<b>1.12</b>	<b>Basic life support for children and pregnant mothers</b>	<b>43</b>	<b>1.25</b>	<b>Non-invasive respiratory support</b>	<b>131</b>
	Barbara Phillips, David Southall			Martin Samuels	
<b>1.13</b>	<b>Advanced life support for children and pregnant mothers</b>	<b>55</b>			
	David Southall, Barbara Phillips				

## Section 2: Pregnancy-related problems

Authors are Katie Christie, Alice Clack, Johan Creemers, Brigid Hayden, Grace Kodindo, Shamsunnisa Sadia, David Southall, Diane Watson and Ann Wright. (Unless otherwise stated)		<b>2.6.D</b>	<b>Multiple births</b>	<b>232</b>	
<b>2.1</b>	<b>Antenatal care and the hospital</b>	<b>136</b>	<b>2.6.E</b>	<b>Malpresentations and malpositions including breech delivery</b>	<b>235</b>
<b>2.2</b>	<b>Nursing pregnant women and girls in hospital (midwifery)</b>	<b>139</b>	<b>2.6.F</b>	<b>Preterm pre-labour rupture of membranes (PPROM) and/or preterm labour</b>	<b>244</b>
	Wendy Martin		<b>2.6.G</b>	<b>Prolapsed umbilical cord</b>	<b>246</b>
<b>2.3</b>	<b>Managing normal labour and delivery</b>	<b>144</b>	<b>2.6.H</b>	<b>Inverted uterus</b>	<b>248</b>
<b>2.4</b>	<b>Pathways of care summarising the diagnosis of complications of pregnancy or delivery</b>	<b>158</b>	<b>2.6.I</b>	<b>Hyperemesis gravidarum</b>	<b>251</b>
<b>2.4.A</b>	<b>Abdominal pain in early pregnancy</b>	<b>158</b>	<b>2.7</b>	<b>Medical disorders complicating pregnancy and delivery</b>	<b>252</b>
<b>2.4.B</b>	<b>Abdominal pain in late pregnancy</b>	<b>159</b>	<b>2.7.A</b>	<b>Heart failure during pregnancy, including rheumatic heart disease</b>	<b>252</b>
<b>2.4.C</b>	<b>Vaginal bleeding in early pregnancy</b>	<b>162</b>	<b>2.7.B</b>	<b>Asthma</b>	<b>255</b>
<b>2.4.D</b>	<b>Vaginal bleeding in late pregnancy</b>	<b>163</b>	<b>2.7.C</b>	<b>Anaphylaxis</b>	<b>258</b>
<b>2.4.E</b>	<b>Vaginal bleeding after delivery</b>	<b>164</b>	<b>2.7.D</b>	<b>Diabetes mellitus</b>	<b>261</b>
<b>2.4.F</b>	<b>The diagnosis of breathing difficulties in pregnancy</b>	<b>165</b>	<b>2.7.E</b>	<b>Reduced consciousness and coma</b>	<b>265</b>
<b>2.5</b>	<b>Life-threatening complications of pregnancy and delivery</b>	<b>166</b>	<b>2.8</b>	<b>Infections complicating pregnancy, delivery and after birth</b>	<b>269</b>
<b>2.5.A</b>	<b>The pregnant woman or girl with shock during pregnancy and the puerperium</b>	<b>166</b>	<b>2.8.A</b>	<b>Pneumonia</b>	<b>269</b>
<b>2.5.B</b>	<b>Severe anaemia, including sickle-cell disease</b>	<b>172</b>	<b>2.8.B</b>	<b>Severe dehydration and gastroenteritis</b>	<b>270</b>
	Gavin Cho		<b>2.8.C</b>	<b>HIV/AIDS</b>	<b>273</b>
<b>2.5.C</b>	<b>Septic abortion or miscarriage</b>	<b>176</b>		Francis Ssali, Katherine Ajdukiewicz	
<b>2.5.D</b>	<b>Obstetric haemorrhage</b>	<b>177</b>	<b>2.8.D</b>	<b>Malaria</b>	<b>276</b>
<b>2.5.D.i</b>	<b>Ruptured ectopic pregnancy</b>	<b>177</b>		Prudence Hamade	
<b>2.5.D.ii</b>	<b>Miscarriage</b>	<b>179</b>	<b>2.8.E</b>	<b>Acute appendicitis</b>	<b>285</b>
<b>2.5.D.iii</b>	<b>Antepartum haemorrhage</b>	<b>183</b>	<b>2.8.F</b>	<b>Cystitis and acute pyelonephritis</b>	<b>286</b>
<b>2.5.D.iv</b>	<b>Postpartum haemorrhage</b>	<b>189</b>	<b>2.8.G</b>	<b>Tuberculosis in pregnancy</b>	<b>286</b>
<b>2.5.E</b>	<b>Hypertension, pre-eclampsia and eclampsia</b>	<b>200</b>		Ejaz Khan	
<b>2.5.F</b>	<b>Prolonged and obstructed labour, uterine rupture and shoulder dystocia</b>	<b>211</b>	<b>2.8.H</b>	<b>Syphilis in pregnancy and the newborn infant</b>	<b>289</b>
<b>2.5.G</b>	<b>Severe infection in the puerperal period</b>	<b>219</b>		Dave Woods (R)	
<b>2.5.H</b>	<b>Pulmonary embolism</b>	<b>223</b>	<b>2.8.I</b>	<b>Varicella zoster (chickenpox) in pregnancy</b>	<b>291</b>
<b>2.5.I</b>	<b>Amniotic fluid embolism</b>	<b>225</b>		Dave Woods (R)	
<b>2.6</b>	<b>Complications that require hospital care</b>	<b>226</b>	<b>2.9</b>	<b>Mental health problems associated with pregnancy and the postnatal period</b>	<b>292</b>
<b>2.6.A</b>	<b>Ovarian cysts in pregnancy</b>	<b>226</b>		Susan Smith	
<b>2.6.B</b>	<b>Reduced fetal movements, intrauterine death and stillbirth</b>	<b>227</b>	<b>2.10</b>	<b>Female genital cutting</b>	<b>298</b>
<b>2.6.C</b>	<b>Fetal distress during labour</b>	<b>230</b>		Comfort Momoh, David Southall	
			<b>2.11</b>	<b>Domestic/intimate partner violence and pregnancy</b>	<b>301</b>
				Comfort Momoh, David Southall	
			<b>2.12</b>	<b>Post-operative care</b>	<b>303</b>
			<b>2.13</b>	<b>Obstetric procedures</b>	<b>305</b>

### Section 3: Neonatal care

	Dave Woods, June Brady, David Southall, Yawar Najam, Tsitsi Chawatama	<b>3.2</b>	<b>Resuscitation of the newly born</b>	<b>334</b>	
<b>3.1</b>	<b>Preparation for and care of the baby at birth</b>	<b>330</b>	<b>3.3</b>	<b>Clinical care of the infant in the early months of life</b>	<b>342</b>
			<b>3.4</b>	<b>Neonatal illnesses and emergencies</b>	<b>352</b>

