; and VAD 513
- sequestration crisis 22, 536, 538
- seroconversion 622
- seroconversion rash 708
- serological tests: and coeliac disease 568; and HIV 524; and leptospirosis 647; for syphilis 369; and TB 665; and typhoid 673
- sertraline 293–4
- serum alpha-fetoprotein 578, 587
- serum bilirubin concentration 351, 353, 488
- severe acute malnutrition (SAM): antiretrovirals in 524; electrolyte problems in 520; management of 518; and shock 460; use of term 516
- severe anaemia: and antibiotics 702; in children 383; and diarrhoea 548–9; emergency treatment of 523; and generalised oedema 388; haemoglobin levels in 21, 173; and heart failure 252–3, 453–5; and HIV 698; labour in 174; and malaria 278, 280, 282, 399, 738–9, 741–3; minimum standards for **172**; and PPH 198; and respiratory distress 362, 365; respiratory rate in 437; and SCD 534, 536; and shock 462, 464–7; and sickle-cell disease 533; and spherocytosis 540; and transfusion 531; and trauma 196; treatment of 173
- severe dehydration: in children 394; emergency treatment of 463, 520; and feeding 518–19; and intravenous rehydration **555**; and pneumonia 440; and shock 460–1, 521; signs of 463
- severe dengue *see* DHF
- severe diarrhoea 459, 513, 534–5, 548–9, 759, 882
- severe headache, and scrub typhus 677
- severe malaria 279–80, 282, 460, 736, 738–45; minimum standards for hospital treatment **736**
- severe malnutrition: and bilirubin levels 368; biochemical abnormalities in 516; and dehydration 518–20; and developmental delay 402; dietary treatment of 525–7; and heart failure 454, 466; and HIV 689; and hypoglycaemia 498;
- inpatient management of 517–18; and mental health problems 404; micronutrient deficiencies in 514, 522–3; and ORS 548; recovery from 522, 527–9; and RUTFS 585; and shock 463–4, 466–7; and strongyloidiasis 759
- severe pain, analgesia for 75
- severe pneumonia: antibiotics for 557; chest X-ray for 596; diagnosis of 438; treatment of 439
- severe respiratory distress: and ALRI 438, 440; and bronchiolitis 430–1; and PCP 701; and pertussis 654; and TB 668
- sex work: children and adolescents in 820–1; and drug abuse 508; enforced 818, 827; and HIV 688; and trafficking 96, 826–7
- sexual abuse: and anal lesions 560; differential diagnosis of 822–3; forensic sampling for 825; and HIV 688; and mental health problems 505; and physical abuse 819; recognition of 96, 821–2; and STIs 655–6, 688
- sexual assaults 396, 821–2, 825; *see also* rape
- sexual exploitation 395, 826
- sexuality, for disabled youths 405, 409, 415
- SFP (Supplementary Food Programme) 517
- SGA (small for gestational age) infants 342, 374
- Shandling catheter 404
- Sheehan's syndrome 200
- sheets, bloodstained 196
- Shigella*: antibiotics for 544; and HUS 478; investigations for 28; and persistent diarrhoea 556, 705
- Shigella dysenteriae* 551, 726–7
- Shigella flexneri* 551
- Shigella sonnei* 551
- shigellosis 550–1, 565, 609, 679, 727
- shingles 291–2, 680, 689
- shock: and blood transfusion 21; and burns 806; and cardiac failure 40; causes of **166**; in children 787; and coma 593; and dengue 681–4; diagnostic pointers in **460**; and diarrhoea 545–6; during pregnancy 166; emergency treatment for 42; and envenomation 815; and FGC 300; fluids in 16, 38–9, 168–9; and inverted uterus 248; and malaria 284, 743–4; and malnutrition 517; managing 459–62; and meningitis 598; and meningococcal disease 650–2; in neonates 341; non-cardiogenic pathway of care **461**; and NSAIDs 73; in obstructed labour 214; pathology of 458; and peritonitis 305; and PPH 192; and pulmonary embolism 224–5; and severe malnutrition 520; signs of 37–8, 458–9; stages 1–4 **168–9**; in trauma 774–6; in triage 31–2
- shockable cardiac rhythms 51, 62, 64, 836