### Section 4: Children in hospital

<b>4.1</b>	<b>The differential diagnosis of common or serious presenting symptoms and signs in children</b>	<b>380</b>	<b>4.1.L</b>	<b>The child with respiratory distress</b>	<b>390</b>
<b>4.1.A</b>	<b>The child with diarrhoea</b>	<b>380</b>	<b>4.1.M</b>	<b>The child with pyrexia (fever) of unknown origin (PUO)</b>	<b>391</b>
<b>4.1.B</b>	<b>The child with jaundice</b>	<b>380</b>	<b>4.2</b>	<b>Caring for children and young people in hospital</b>	<b>392</b>
<b>4.1.C</b>	<b>The child with lymphadenopathy</b>	<b>381</b>	<b>4.2.A</b>	<b>Nursing sick children</b>	<b>392</b>
<b>4.1.D</b>	<b>The child with abdominal pain</b>	<b>382</b>		Andrew Clarke	
<b>4.1.E</b>	<b>The child with anaemia</b>	<b>383</b>	<b>4.2.B</b>	<b>Nursing care for adolescents</b>	<b>395</b>
<b>4.1.F</b>	<b>The child who is vomiting</b>	<b>384</b>		Gill Barber	
<b>4.1.G</b>	<b>The child with a rash</b>	<b>385</b>	<b>4.2.C</b>	<b>The child with a disability in hospital</b>	<b>397</b>
<b>4.1.H</b>	<b>The child with failure to thrive</b>	<b>386</b>		David Cundall, Anne Nesbitt	
<b>4.1.I</b>	<b>The child with fits, faints and apparent life-threatening events (ALTEs)</b>	<b>387</b>	<b>4.2.D</b>	<b>Care of children and young people with a spinal cord injury</b>	<b>406</b>
<b>4.1.J</b>	<b>The child with generalised oedema</b>	<b>388</b>		Wagih El Masri, David Southall	
<b>4.1.K</b>	<b>The child with headaches</b>	<b>389</b>	<b>4.2.E</b>	<b>Facilities for children with special needs and learning difficulties</b>	<b>418</b>
				Susan O'Halloran, Prudence Hamade	

### Section 5: The child presenting with a system or organ dysfunction

<b>5.1</b>	<b>Upper airway disorders</b>	<b>422</b>	<b>5.3.B</b>	<b>Pleural effusion, empyema and bronchiectasis</b>	<b>441</b>
<b>5.1.A</b>	<b>Acute upper airway infections: croup and epiglottitis</b>	<b>422</b>		Alan Smyth, Massimo Serventi (R), Anne Nesbitt (R)	
	David Southall, Barbara Phillips		<b>5.3.C</b>	<b>Cystic fibrosis</b>	<b>442</b>
<b>5.1.B</b>	<b>The child with anaphylaxis</b>	<b>425</b>		Alan Smyth, Massimo Serventi (R), Anne Nesbitt (R)	
	Diane Watson, David Southall		<b>5.4</b>	<b>Cardiac disorders</b>	<b>446</b>
<b>5.1.C</b>	<b>The child with tonsillitis, otitis media, mastoiditis or retropharyngeal abscess</b>	<b>426</b>	<b>5.4.A</b>	<b>Congenital and rheumatic heart disease</b>	<b>446</b>
	David Southall			Christopher Duke, Shakeel Qureshi, Zdenka Reinhardt	
<b>5.1.D</b>	<b>The child with sleep-related upper airway obstruction</b>	<b>429</b>	<b>5.4.B</b>	<b>The child with heart failure and cardiomyopathy</b>	<b>453</b>
	Martin Samuels			Christopher Duke, Shakeel Qureshi, Zdenka Reinhardt, David Southall	
<b>5.2</b>	<b>Lower airway disorders</b>	<b>430</b>	<b>5.4.C</b>	<b>The child with a cardiac arrhythmia</b>	<b>456</b>
<b>5.2.A</b>	<b>Bronchiolitis</b>	<b>430</b>		Christopher Duke, Shakeel Qureshi, Zdenka Reinhardt	
	David Southall		<b>5.5</b>	<b>Shock</b>	<b>458</b>
<b>5.2.B</b>	<b>Asthma</b>	<b>431</b>	<b>5.5.A</b>	<b>Shock</b>	<b>458</b>
	Martin Samuels			David Southall, Barbara Phillips	
<b>5.2.C</b>	<b>The child with an inhaled foreign body</b>	<b>435</b>	<b>5.5.B</b>	<b>The child with shock from dehydration</b>	<b>463</b>
	David Southall			Barbara Phillips, David Southall	
<b>5.3</b>	<b>Lung disorders</b>	<b>436</b>			
<b>5.3.A</b>	<b>Pneumonia</b>	<b>436</b>			
	Alan Smyth, Massimo Serventi, Anne Nesbitt				

<b>5.5.C</b>	<b>The child with septic shock</b> Barbara Phillips, David Southall	<b>466</b>	<b>5.12.C</b>	<b>Constipation</b> Brian Coulter, Su Bunn, Alli Morrison	<b>559</b>
<b>5.6</b>	<b>Renal disorders</b>	<b>469</b>	<b>5.12.D</b>	<b>Inflammatory bowel disease</b> Brian Coulter, Su Bunn, Alli Morrison	<b>561</b>
<b>5.6.A</b>	<b>Medical renal disorders</b> Heather Lambert, Miriam Adhikari	<b>469</b>	<b>5.12.E</b>	<b>Upper gastroenterological disorders</b> Brian Coulter, Su Bunn, Alli Morrison	<b>563</b>
<b>5.6.B</b>	<b>The child with vesico-ureteric reflux</b> Aqeel Safdar, David Southall	<b>480</b>	<b>5.12.F</b>	<b>Gastrointestinal bleeding</b> Brian Coulter, Su Bunn, Alli Morrison	<b>565</b>
<b>5.6.C</b>	<b>Acute renal failure</b> Heather Lambert, Miriam Adhikari	<b>481</b>	<b>5.12.G</b>	<b>Malabsorption, including coeliac disease</b> Brian Coulter, Su Bunn, Alli Morrison	<b>566</b>
<b>5.7</b>	<b>Liver disorders</b>	<b>486</b>	<b>5.13</b>	<b>Rheumatology</b> Taunton Southwood, Sarah Malleson, Surjit Singh, Christiaan Scott	<b>569</b>
<b>5.7.A</b>	<b>Acute liver failure</b> Alastair Baker	<b>486</b>	<b>5.14</b>	<b>Cancer in children</b> Ramandeep Arora, Tim Eden, Barry Pizer, Jay Halbert (R)	<b>574</b>
<b>5.7.B</b>	<b>Chronic liver disease</b> Alastair Baker	<b>489</b>	<b>5.15</b>	<b>Eye disorders</b> John Sandford Smith, Geoff Woodruff	<b>588</b>
<b>5.8</b>	<b>Endocrine disorders</b>	<b>494</b>	<b>5.16</b>	<b>Neurological disorders</b>	<b>592</b>
<b>5.8.A</b>	<b>Diabetes</b> Jerry KH Wales, John W Gregory	<b>494</b>	<b>5.16.A</b>	<b>Coma</b> Charles Newton	<b>592</b>
<b>5.8.B</b>	<b>The child with hypoglycaemia</b> David Southall	<b>498</b>	<b>5.16.B</b>	<b>Bacterial meningitis</b> Elizabeth Molyneux, Sarah Morley	<b>597</b>
<b>5.8.C</b>	<b>Other endocrine disorders</b> Jerry KH Wales, John W Gregory	<b>500</b>	<b>5.16.C</b>	<b>Encephalitis</b> Saraswathy Sabanathan, Bridget Wills	<b>601</b>
<b>5.9</b>	<b>The child or adolescent with a mental health problem</b> Pamela Yerassimou, Anita Ajjaz, Shoba Srinath, Susan O'Halloran	<b>504</b>	<b>5.16.D</b>	<b>Epilepsy</b> Charles Newton	<b>606</b>
<b>5.10</b>	<b>Nutritional disorders</b>	<b>512</b>	<b>5.16.E</b>	<b>Convulsive status epilepticus</b> Yawar Najam, Charles Newton, Bernhards Ogutu	<b>610</b>
<b>5.10.A</b>	<b>Vitamin or mineral deficiencies</b> Qudrat Malik, Rob Moy, Susan O'Halloran (R), Bernadette O'Hare (R)	<b>512</b>	<b>5.16.F</b>	<b>Neuropathies</b> Allie Moosa	<b>613</b>
<b>5.10.B</b>	<b>Severe malnutrition</b> James Bunn, Massimo Serventi	<b>516</b>	<b>5.16.G</b>	<b>Guillain–Barré syndrome</b> Charles Newton, Ejaz Khan	<b>614</b>
<b>5.11</b>	<b>Haematological disorders</b>	<b>530</b>	<b>5.16.H</b>	<b>Muscular dystrophy</b> Allie Moosa	<b>615</b>
<b>5.11.A</b>	<b>Anaemia</b> Simon Parke, Susan O'Halloran, Bernadette O'Hare	<b>530</b>	<b>5.16.I</b>	<b>Breath-holding episodes</b> Allie Moosa	<b>616</b>
<b>5.11.B</b>	<b>Sickle-cell disease</b> Michele Afif, Simon Parke	<b>532</b>	<b>5.16.J</b>	<b>Migraine</b> Allie Moosa	<b>617</b>
<b>5.11.C</b>	<b>Haemolytic anaemias</b> Susan O'Halloran	<b>539</b>	<b>5.16.K</b>	<b>Neurosurgical disorders</b> Jamshed Akhtar, Aqeel Safdar	<b>618</b>
<b>5.11.D</b>	<b>Blood clotting disorders</b> Susan O'Halloran	<b>543</b>	<b>5.17</b>	<b>Orthopaedic problems</b> Jamshed Akhtar, Yogesh Nathdwarawala, Ian Mackie (R)	<b>620</b>
<b>5.12</b>	<b>Gastrointestinal disorders</b>	<b>544</b>	<b>5.18</b>	<b>Skin disorders</b> Roderick Hay	<b>625</b>
<b>5.12.A</b>	<b>Acute diarrhoea</b> Peter B Sullivan, Sapthagiri Gantasala, Barbara Phillips, David Southall	<b>544</b>	<b>5.19</b>	<b>Surgical disorders</b> Aqeel Safdar	<b>628</b>