- shoulder dystocia: all-fours position for 279; and delayed labour 153; management of 217–18; and nerve palsies 351; and prolonged pregnancy 150; risk factors for 217; and symphysiotomy 319; and transport 97
- shoulder tip pain 162, 178
- shunt blockage 619–20
- shunt infections 620
- SIADH (syndrome of inappropriate secretion of ADH) 269, 376, 602–3
- sickle-cell anaemia 23, 27, 174, 659
- sickle-cell crises: acute painful 175, 533–4, 536, 539; and anaemia 383; antibiotics in **535**; fluids in **534**; and juvenile idiopathic arthritis 572; management of **534**; postpartum 176; precipitants of **533**; in pregnancy 175–6; preventing 538
- sickle-cell disease (SCD): and abdominal pain 383; and anaemia 21, 383; and blood transfusion 22–3; and Buruli ulcer 642; in children 534; early testing for 176; and jaundice 380; and malaria prophylaxis 746; minimum standards for **172**; neurological involvement in 536–7; and osteomyelitis 621; pathogenesis of 532–3; and pregnancy 174–5; presentations of 533; preventing infection in 538; priapism in 538–9; and puerperal sepsis 221; and *Salmonella* 551; and shock 166; sleep apnoea in 387, 429
- sickle-cell test 27
- sickle solubility test 533
- signing respiration 167, 774

- sigmoidoscopy 562, 747  
signs of life 37, 47  
silver nitrate 633  
silver sulphadiazine 808  
Sims' position 247  
Sims' speculum 181, 196  
*Simulium* 757  
single-dose nevirapine (sdNVP) 273, 695  
sinks, accessible 4, 7  
sinus tachycardia 224, 455–6  
sinusitis, and *Streptococcus* 658–9

*Staphylococcus* 679; antibiotics against 219, 440; and mastitis 222–3; in neonatal sepsis 350, 353, 355; and septic shock 466, 468  
*Staphylococcus aureus*: and burns 809; and cannulation 855; and chickenpox 680; and croup 422–3; and cystic fibrosis 444–5; and eczema 627; and empyema 633; and endocarditis 456; and foreign body aspiration 435; and HIV 696, 701, 709; and impetigo 626; and measles 720; and neonatal sepsis 350, 352, 357; and osteomyelitis 621; and parotitis 721; and pneumonia 269, 436, 439–40; and pyomyositis 620; and retropharyngeal abscess 428; and septic arthritis 622; in shunt infections 620; and skin infections 658; as STI 657  
*Staphylococcus epidermidis*, in shunt infections 620  
starvation, deliberate 96, 819  
status epilepticus 203, 403, 593, 610–12, 612, 813; *see also* CSE  
steatorrhoea 383, 444, 479, 493, 566, 568  
sterile gloves: for burns 808; in childbirth 142, 144; in forceps delivery 312; and intra-osseous infusion 860; and lumbar puncture 866; in placenta removal 197; in spinal anaesthesia 123; and uterine compression 192  
sterile urine 869–70  
sterilisation 6, 8–9, 14–15, 663  
sterilisers 4, 16, 69  
steroids: and adrenal crisis 500; antenatal 245; as anti-emetic 580; and asthma 257; and croup 423; and dyspnoea 87; and emergency treatment 42, 110; and haemangiomas 632; and ingestion burns 803; and IRIS 700; and LIP 703; in palliative care 84–5, 89, 587; and rabies 725; and septic shock 469; and typhoid 674; *see also* oral steroids  
stethoscope, as basic equipment 29  
Stevens–Johnson syndrome (SJS) 385, 699, 702, 709, 717, 731  
stillbirths: definitions of 229; in adolescent girls 395; in history taking 29; and malaria 276; and multiple pregnancy 232; preventing 229; and prolonged labour 211; in SCD 175  
Still's murmur 451  
stimulant laxatives 87, 559–61  
STIs (sexually transmitted infection) 655–7; and adolescents 395–6; and child abuse 821, 824–6; screening for 174  
stolen medications 577  
stomach: blood in 86; decompression of 61; emptying 214  
stomatitis 137, 383, 581, 719  
stomatocytosis 383, 540  
storage boxes 69  
straight-blade laryngoscope 131, 838–9, 842  
street children 405, 507, 818  
streptococcal disease 386, 658–9; antibiotic doses for 659  
*Streptococcus*: and erythema nodosum 386; on microscopy 868; other groups of 660; related conditions 660; and rheumatic fever 570; and septic shock 468; *see also* beta-haemolytic  
*Streptococcus*  
*Streptococcus agalactiae* 597, 659  
*Streptococcus pneumoniae* 659–60; and coma 268; and croup 422–3; and HIV 701; immunisation against 599; and meningitis 597, 794; and otitis media 427; and pneumonia 436; and septic shock 466; and tonsillitis 426  
*Streptococcus pyogenes* 466, 658, 680, 809  
*Streptococcus viridans* 456  
streptomycin: and Buruli ulcer 642; during pregnancy 287–8; and hearing loss 288, 401; and plague 679; and TB 670  
stress, ill treatment resulting from 96  
stress response 168  
stress ulcers 407  
stridor: and anaphylaxis 258, 425–6; and cystic hygroma 632; during sleep 387; and inhalational injury 808; and laryngeal oedema 208; and measles 720; and respiratory difficulty 36, 42; in triage 31; and upper airway obstruction 422  
stroke: and blood transfusion 22; and HIV 706, 708; and SCD 533, 536–7  
*Strongyloides* 748–9, 759–60  
strongyloidiasis 748–50, 759  
Stuart's medium 28  
stylets: in anaesthesia 122–4; and intubation 57  
sub-galeal haemorrhage 311  
subacute haematogenous osteomyelitis 621  
subaponeurotic haemorrhage 351  
subarachnoid haemorrhage 371, 536, 707  
subclavian vein 857; cannulation of 188, 465, 776, 857–8  
subconjunctival haemorrhage 653  
subcostal recession 363–4, 390, 422  
subcutaneous diamorphine 83  
subcutaneous emphysema 719, 772, 779, 843  
subcutaneous heparin 223–5  
subcutaneous infusion 72, 83, 87  
subcutaneous injection 854: alternatives to 83; and anti-emetics 86; drugs available by 90; of growth hormone 504; of insulin 265, 496; of methotrexate 573; procedure for 853–4  
subcutaneous morphine 82–3, 88  
subcutaneous nodules 570, 659, 757–8  
subdural effusion 599–600, 619  
subdural haematoma 41, 389, 779, 794  
subglottic oedema 841  
subglottic stenosis 422, 772  
submersion injuries 796  
subperiosteal haemorrhage 514  
subphrenic abscess 633  
substance abuse 504–8, 819–20  
substernal pain 563, 734  
sucking inability 376  
sucrose, sublingual 354, 373  
suction catheters 58, 69, 129  
suction devices: in advanced life support 55, 57; for anaesthesia 129; in CNEP 847; in emergency room 109; in high-dependency care 69; in intubation 130, 839; for neonates 331, 335  
suction machine 14  
Sudan, FGC in 299  
SUFE (slipped upper femoral epiphysis) 572, 624  
suffocation 332, 814, 819, 823  
sugar: on dummies 76; and hypoglycaemia 261; in ORS 272; and pressure sores 417; sublingual 41, 499–500, 550  
suggestions box 3  
suicide ideation 113, 293, 821  
suicide: in adolescents 505; assisted 101; and grief 113; and postnatal depression 294  
sulfadiazine 706, 708–9, 747; *see also* SP  
sulfamethoxazole: and brucellosis 679; and otitis media 427; and PCP 701  
sulphasalazine 562–3, 569, 573  
sulphonamides 540–1  
sulphuric acid 814  
sumatriptan 618  
sunken eyes, and dehydration 263, 271, 394, 519  
superior vena cava (SVC) obstruction 87–8, 587  
superior vena cava (SVC) syndrome 632  
supine hypotensive syndrome 50, 123  
supine posture 589  
supplemental oxygen 354, 362–4, 781, 808  
support services, head of 2  
support staff, in intensive care 68  
suppositories: analgesic 74, 83; in bowel training 411; effectiveness of 17, 851; and hyperemesis 251; and spinal cord injury 407  
suprapubic pressure 218, 244, 412  
suramin 730–1  
surface cultures 351, 353  
surfactant deficiency: and diabetes 351; and endotracheal intubation 339; minimising risk of 330; in neonates 245–6, 363; preventing 331; and respiratory distress 361–2  