# Foreword

Professor David Southall and the expert contributors to this textbook must be commended. They have delivered a consolidated, practical guide on maternal and child health with an understanding that care should not be compromised even in the face of conflict, material shortage, or human resource limitations.

Maternal and child health has made great strides in recent decades, but requires continued work. This textbook tackles the challenge by taking a uniquely holistic perspective and will help to push forward this public health agenda. This book is enriched by in-depth clinical questions, in addition to a sympathetic and exceptional understanding of the challenges facing health systems worldwide.

The segment on respectful and compassionate care caught my attention in particular. It is a crucial aspect of quality medical service and a patient's continued engagement in

the healthcare system. This goes hand-in-hand with grief management, medical and nursing ethics, and the realisation that healthcare moves well beyond the clinical setting alone. Comfort and communication go a long way, and I applaud the authors for their promotion of complete care.

I am particularly grateful to the authors for providing this textbook free of charge in resource-limited clinical settings. I am excited to see literature that understands the importance of continued education for a strong health workforce.

It is with the help of textbooks like this that we can move towards increased access to evidence-based, comprehensive healthcare for women and children. It is my hope that this textbook will become an essential part of a holistic, systems-based approach to maternal and child healthcare.

**Dr Bernice Dahn MD MPH FLCP**  
**Deputy Minister of Health/  
Chief Medical Officer-Republic of Liberia**  
*July 2014*

# Preface

This textbook is written to help health workers treating pregnant women and adolescents, their newborn infants, and children admitted to hospitals in countries all over the world. It is especially aimed at those working in settings in which material and human resources are limited, where borders and infrastructures are insecure, and in rural areas where health workers may find it particularly difficult to work. Building on existing global efforts, dedicated doctors, nurses and midwives in these settings are already providing life-saving healthcare, but often find their work hard and sometimes overwhelming. Access to up-to-date evidence-based guidelines in such settings is often extremely difficult. The Internet is often too slow, printing from computers is often too expensive, and so, in our experience, books remain essential.

This textbook has been written and peer-reviewed by over 100 experts from around the world, with experience in hospital settings in which there are poor resources, who have freely given their time and expertise. Covering all aspects of hospital care for pregnant women and adolescents, newborn infants and children, this textbook addresses a full range of possible illnesses, conditions, and injuries and includes complications of pregnancy and delivery. Based on the latest evidence and guidelines available, including Cochrane reviews and World Health Organization (WHO) guidelines, this textbook builds on existing efforts and identifies an internationally applicable minimum standard of healthcare in poorly resourced

hospitals and reflects the management of problems often inherent in resource-limited countries. The textbook proposes minimum standards, both in the treatments given and also in the medical ethics and professional standards, which should be practised in caring for the particularly vulnerable patients attending hospitals in resource-limited settings.

MCAI is funding the costs of publishing, printing and distributing this textbook on a 'not for profit' basis. Following requests from health workers in resource-limited settings, the aim of the editors and authors is to provide this textbook free of charge (on condition that health workers agree to use and look after the textbook; see inside cover). The textbook is particularly targeted at front-line health workers in the most disadvantaged hospitals in the world, particularly those in rural areas of low-income countries, especially those treating all women and children regardless of their or their family's ability to pay. In all other countries, the textbook will be charged at above cost price with all profit from these sales going to help fund the provision of further copies of the textbook for health workers in low income countries and to the work of MCAI in strengthening the emergency healthcare systems of hospitals in the world's poorest countries.

The aim of all authors and editors is to provide a useful, comprehensive reference for all health workers in all settings to help them provide the best possible clinical care and management for pregnant women and adolescents, their newborn infants, and children.

# Introduction

## HOW TO USE THIS MANUAL

This is a comprehensive manual designed for all health workers caring for pregnant women and adolescent girls, infants and children in hospitals. It can be used by those with limited resources and also where greater resources are available.

Minimum standards required to practice well are given in a highlighted box at the beginning of each section addressing clinical practice.

Aspects of care where resources are so limited that they cannot at present be undertaken in most poorly resourced settings are highlighted in grey.

Key points, especially those where inappropriate actions might be dangerous, are presented in **bold font**.

This in-depth manual has been written for doctors, midwives and nurses caring for pregnant women and adolescent girls, newborn infants and children in the poorest, most disadvantaged, countries of the world, particularly concentrated in sub-Saharan Africa and South Asia. It is primarily designed to develop a minimum standard of care in hospitals for every woman, baby and child, regardless of the resources available for the country as a whole.

The startling numbers in the Tables below illustrate the unethical and unacceptable mortality rates for pregnant women, newborn infants and children in resource-poor countries. The continued presence of armed conflict and,

in many cases, the associated and deliberate targeting of healthcare (see [www.ihpi.org](http://www.ihpi.org)) has contributed to a worsening situation in many countries.

ARTICLE 25 of the Universal Declaration of Human Rights adopted in 1948 states the following: 'Everyone has the right to a standard of living adequate for the health and well-being of himself and of his family, including food, clothing, housing and medical care and necessary social services, and the right to security in the event of unemployment, sickness, disability, widowhood, old age or other lack of livelihood in circumstances beyond his control. Motherhood and childhood are entitled to special care and assistance. All children, whether born in or out of wedlock, shall enjoy the same social protection'.

There is no question that a considerable burden of unnecessary suffering is endured by women and children in hospitals; not only those in poorly-resourced settings. This situation is not all related to a lack of funds; much also relates to deficiencies in the training of health workers. Often, the training and continuous professional development of doctors, midwives and nurses is a low priority and even after training they are often not provided with adequate salaries, professional recognition or up to date evidence-based teaching and clinical materials. Standard medical textbooks for health workers in disadvantaged countries are usually too expensive and out-of-date, hampering their continuing medical education.