surfactant production 245, 334, 363  
surgeons, traditional 105  
surgical airway, in emergencies 35, 42  
surgical airway packs 55  
surgical cricothyrotomy 58, 772, 840–1  
surgical debridement 305, 325  
surgical emphysema 762, 780, 841, 850  
surgical patients, monitoring 15  
survival motor neuron (SMN) 613  
sustained-release morphine 82  
sutures, removal of 763  
suxamethonium 35, 124–5, 127, 771  
suxamethonium bromide 130  
SVT (supraventricular tachycardia) 40, 450–1, 453–4, 456–8, 457, 862  
sweat test 390, 443–4  
Sydenham chorea 659  
symplysiotomy: alternative to destructive operations 324; in breech delivery 244; delivery by 239; and forceps delivery 313; post-procedure care 320–1; and shoulder dystocia 219; site of incision 319–20; technique of 319–20; and vacuum delivery 311  
symptomatic relief 101, 114, 117–20, 430  
syncope 223, 606  
syntometrine 154, 192, 210, 232, 255

- syphilis: and bilirubin levels 368; and Buruli ulcer 642; and chancres of primary 657; and encephalitis 602; and fetal deaths 228; and HIV 707; in infants 354; and miscarriage 182; mother-to-child transmission of 289, 358; stages of 289–90; at STI 656–7, 826; and stillbirth 229; testing for 22, 138, 290, 508; treatment of 290–1
- syringe withdrawal technique 71
- syringes: in emergency room 109; in intubation 130
- systemic arthritis 572–3
- systemic steroids 432–3
- T-cell lymphoma 582–3
- T waves 263–4
- T2\* imaging 174
- TAC (tetracaine-adrenaline-cocaine) 71
- tachyarrhythmias 108, 433, 455–6
- tachycardia: definition of 37; and aminophylline 433; and anaemia 383; and anthrax 678; and antihypertensives 202–3; and beriberi 513; and cardiac failure 40; and croup 422; and dehydration 138; and drowning 796; fetal 231, 245; and heart failure 252, 454; and hypovolaemia 187; and intestinal obstruction 636; and intussusception 635; and inverted uterus 250; in JHR 655; and metabolic acidosis 284; neonatal 361–2, 366; and nifedipine 245; and over-hydration 272; and pain 69; and poisoning 811; and puerperal sepsis 221; and pulmonary contusion 781; and RIPC 618; and SCD 533; and shock 167, 192, 458–9, 466, 787; and thyrotoxicosis 501–2; and trauma 774; and tricyclic antidepressants 813; and trypanosomiasis 730; unexplained 223
- tachypnoea: and acidosis 187, 192; and ACS 536; and circulatory failure 38; and heart failure 454; neonatal 352, 361, 363, 366; and pain 69; and PPRM 245; and pulmonary embolism 223–4; and respiratory distress 390; and SCD 533; in shock 787
- tafenoquine 739, 745
- TALC (Teaching-aids At Low Cost) 11, 131, 242, 416
- talipes equinovarus 352, 623
- Tanzania: child abuse in 821; FGC in 301; leprosy in 645
- tapeworm 748, 750–1
- taps, elbow-operated 7–8
- TB (tuberculosis) 665–71; abscesses in 864–5; and asthma 431; and BLS 50; and Buruli ulcer 642; diagnosis of 286–7; DOTs for 288–9; and ectopic pregnancy 177; and erythema nodosum 386; and HIV 275–6, 696–7, 703–4; immunisation against 93, 398; infants of mothers with 356; investigations for 28; and IRIS 699; and lymphadenopathy 381, 631; and measles 720; and nephrotic syndrome 476; and pleural effusion 441; and pneumonia 440; in pregnancy 287; protecting staff from 5; and severe malnutrition 524, 528; smears for 27; and spinal cord injury 406; and steroids 245
- TBAs (traditional birth attendants): and domestic violence 302; herbal remedies used by 107; in labour 143, 145; in neonatal care 330; use of term 105
- TBRF (tick-borne relapsing fever) 654–5
- TBSA (total body surface area) 805–6, 808
- TCD (Transcranial Doppler) 537
- TDF (tenofovir) 274–5, 695, 698, 700
- teicoplanin, and cancer treatment 580
- temephos 759
- tendon hammer 29, 418