**TABLE 1 Comparison of maternal and child mortality rates in rich versus poor countries in the world**

	47 high income countries defined as those with GNI ≥ 12,616 USD per capita per annum <sup>†</sup>		33 low income countries defined as those with GNI ≤ 1035 USD per capita per annum <sup>†</sup>	
	Range	Median	Range	Median
Under 5 year mortality rate per 1000 live births: 2012 data	2–21	5	40–182	90
Maternal mortality ratio (MMR)* per 100,000 live births: 2010 data 'adjusted'	2–47	8	70–1100	460

Data from State of the World's Children (2014) by UNICEF.

\*MMR is the number of deaths of women from pregnancy-related causes per 100,000 live births during the same period. The data that are 'adjusted' refer to 2010 United Nations inter-agency maternal mortality estimates released in May 2012.

<sup>†</sup>GNI = Gross National Income from World Bank data; USD = United States Dollars

**TABLE 2** Details of individual numbers of maternal and under 5 year deaths comparing low and high income countries

	Total number of births 2012	Total number of maternal deaths 2010 adjusted*	Total number of child deaths under 5 years 2012	Number of live births resulting in 1 maternal death	Number of live births resulting in 1 child death
Low income countries (N = 33, 32 with data on maternal deaths and 33 with data on under 5 year child deaths)	26,007,000	110,376 (median number for individual countries = 2049)	2,197,982 (median number for individual countries = 43,228)	<b>236</b>	<b>12</b>
High income countries (N = 47, 45 with data on maternal deaths and 47 with data on under 5 year child deaths)	14,149,000	2190 (median number for individual countries =7)	84,479 (median number for individual countries = 420)	<b>6461</b>	<b>167</b>

Data from State of the World's Children (2014) by UNICEF.

Editing and writing this book has been challenging for the editors and authors. We have identified what we regard as the acceptable minimum standards of treatment for all major diseases and injuries that affect the pregnant woman, newborn baby, infant and child, wherever they are cared for. But we also wanted to offer a set of ideal standards for care where resources are adequate. Therefore, we have incorporated the essential minimum standard of care alongside some of the best standards currently available. However, readers will notice that for most of the treatments recommended, the minimum and gold standards are identical because there are certain treatments that should be provided as essential hospital care, whatever the

pressures. This manual should ideally be supplemented by scenario- and skill-based short training courses, combined with apprenticeship and small group teaching on the wards and in the operating theatre.

We believe in the continuing value of printed books to the practical application of healthcare, recognising that with time and improved access to high-speed internet in low resource settings, electronic materials, particularly videos and an easily accessed internet, will introduce major benefits. In the meantime books should be available for all health workers regardless of their ability to pay for them. We hope that you will find this in-depth manual helpful.

# Acknowledgements

The editors are extremely grateful to the following people, without whom, producing this textbook would not have been possible:

- All of our authors (see contributor list)
- Radcliffe Publishers, with particular thanks to Tanya Dean, Jamie Etherington and Gillian Nineham
- Jo Hargreaves (freelance copyeditor)
- Vivianne Douglas from Darkriver Design
- Alison Grove, Janette Latta and Mairi Stephen (all three MCAI staff), Bethany Jones (manuscript work), Rachel Drummond and Laura Ella-Kirk (artists) and Dr Joan Robson (fundraising) for their invaluable contributions
- Dr Alison Earley Trustee of MCAI for her review of the HIV in children proof and Professor Helen Foster, Professor of Paediatric Rheumatology, Newcastle University for her input on pGALS to the chapter on Rheumatology disorders
- Dr Maurice King and Professor Glen Mola for allowing us to use copyright-free a large number of figures (some of which we have modified) from their book *Safe Motherhood in Developing Countries*
- The paediatric section of this textbook is partially based on an earlier book published in 2002 by BMJ Books on behalf of MCAI and entitled *International Child Health Care: a practical manual for hospitals worldwide*. We thank all of the Editors and authors of this previous book. In particular, we dedicate this new book in memory of Dr Christiane Ronald, a paediatrician who worked for MCAI for many years.

## Disclaimers

1. The authors and editors have done all they can to ensure that drug doses and other facts in this book are accurate. While every effort has been made to ensure the accuracy of the information, as publishers we can give no guarantee on information about drug dosages or the applications of the drugs or procedures described in this textbook. In every individual case the user must check current indications and accuracy by consulting relevant pharmaceutical literature and following the guidelines laid down by manufacturers of specific medical devices. Users must also follow the guidelines of relevant authorities in the countries in which they are practising. The publishers cannot accept responsibility or legal liability for any errors in or misuse of material in this textbook.
2. The Advanced Life Support Group (ALSG) is very pleased to be a partner in this landmark text which presents up-to-date and practical information in an accessible form to clinicians working in low resource settings. ALSG clinicians have made a significant contribution to the textbook but the organisation must make it clear that their contribution has been confined to emergency topics as this is the organisation's field of experience and expertise in both high and low resource settings.

\* The contents of this work are intended to further general scientific research, understanding and discussion only and are not intended and should not be relied upon as recommending or promoting a specific method, diagnosis or treatment by physicians for any particular patient. The publisher and the author make no representations or warranties with respect to the accuracy or completeness of the contents of this work and specifically disclaim all warranties, including without limitation, any implied warranties of fitness for a particular practice. In view of ongoing research, equipment modifications, changes in governmental regulations and the constant flow of information relating to the use of medicines, equipment and devices, the reader is urged to review and evaluate the information provided in the package insert or instructions for each medicine, equipment or device for, among other things, any changes in the instructions or indication of usage and for added warnings and precautions. # Section 1

## General issues regarding hospital care

## 1.1

## Hospital management: non-clinical support and facilities

### Introduction

For effective delivery of healthcare, a secure financial strategy with robust financial and manpower controls, a properly maintained technical infrastructure, clear lines of accountability, and good management and communication lines all need to be in place. Ideally there should be clearly defined written personnel procedures, good training systems, and written policies and guidelines for all staff functions. The facilities and functions described in this section need to be in place, and are as important as the quality of medical care given. The services and facilities discussed in this text are basic, not comprehensive; well-resourced countries may have many additional ones. **If these services and facilities are in place, and are managed efficiently, supported and maintained, mainline healthcare delivery will be effective.**

Giving advice on generic hospital management is difficult, since the ability to deliver a minimum standard of care depends on the political, social and economic context in which the hospital is situated. Ideally there should be a named person responsible for each facility and service, in addition to an overall hospital manager or management team. The hospital manager or management team should have overall responsibility for finances, estates and facilities, human resources, direct clinical patient care and support services (laboratories, radiology, therapies, pharmacy, etc.), training for all staff and the administrative services necessary to support all of these activities. There should always be a head nurse, a head of support services and a senior doctor within the management team.

### Staff management

**Staff motivation and retention (human resource management) is an essential component of hospital management.**

In order to provide good-quality essential health services to the people whom they serve, hospitals must put in place strategies and mechanisms to retain staff and help them to provide the best possible care for patients. The reasons for the healthcare worker crisis in hospitals in resource-limited countries include inadequate numbers of healthcare professionals, who are poorly distributed due to an unplanned 'brain drain' both regionally and internationally (attrition). According to the World Health Organization (2006), this phenomenon is caused by workers experiencing **low salaries, poor, unsafe work environments, a lack of defined career paths, and poor-quality education and training.**

**Another most important issue is the support of every healthcare worker's family. Ministries of Health must not disrupt such vital bonds by moving staff away from their families, without their full and freely given agreement.**

In the light of the above factors that face health services and compromise hospital-based care, managers must endeavour to motivate the limited human resources available to ensure retention.