- tendon reflexes: increased 210; loss of 207
- tenesmus 561, 679
- TENS (transcutaneous electrical nerve stimulation) 86
- tension headache 389
- tension pneumothorax: and bronchiolitis 431; and cardiac arrest 63; emergency procedures for 37, 841; in neonates 341, 364; and pericardial effusion 862; and shock 166, 459; signs of 36; in trauma 773, 776, 780–1, 791
- tepid sponging 610, 684, 738, 741
- teratogenicity 107, 174, 254, 287
- teratoma 406, 577, 587
- terbinafine 709
- terbutaline 152, 232, 247–8, 250, 256
- terminal care: and HIV 711; pain management in 78; seizure management in 89
- terminal haematuria 753
- terminal restlessness 90
- testes: torsion of 628–9, 658, 721; undescended 333, 503, 628–30
- testicular volume 875
- testosterone 503, 629
- tetanus 660–3; and Buruli ulcer 642; global reported cases of 660; neonatal 375; and seizures 371; and traditional medicine 105, 107; and wounds 764
- tetanus immunisation 104, 397–8, 723, 763, 787, 799–800
- tetanus immunoglobulin *see* HTIG
- tetanus prophylaxis 662, 763, 787, 800, 816
- tetanus toxoid (TT) vaccine: in burns 809; and detonation injuries 799; and gunshot wounds 801; neonatal 95, 138, 333; postnatal 157; prophylaxis with 662–3; and sexual abuse 656; and trauma 763, 787
- tetanus vaccines 93–4, 275, 663, 763, 787, 809
- tetany 509, 514, 542, 661
- tetracycline: and cholera 551; and conjunctivitis 356; and plague 679; and relapsing fever 655; resistance to 626; and rickettsial disease 676–7; and trachoma 664; and xerophthalmia 523
- tetracycline ointment 358, 590, 720
- Tetralogy of Fallot 446, 448–51
- TF (trachomatous inflammation – follicular) 663–664
- TGA (transposition of the great arteries) 447–9, 447
- Thailand: malaria in 736; RDTs in 278; sex trafficking in 826
- thalassaemia: and anaemia 383; and blood transfusion 21–2; and DSD 503; and jaundice 380; and juvenile idiopathic arthritis 572
- thalidomide 705
- theophylline 256, 357, 365–6, 432, 853
- therapeutic occultism 105
- thermometer: as basic equipment 29; in emergency room 110; for examination 29; for infants 349
- thiabendazole 748–50
- thiacetazone 669, 703, 709
- thiamine (vitamin B<sub>1</sub>) 251, 513; deficiency *see* beriberi
- thioguanine 582
- thiopentone 124, 127, 130, 610–12
- third-generation cephalosporins: and anaemia 468, 532; and conjunctivitis 356; and meningitis 267, 352, 598; and peritonitis 637; and septicaemia 355; in sickle-cell crises 535; and typhoid 672
- Thomas' splint 767
- thoracic aorta rupture 781
- thoracic spine: injuries 790–1; X-rays of 790
- thoracic trauma 780, 786
- thoracocentesis 633, 780
- threadworms 748–50
- threatened miscarriage 162, 178–80
- thrombocytopenia: and amniotic fluid embolism 225; and anaemia 383; and cancer 581; and chickenpox 680; and exchange transfusion 23; and folic acid 515; and haemophilia 543–4; and heparin 224; and HIV 694; and jaundice 368; and leptospirosis 647–8; and magnesium 207; and malaria 738; and measles 719; and mumps 721; and platelet transfusion 22; and rash 385; and scrub typhus 677; and spinal anaesthesia 210; and trypanosomiasis 732; and yellow fever 729
- thromboembolic phenomena 63
- thrombolytic therapy 224
- thrombophilia 223
- thromboprophylaxis: in Caesarean section 314; in heart failure 253; in post-operative care 303
- thrombosis, and spinal cord injury 411
- thrush: antibiotics for 357–9; oral 433, 688–90, 697, 720; *see also* candidiasis
- thymic shadow, lack of 694
- thyroglossal cysts 502, 630, 632
- thyroid disorders 386, 498, 501
- thyroid function tests 369, 400
- thyroid hormones 515, 596
- thyroiditis 502, 721
- thyrotoxicosis 501–2
- thyroxine 501–2
- TI (trachomatous inflammation – intense) 663, 664
- TIA (transient ischaemic attacks) 536–7
- TIBC (total iron binding capacity) 174, 566
- tibial shaft fractures 768
- TIBOLA (tick-borne lymphadenopathy) 675
- ticks bites 593, 648–9
- tick paralysis 615, 640
- TIG (tetanus immune globulin) 662–3
- tinge capitis 626–7
- tissue hypoxia 168, 682, 784, 807
- tissue necrosis: and adrenaline 70; and compartment syndrome 765; and interosseous infusion 860; and melarsoprol 731; and puerperal sepsis 221; and snake bite 816; and wound infections 221
- tissue oedema 122, 571, 629
- tissue perfusion 21, 38, 166–7, 284
- TLS (tumour lysis syndrome) 577, 579, 581
- tobacco pickers 814
- tobramycin 444, 809
- tocolytics 232, 245, 373
- toddler's diarrhoea 380
- Togo, FGC in 301
- toileting, and paraplegia 408
- toilets, in hospitals 4, 6–7
- tongue depressor 56
- tongue lacerations 764
- tonsillectomy 427
- tonsillitis: in children 426–7; and *Streptococcus* 658; and upper airway obstruction 422
- tonsils, enlarged 387
- topical antibiotics 357, 513, 590–1
- topical azoles 657
- topical corticosteroids 572, 574, 627
- topical steroids: and conjunctivitis 590; and lichen sclerosis 822
- torture 98, 103
- total iron binding capacity (TIBC) 174, 566
- total parenteral nutrition (TPN) 567, 581, 852
- touch, and sick children 393
- tourniquet: pneumatic 802; in venous cannulation 854
- tourniquet test 683
- toxic epidermal necrolysis 385, 709
- toxic megacolon 563
- toxic shock syndrome 385, 659–60, 676
- toxins, and haemolytic anaemia 542
- Toxocara* 749–50
- toxoplasmosis 747; and bilirubin levels 368; and co-trimoxazole 701; and encephalitis 706; and HIV 710
- TPHA (Treponema pallidum haemagglutination assay) 290
- trachea, blocked neonatal 337
- tracheal deviation 390, 773, 779–80, 842
- tracheal intubation: in children 787; chronic 363; for neonates 338; in neonates 337
- tracheal shift 41, 772
- tracheal suction catheters 57, 58
- tracheal tubes: in advanced life support 55–7; in airway management 35; introducers and connectors 57; taping of 840
- tracheo-oesophageal fistula 365
- tracheobronchial disruption 781
- tracheobronchitis 719
- tracheomalacia 845
- tracheostomy: and burns 803, 809; and envenomation 817; in epiglottitis 424; and foreign bodies 423; in tetanus 662
- trachoma 400, 588, 590, 663–5, 679
- traction 767
- traditional medicine 108; and cancer 576; causing fits 376; and FGC 298; and hospital care 104–8; and malnutrition 517
- trafficking, human 96, 818, 826–7
- TRALI (transfusion-related acute lung injury) 24–5
- tranexamic acid: and bleeding 88; and menorrhagia 544; for obstetric haemorrhage 187, 195; and shock 170, 774
- transfusion haemosiderosis 541
- transient tachypnoea of the newborn 339, 361–4, 845
- transport: checklist for 97; of critically ill patients 67, 97; safety rules for 97; for trauma patients 787–8
- transtracheal insufflation 841
- transverse and oblique lies 234, 241; and Caesarean section 229, 316, 318; and shoulder presentation 237; in twins 233
- transverse myelitis 406, 605, 680
- trauma: analgesia in 777; children affected by 509, 786–7; continuing care for 787; emergency radiography for 788–9, 791; life-threatening 769–70; mitigating effects of 827; peri-operative care in 788; primary assessment and resuscitation in 770–2; secondary assessment and emergency treatment in 778–9; and shock 166, 171
- traumatic experiences: and loss 115; and mourning 114
- Treatment Action Campaign (TAC) 98
- treatment chart, for family use 80
- trench fever 675
- Trendelenburg position 249
- Treponema pallidum* 289, 355, 656, 826
- triage 30–3, 109, 279, 769; scale 31
- triage nurses 29
- triamcinolone hexacetonide 573
- triceps skinfold thickness 493, 873
- trichiasis 663–5
- trichinosis 574, 750
- trichloroacetic acid 657