A systematic review of six papers evaluating the management and leadership strategies that promote healthcare worker retention in resource-limited countries has identified a number of key lessons, which can be summarised as follows.

#### Payment of financial incentives to healthcare professionals

This particularly refers to professionals working in unpopular rural areas. Hospitals are run by boards which, as such, should be able to autonomously initiate better financial incentives for their staff. The above-mentioned review found that 86% of the studies showed payment of an attractive salary and allowances was a key motivational strategy for maintaining healthcare workers in their posts. Often what made most healthcare workers leave their jobs, particularly in the public health sector, was being unable to provide basic support for their families on the meagre salaries provided. According to a study conducted in South Africa, an increase in salary of healthcare workers has resulted in many health professionals who had previously left the public health sector, to work in private facilities, returning to the public sector.

#### Appreciation of healthcare workers

The community loyalty, personal commitment and willingness to make personal sacrifices that are shown by healthcare workers must be recognised and encouraged. This means that both the hospital management and the communities that they serve must demonstrate their appreciation of these attitudes.

Staff must be respected for and thanked for the work they do. Personal appraisal followed by periodic awards is a motivating factor for staff retention. The views of all staff should be listened to, and they must be involved in decision making to enable the best problem-solving approaches to be identified and implemented – it is their hospital and their community.

Orderlies, porters and cleaners are just as important in patient care as doctors and nurses, and this needs to be made clear to all staff. It can be helpful for doctors, nurses and hospital managers to participate and help the cleaners during, for example, the monthly deep cleaning of a ward.

An annual awards ceremony can be very helpful. For example, each department could be awarded certificates for:

- the most punctual member of staff
- the most improved member of staff
- the best dressed member of staff
- an award of excellence for the best all-round member of staff.

The awards could also include special categories, such as:

- the most long-serving member of staff (e.g. the refuse collector)
- an award for providing services above and beyond the 'call of duty'.

This allows awards to be made to staff who might not be in a position to further their education and to receive a certificate.

Receiving such recognition in front of management and invited guests who are prominent in the hospital's catchment area is a huge honour and boost to morale.

### **Training and supervision**

Studies conducted on human resource management for health services in Africa indicate healthcare workers' frustration at having to be assigned to responsibilities and functions for which they have limited or no training. This can be effectively managed by providing 'on-the-job' support through the provision of simple and clear guidelines on clinical procedures. Although resources may be limited for specialised advanced training, priority should be given to locally conducted ongoing training that is cost-effective and sustainable, aimed at equipping healthcare staff with the knowledge necessary to provide efficient and good-quality patient care.

Providing a programme, space and encouragement for healthcare workers to take turns to train and update their peers (e.g. an internal continuing medical education programme) can also be a low-cost and effective way for healthcare workers to share new or updated practice, as well as to develop their own teaching skills.

Similarly, provision of basic information technology, computers and an Internet connection where possible is an important way of reducing professional isolation, helping healthcare workers to remain updated in their practice and to connect with the wider health community.

Some hospitals have benefited greatly by training the locally recruited nurse attendants (healthcare assistants) to second level (state-enrolled nurses) at the local nurse training school. Such nurses are usually born locally and their families live nearby, which often ties them to continuing to serve the community in which they live. In one site that has used this approach, the hospital has been able to train over 30 nurse attendants to the second level.

The introduction of an on-call support service to nurses working out of hours can be valuable. Senior nursing staff who are knowledgeable and experienced have volunteered to help with difficult health or social problems that arise. This provides a link between management and the nursing and clinical staff, facilitating resource mobilisation and ensuring that staff are on duty at the right time and filling gaps where necessary. Many social problems for both staff and patients can be heard and addressed appropriately.

Similarly, it is important to have a suggestions box that allows any member of staff to air their views anonymously if they wish to do so.

### **Provision of essential equipment and supplies**

The lack of or inadequate provision of medical supplies, drugs and equipment in hospitals is one of the most difficult situations that healthcare workers have to cope with. Research has shown the demotivating situation that healthcare workers face when trying to treat patients without the necessary drugs and equipment. The provision of adequate and regular medical supplies, drugs and equipment is part of the answer to the ongoing question of how health systems in developing countries can best retain their health workforces. Such provision should be a management priority.

### **Provision of social and family amenities**

Provision of basic facilities such as housing and good accommodation for healthcare staff is found to have contributed immensely to retention in many parts of the resource-limited countries where such projects have been implemented as part of a retention package.

For example, this is evident in Bansang Hospital, Gambia, West Africa, where staff retention for the past 5 years has been well recognised by authorities. Healthcare workers in Bansang Hospital are given fully furnished accommodation with water and electricity at no cost to the staff. This helps staff to increase their savings and thus boost their income, as they do not have to pay rent or utility bills. This initiative has not only enabled the hospital to retain its staff, but has also served to attract other healthcare workers to come and work there.

A particular challenge for recruiting and retaining experienced healthcare professionals in remote regions is the provision of education for their children, particularly at secondary level. Arrangements for children to be educated and looked after elsewhere are offered in some countries, but this remains a barrier to retention.

Nutrition is an important aspect of medical care for inpatients, particularly those whose relatives cannot provide the nutritious or special diets required. Encouraging all staff to grow their own vegetables and fruit for both patients and staff gives staff a sense of belonging, and extends their care for patients. In Bansang Hospital, Gambia, staff have for the past 3 years formed their own 'Charitable Farming Association'. They pay to become a member, and in return for this they can sustain the feeding of the patients with couscous and beans. Farming activities are to increase in 2014, as the hospital has been given 20 hectares of land, and will now grow rice.

A social centre for staff (with a television, sports facilities, etc.), particularly those who are not living close to or with their families, can be very helpful.

In conclusion, financial incentives can contribute to retention, but other non-financial incentives are equally likely to lead to sustainable retention. Given the economic situation in most resource-limited countries, the wages paid to healthcare workers in prosperous economies might not be realistic in low-income countries. However, the implementation of cost-effective human resource strategies is a more realisable step forward.

Furthermore, the implementation of one strategy at the expense of others is unlikely to result in the long-term aim of achieving healthcare worker retention. Therefore there is a need to adopt both financial and non-financial strategies to retain healthcare staff. Strategies might differ between low-income countries, due to socio-cultural and economic differences.

### **Essential services and facilities**

#### **Hospital security and access**

The security and accessibility of the hospital are of paramount importance, especially given the relative lack of police resources in many resource-limited countries. There is also a need for governmental and international agencies to ensure that hospitals are protected and do not become targeted during armed conflict.

At the local level, the hospital should have a perimeter fence with secure entrances where all persons attending

have to demonstrate a legitimate reason for entry. No weapons should be allowed into the hospital, and in some countries it may be necessary to have a metal detector to screen all visitors.

A well-organised car parking system is required, with strictly policed access areas for emergency vehicles and for parents or relatives bringing very sick patients to and from the hospital.

### **Safety and cleanliness**

There should be clear written evacuation and fire policies, together with appropriate equipment (e.g. fire extinguishers). The perimeter fence should be of a construction that will keep out animals.

### **Communication systems**

Good communication systems for staff, visitors and patients are essential. Ideally both outside and internal telephone systems should be available. If telephone systems are not feasible, alternative effective reliable systems of communication should be used. A hospital paging system for doctors, senior nurses and managers aids communication in emergency situations.

Internet access is invaluable for information sharing and education, both within a country and globally. Provision can be sought via governmental or non-governmental donor sources. A nominated person with overall responsibility for hospital computer systems predisposes to a cohesive service both internally and externally, avoiding duplication and ensuring appropriate usage.

Effective communication between groups of staff improves the effectiveness and efficiency of care. Regular meetings should discuss individual patients, debrief following deaths and clinical incidents, and audit specific aspects of clinical and unit management, such as infection control. The outcome of audit, particularly any changes in practice, needs to be available to those staff it affects, but such meetings should be educational and not used for apportioning blame.

## **Utilities**

### **Water and sanitation**

Hygiene within the hospital is paramount, and is dependent on a constant and high-quality water supply and adequate sanitation and washing facilities (i.e. bathrooms, showers, toilets and accessible sinks with an effective, functioning drainage system), all of which are vital if hospital-related infection (see Section 1.2) is to be minimised.

### **Electricity**

An electricity supply within the hospital, which functions independently of any power losses to the rest of the area, is mandatory. Therefore a generator of sufficient power should be an essential item of equipment (the generator size is calculated from bed dependency and operating theatre requirements). In resource-limited countries where an erratic power supply is common due to high fuel costs, solar back-ups are needed for hospitals to function efficiently and effectively. There should be special emergency circuits. Power-cut simulations should be carried out regularly to test the system.

### **Heating and ventilation**

Ideally there should be a functioning central heating system within the hospital. For this to work, there will also need to be a continuous water supply. If either of these cannot be ensured, electric heaters should be installed in all areas where there are patients.

In hot weather, there should be sufficient windows (that can be opened) to allow a comfortable temperature to be maintained during the hottest part of the day. An air-conditioning system or fans, either electric or manual (to be operated by relatives), should be available in areas of the hospital that become particularly hot, and for patients who must be kept cool (e.g. children with high fevers or head injuries).

### **Laundry service**

Bedding and other items must be frequently washed. Therefore the hospital must have a staffed laundry service, ideally with a sufficient number of industrial washing machines and drying facilities. Where hand washing is the only option, staff should wear protective clothing and high-quality thick gloves. Clean bedding, towels and nappies must be available. A small supply of nightwear and other clothing may be needed on the wards for families who do not have a change of clothes with them.

### **Cleaning services**

**Patients who are being cared for in hospital are particularly vulnerable to nosocomial (hospital-acquired) infection (see Section 1.2). To reduce this risk, sufficient staff should be employed on a rota over the 24-hour period to keep all areas of the hospital and grounds clean at all times. Written cleaning policies and training for cleaners should be in place, and a supply of appropriate cleaning materials and disinfectants readily available.**

Clean hospital grounds, pathways and entrances reduce the risk of dirt being transmitted to the ward and other patient areas by staff, relatives and other visitors. Stray animals must be kept away from the hospital premises.

Vermin must be kept away from the hospital buildings. Professional advice must be sought as soon as any signs of vermin are found.

**Toilets, bathrooms and other facilities needed for personal hygiene and for equipment cleaning are of particular importance, and these areas should always be kept scrupulously clean.**

Certain areas, such as operating theatres, as well as certain items of equipment, must always be aseptic (see Section 1.5). Ideally there should be a central sterilising service. If this is not possible there should be suitable sterilisers and a supply of appropriate disinfectants at a range of dilutions. Wherever possible the manufacturers' instructions for specific items of equipment should be followed.

### **Waste disposal system**

A powerful incinerator that operates 24 hours a day is essential for the safe disposal of clinical waste. A system for handling and disposal of all clinical and non-clinical waste, including 'sharps', is also needed. Written policies for various types of waste disposal, and appropriate training, should be available to all staff.

## Facility and utility maintenance services

### Buildings, utilities and equipment

It is essential for these to be maintained to as high a standard as possible. Suitably trained engineers, builders and other maintenance staff are necessary. **There is no point in having expensive medical and surgical equipment if it cannot be maintained or used.** A sufficient number of trained bioengineers are therefore essential. All equipment that is used in the hospital should be robust, compatible if at all possible, suitable for the conditions and level of expertise available, and, when new, should be purchased with accompanying staff training and servicing arrangements.

### Porters

For the functional relationships between different departments (e.g. the movement of patients to and from the operating theatres), a well-organised, trained and sympathetic team of porters is essential.

### Caterers

Hospital food must be prepared under scrupulously hygienic conditions, and by staff who do not have gastroenteritis or superficial skin infections. Ideally, nutritious food should be provided free of charge. Special diets for malnourished children should be available (see Section 5.10.B).

### Administrative support

Rather than diverting away the skills of a trained nurse, dedicated reception and other administrative support staff need to be employed to aid facility managers and other non-clinical and clinical staff. There must be a staffed system for storing and processing medical and nursing records. There should be strict rules about who has access to these records, where they are stored and for how many years they are kept.

## Human resource issues

### Hiring and dismissing staff

There should be transparent procedures for advertising for, interviewing and employing staff. These must include non-discriminatory policies, in particular with regard to gender, age, and ethnic and religious status.

### Employment and financial issues

**It is essential that the medical and nursing professions in all countries are highly regarded and respected, so it is important that the salaries for doctors and nurses in the national health services reflect this.** If not, the staff may have to undertake other jobs during the day, and will not feel valued for their work. A lack of funding for salaries also increases the risk of corrupt practices, with some doctors taking supplies and equipment from their hospital to use in private clinics, thus depriving the poorest and most needy in the community.

Individual job descriptions and responsibilities should be agreed between healthcare professionals, their professional organisations and hospital management.

Arbitrary and compulsory transfer of staff from one place to another, at short notice and without consultation, is damaging both to morale and to the effectiveness of health services, and should be avoided.

There should be systems for ensuring the regular

and secure recording of the time spent at work and the appropriate payment arrangements based on the contracted number of hours worked (part- or full-time). On-call emergency work and its payment should also be part of the contract.

There should be a professional registration system for each country, which ensures a basic level of training, as well as a system that validates experience and ability at specific intervals after initial registration.

Concern about individual performance should be addressed by a senior staff member on a one-to-one basis. Written guidelines should be used in a transparent way. Sometimes a period of supervised practice or retraining is appropriate.

**Training and continuing staff education** (see also Section 1.3)

Induction training concerning hospital policies should be mandatory for all staff.

Governments in well-resourced countries could encourage a support system of education for those working in less well-resourced regions.

**New teaching techniques, such as skill- and scenario-based teaching (e.g. EMNCH courses) (see Section 1.3), should be introduced.**

### Professional registration requirements for healthcare workers

These will vary from one country to another. However, some form of governmental registration is essential. There should also be procedures governing the employment of expatriate staff in the health service.

### Vetting of healthcare workers

All staff who are working with patients, whether they are local or from abroad, should be checked to ensure that they are suitably trained and have not been involved in the abuse of children. This is also important with regard to expatriate staff.

**Staff health** (see also Section 1.17)

There needs to be a system to advise the hospital management about staff health problems that may affect patient care. Staff with health-related problems that are affecting their performance need access to a supportive **occupational healthcare system**. There should be systems in place to protect patients from staff who are ill. This is a difficult but extremely important issue, particularly with regard to illnesses such as TB, HIV and hepatitis. Sometimes other support is necessary so that a healthcare worker's performance can be restored in the interests of all.

### Needlestick injury

Although the risk of infection is very small, a policy should be in place to deal with this issue urgently, especially in hospitals where there are many patients with HIV infection and hepatitis.

Needlestick injuries are the commonest type of sharps injury, although other contaminated sharp instruments may also cause injuries. All healthcare workers must be educated about the potential exposure that can occur during their duties, and should have appropriate vaccinations. The risk of hepatitis B, hepatitis C and HIV infection should be assessed and appropriate immunisation or chemoprophylactic steps taken after an incident. Immediate treatment of such injuries should encourage washing thoroughly with

running water and an antiseptic solution. Consult the infection control team for further advice, and follow their basic protocol. An incident-reporting system should be in place. This should not be seen as punitive; active support by managers should encourage prompt and accurate reporting.