- trichloroethylene 129
- Trichomonas* 183, 657
- Trichomonas vaginalis* 656, 825–6
- Trichophyton* 626–7
- triclabendazole, and liver flukes 754
- tricuspid atresia 448–9
- tricyclic antidepressants: for adolescents 507; and nerve pain 84–5; overdose with 65–6, 812–13; for pregnant women 293
- trimethoprim: and brucellosis 679; and otitis media 427; and PCP 701; and pneumonia 580; routes of administration 851; and UTIs 473; and VUR 480
- trimethoprim/sulfamethoxazole 286, 657, 672
- trismus 427–8, 660–1
- trolleys, cleaning 142
- tropical pulmonary eosinophilia (TPE) 756–7
- tropical ulcer 626, 642
- trumpet guide 327
- trunk trauma 775
- trust: of children 80, 117–18, 393; relationships of 396
- Trypanosoma brucei* sp. 28, 730–1
- Trypanosoma cruzi* 732
- trypanosomiasis 27–8, 381, 730–2
- TS (trachomatous scarring) 664
- tssetse flies 730
- TSH (thyroid-stimulating hormone) 368–9, 501–2, 506, 568
- Tsutsugamushi disease 675
- TT (trachomatous trichiasis) 664
- tTG (tissue transglutaminase) 567–8
- tubal abortion 177
- tube feeding: and Guillain-Barré syndrome 614; and neonatal seizures 375–6; in preterm infants 349
- tube thoracostomy 633, 802
- tubercular empyema 633
- tubercular lymphadenitis 631
- tuberculin skin test (TST) *see* Mantoux test
- tuberculous meningitis: diagnosis of 597; and fever 599; and HIV 703; and hydrocephalus 619; and measles 720; presentations of 667; suspicion of 668
- tuberous sclerosis 510–11
- tubing, cleaning 15
- tumour necrosis factor alpha 563, 573, 672, 743
- tumour resection 584, 587
- tunnel vision 758
- Turk's solution 27
- Turner's syndrome 503–4, 567
- turpentine 812–13
- twin delivery 143, 233, 235, 311
- twin pregnancy 232–4, 244
- twin-to-twin transfusion 21, 232, 340, 371, 383
- twinning 575–6, 578, 587
- twins: conjoined 315; excluding possibility of 154; locked 234–5, 234
- typhoid: algorithm for treatment 673; and gastroenteritis 271; pathogenesis of 672; and rickettsial disease 676
- typhoid fever 648, 671–4, 726; clinical features of 672
- typhoid vaccine 93, 95, 711
- typhus, louse-borne 675–6
- Uganda: hospitals in 79; opiate use in 82, 84
- ulcerative colitis 380, 386, 561–3, 561–2; drug dosages for 562
- ultrasound equipment 13–14, 69
- ultrasound examination: in antenatal care 138, 175; and appendicitis 634; and ART 481; and cancer diagnosis 578, 582, 587; and ectopic pregnancy 178; and empyema 633; for haematuria 478;

- and intussusception 635; in labour 143; and malpresentation 241–2; in multiple pregnancy 232; and pleural effusion 441; in PPRoM 244; and trauma in pregnancy 785; for UTIs 472–3; and VUR 480
- ultraviolet light 825
- umbilical arterial catheter, malpositioned 373
- umbilical cord: antiseptic for 333; around neck 154; care for 350; compression 231, 241, 246, 584; cutting 332; milking 360; snapped 340
- umbilical cord accidents 228, 232, 383
- umbilical cord clamping: early 154, 189–90; and neonatal resuscitation 338
- umbilical cord clamps, sterile 143, 335
- umbilical cord prolapse 246–7, 247; and ARM 151; and breech presentation 241–2; and fetal death 321; managing 153; and manual rotation 238; pathway of care for 248; and PPRoM 244; relieving pressure on 247; signs of 32
- umbilical discharge 633
- umbilical hernia 501, 633
- umbilical infection 357, 375
- umbilical stump: blood loss from 366, 851; haemorrhage from 18; managing 332; and tetanus 660; in traditional medicine 106
- umbilical venous catheter (UVC) 858–9, 859; and exchange transfusion 370; in neonatal resuscitation 335, 339; in septicaemia 354
- umbilical vessel dilator 109
- uncal syndrome 266
- uncompensated shock **167**, 168, 650
- UNCRC (UN Convention on the Rights of the Child) 100, 301, 392, 398, 818