### **Exposure to human immunodeficiency virus (HIV)**

The route of transmission of HIV is from person to person via sexual contact, sharing of needles contaminated with HIV, infusions that are contaminated with HIV, or transplantation of organs or tissues that are infected with HIV. The risk of a healthcare worker acquiring HIV after a needlestick or other 'sharps' injury is less than 0.5%. Risk reduction must be undertaken for all bloodborne pathogens, including adherence to standard precautions using personal protective equipment, appropriate safety devices, and a needle disposal system to limit sharps exposure. Training for healthcare workers in safe sharps practice should be ongoing.

Information on preventive measures must be provided to all staff who may potentially be exposed to blood and blood products. Policies that are in line with the local and national guidelines must include screening of patients, disposal of sharps and wastes, use of protective clothing, management of inoculation accidents, and sterilisation and disinfection procedures. Hospital policy must include measures to obtain serological testing of source patients promptly where necessary, usually with the patient's informed consent. Post-exposure prophylaxis should be started as per local or national guidelines.

### **A suggested strategy for use when a healthcare worker has been potentially exposed to HIV**

- 1 Discuss with the patient (or in the case of a child, the family) what has happened, and ask whether the patient's HIV status is known. If it is not, discuss the possibility of testing, if the injury occurred during normal working hours. Remember that anyone undergoing an HIV test has the right to counselling. If the injury occurred out of hours, or the family decline testing, proceed to Step 3.
- 2 If the patient has negative HIV ELISA and is over 18 months of age, infection is extremely unlikely. If they are under 18 months of age, a positive ELISA may reflect maternal antibodies. However, any positive test result should lead to Step 3. If the result is negative, the healthcare worker is not at risk of HIV infection. However, further testing of both the child and the healthcare worker for hepatitis B and C may be warranted.
- 3 Arrange a baseline HIV ELISA for the healthcare worker after appropriate counselling. If the result is positive, they will need to discuss further treatment with their own doctor.
- 4 If the healthcare worker's baseline serology is negative and the patient is HIV positive, antiretroviral prophylaxis should be started urgently. Current recommendations advise 1 month of treatment. The healthcare worker will need a repeat ELISA after 3 to 6 months to check their status.

### **Exposure to hepatitis B virus**

The route of transmission of hepatitis B virus is through body fluids such as blood, saliva, cerebrospinal fluid, peritoneal, pleural, pericardial and synovial fluid, amniotic fluid, semen,

vaginal secretions and any other body fluid containing blood, **and also through blood products**. It is important to follow standard precautions, but immunisation is the best way of preventing transmission to healthcare staff. All healthcare workers who are in contact with patients or body fluids must be vaccinated against hepatitis B.

Staff who are infected with bloodborne pathogens may transmit these infections to patients, and therefore require careful evaluation with regard to their duties. This status should not be used to discriminate against them.

### **Exposure to hepatitis C virus**

The route of infection is mainly parenteral. Sexual transmission does occur, but is far less frequent. No post-exposure therapy is available for hepatitis C, but seroconversion (if any) must be documented. As for hepatitis B viral infection, the source person must be tested for hepatitis C virus infection. For any occupational exposure to bloodborne pathogens, counselling and appropriate clinical and serological follow-up must be provided.

### **Confidentiality**

Systems need to be in place to ensure that patient's records and the personal files of employed staff are kept confidential.

### **Other services for patients and their relatives**

Health information should be available (see the Maternal and Child Healthcare Initiative (MCHI) manual).

Toilets should be available for visitors, as well as facilities for those visitors with a disability. If possible, telephones should also be available for visitors.

Ideally there should be written policies concerning the rights and responsibilities of patients, resident parents/carers and visitors. These policies should be prominently displayed around the hospital, and should include issues such as the prevention of smoking, the effects of alcohol, violence (verbal and physical) and weapons in the hospital. Smoking is particularly important in relation to children's health, but in the case of stressed parents it may be inappropriate to ban it altogether. Instead it should be limited to defined areas.

### **Family-centred care**

The role of families in caring for patients alongside and in partnership with professional staff is vital, but must be handled extremely carefully. Families must not be exploited, but equally in resource-limited countries hospital care would not be possible without their assistance. Good understanding of roles and effective communication are of paramount importance (see *also* Section 1.20 and the MCHI manual).

### **Play, sensory stimulation and support for children's wards**

The importance of play and developmental support cannot be overemphasised. A friendly and stimulating environment helps the child to understand and cope with their hospitalisation and to get better far more quickly (as advocated in the World Health Organization recommendations for the recovery management of children with malnutrition). It also helps to support the parents, and can provide them with additional skills that they can continue to use at home once the patient has been discharged. Many mothers cannot

afford to stay at the hospital for long periods because there is strong pressure to return to their village, where they are pivotal to the daily routine, farming, etc. Mothers can be supported by passing on the knowledge of play as taught by a play worker. Giving the sick child access to play and information facilities in hospital also helps to reduce loneliness and fear.

Some well-resourced countries have training programmes and qualifications for play specialists. These are not available in most low-income countries. However, much can be achieved by recruiting suitable people to support therapeutic, informational and recreational play with children in hospital. It is effective, as both an adjunct and core part of treatment, in the hands of a skilled play worker, and any resources can be made of local and low-cost materials.

Play workers need to have good communication and empathy skills with children and families. They also need to have a good understanding of child development and the particular needs of children in hospital (especially children

who are alone and/or who have disabilities or other additional needs). In addition, play workers need to be trained in how to deal with some specific situations, such as the comatose child (the fact that these children can hear and have feelings when touched, and how to encourage the parents to talk and play with the child).

## Conclusion

The provision, organisation and financing of these services, facilities and functions, and the management of the human resources needed to service them, are as important as those needed to provide the clinical and clinical support services. A sound hospital infrastructure and management are of paramount importance for the provision of good-quality care.

Further information on other work-related issues concerning healthcare staff can be found in Sections 1.17 and 1.20.

## 1.2

# Prevention of hospital-acquired infection

## Introduction

**Nosocomial or hospital-acquired infection** is a major problem not only in terms of cost but also, more importantly, because it increases morbidity and mortality in patients. Such infections may affect up to 10% of all patients. Nosocomial infection requires a source of microorganisms and a chain of transmission. It is essential that all healthcare staff scrutinise their own practice to ensure that they are not part of this chain of transmission.

**Please see the *Maternal and Child Healthcare Initiative Manual* for more information on standards of care relating to the prevention of hospital-acquired infection ([http://media.wix.com/ugd/dd2ba4\\_ef4f40edd7a8993a8621a2caea7e4338.pdf](http://media.wix.com/ugd/dd2ba4_ef4f40edd7a8993a8621a2caea7e4338.pdf)).**

**The combination of use of powerful antibiotics and poor hygiene also predisposes to the development of antibiotic-resistant microorganisms, which are difficult both to eradicate from the environment and to treat.**

Pregnant women and girls, as well as children with chronic and debilitating illness, are particularly at risk of infection. However, not all infections are related to their particular disease process, but rather they may be caused by failure of both hospital management and individual healthcare workers to introduce and adhere to strict infection control policies.

Every research study relating to the prevention of infection and cross-infection in hospitals during the last 100 years has emphasised the importance of hygienic conditions **in the entire hospital**.

## Requirements and procedures

The following measures are essential in order to minimise the risks of infection and cross-infection.

### A clean and adequate water supply

Just as water and sanitation are of central importance in the prevention of cross-infection in emergency refugee camps, they are also of vital importance in hospitals, particularly where there are vulnerable patients. Running water (both hot and cold) is preferable. Hot water should be stored at 65°C, distributed at 60°C, and the temperature then reduced to 43°C to be used from the taps. This process helps to ensure that water-borne infections such as Legionnaire's disease are not passed on to staff or patients.

### Accessible sinks in all areas

These should preferably be equipped with elbow-operated taps, and there should be **adequate washing and toilet facilities for staff and patients**.

### Effective cleaning policies

The whole of the hospital, including the grounds, should be kept clean. Entrances should screen visitors' shoes for dirt, and corridors need to be cleaned at least twice a day with a disinfectant (see below). **Ward areas, floors, window-sills, light fittings and curtains need to be kept scrupulously clean, but the priority is the adequacy and cleanliness of the toilets and bathrooms.** These should be kept scrupulously hygienic by frequent cleaning and disinfection. **Staff appointed as cleaners should be given adequate status and salaries to reflect the importance of the work they are doing, as well as training in how to keep the hospital clean and why this is so important.**

### Effective services for disposal of human and other waste

Human and other waste should be disposed of and collected separately. Foot-operated bins are preferable, and frequent rubbish collections are essential. Ideally the hospital should have its own incinerator.

### Laundry service

All bedding, towels, flannels and curtains must be regularly washed with a detergent and disinfectant. Industrial washing machines are essential.

### Strict hand-washing policies

Viruses and bacteria can survive on the hands for 2 to 3 hours. **Correct hand-washing technique for all staff, visitors and patients is the most important factor in the prevention of cross-infection.** It is easily taught, and frequently an improvement in practice is demonstrated in the short term. However, when examined over a longer period of time, old habits and short cuts reappear.

Good hand-washing techniques are dependent on adequate supplies of clean water, ideally elbow-operated taps, a liquid soap supply and an effective method of hand drying (see Figure 1.2.1). Where it is impossible to provide liquid soap and paper towels, some ingenious solutions have been attempted. Bar soap suspended in a net bag over the sink area and individual cloth towels for each patient, changed every 24 hours or at the discharge of the patient and kept within their bed space, can be effective. Added emollient protects the hands from chafing. Antiseptics can be added to liquid soap to improve antimicrobial activity, and chlorhexidine is a cheap and effective antiseptic that is widely available throughout the world. However, there is no good evidence that this increases the effectiveness of hand washing substantially. Antiseptics should be used before invasive procedures and where there is heavy soiling with potentially contaminated body fluids or other human waste. Povidone iodine should be reserved for use as a surgical scrub.

When running water is not available or hand washing is difficult, a 70% alcohol gel is useful. This is a new but fairly expensive product that has a significant part to play in the prevention of introduction of cross-infection in high-risk areas. When rubbed on and allowed to dry, it is effective in disinfecting the hands. After initial conventional hand washing it can be used between each patient contact, but further hand washing is still recommended after every five to six rubs.

**All of the above-mentioned items may be regarded as a considerable extra cost for a health service, but are cost saving when balanced against an increased length of hospital stay due to infection, the additional medications required and sometimes unnecessary deaths caused.**

All staff should have a personal responsibility for hygiene, but every ward should also identify an individual (ideally a nurse with the support of a microbiologist, if available) to be responsible for the education of all staff in techniques that will prevent the spread of infection, particularly effective hand washing and drying. This education programme will need to be ongoing, as even in the best centres these programmes are only effective for relatively short periods of time. The organisation needs to support the identified staff member in reinforcing that all grades and members of staff have responsibility for their practice (especially doctors,

who should act as role models). In addition, it needs to become the norm for this identified staff member, no matter how junior they are, to be recognised as the expert in their unit, and anyone who is asked to carry out hand washing must immediately and unquestioningly comply with this request.

**FIGURE 1.2.1** Effective hand washing.

### Disposal of body fluids

Each ward or unit must have an area set aside for this purpose. It and all the equipment that it contains must be kept scrupulously clean and body fluids disposed of quickly, with any spillage removed immediately. If there is likely to be a risk of body fluids being contaminated with life-threatening organisms, additional precautions should be taken. After hand washing, disposable clean gloves should be used by all staff and family members who will be assisting with the toileting of patients. Care must be taken with sharp objects such as hypodermic needles, in order to protect the patient, their family, other unit visitors and staff. An empathetic approach is necessary to ensure that the patient and their family do not feel stigmatised and undeserving of normal care and attention.

### Cleaning, disinfection and sterilisation of equipment and furniture

The manufacturer's instructions for individual items of equipment must always be followed. These will usually clearly state which items need to be sterilised and where disinfection will be sufficient. They will also indicate appropriate dilutions for disinfectants. All equipment should be cleaned before being sterilised or disinfected.

### Sterilisation

This is the complete elimination and destruction of all forms of microbial life. This is frequently achieved by steam under pressure, dry heat, gas or liquid chemicals. Such a sterilisation system must be available in every ward where invasive procedures are undertaken, and such systems are also required for instruments and towels used in the operating theatre.

### Disinfection

This is a process that eliminates the majority of microorganisms, with the exception of the most resistant endospores. It is usually accomplished using liquid chemicals called disinfectants. Hypochlorites are inexpensive and effective disinfectants. They are active against most microorganisms, including HIV and hepatitis B. However, they do have a corrosive effect on metals, and if used on fabric or carpet can bleach out colours. Hypochlorites in a diluted form (usually 0.1% solution) for domestic use are contained in household cleaners available worldwide. These household cleaners can be used in the hospital environment for general cleaning, but stronger solutions (0.5% chlorine solution) must also be available, particularly for the disposal of body fluids, for initial cleaning of bloodstained instruments, and following outbreaks of notifiable infections. A 0.5–1% solution is recommended for the treatment of blood and body fluid spills, and 0.05–0.1% solution can be used for all surfaces. Hypochlorites are available as tablets, which makes the process of dilution easier.

#### How to prepare high-level disinfectant solutions

The best compound for the preparation of chlorine solutions for disinfection is household bleach (also known by other names such as Chlorox® and Eau de Javel). Household bleach is a solution of sodium hypochlorite which generally contains 5% (50 g/litre or 50 000 ppm) available chlorine.

Thick bleach solutions should never be used for disinfection purposes (other than in toilet bowls), as they contain potentially poisonous additives.

When preparing chlorine solutions for use, the following points should be noted:

- Chlorine solutions gradually lose strength, and freshly diluted solutions must therefore be prepared daily.
- Clear water should be used, because organic matter destroys chlorine.
- A 1:10 bleach solution (0.5%) is caustic. Avoid direct contact with the skin and eyes.
- Bleach solutions give off chlorine gas, so must be prepared in a well-ventilated area.
- Use plastic containers for mixing and storing bleach solutions, as metal containers are corroded rapidly and also affect the bleach.

Two different dilutions of bleach are used for disinfection.

#### 1:10 bleach solution (containing 0.5% chlorine)

This is a strong disinfectant, which is used to disinfect the following:

- excreta
- bodies
- spills of blood or body fluids
- medical equipment (e.g. delivery sets, kidney dishes, suture instruments, catheters, speculum).

To prepare a 1:10 bleach solution, add one volume (e.g. 1 litre) of household bleach to nine volumes (e.g. 9 litres) of clean water.

**Always wear gloves.** Immediately after delivery or examination, clean the instruments below the level of solution in the plastic bucket using a brush. Leave for 10 minutes and then place them in soapy water, wash with a brush, and flush every catheter with a 10–20 mL syringe. Next rinse with clean water and air dry, and then sterilise or boil for 20–30 minutes. Store dry in a metal bowl.

Change the solution after 24 hours or when it becomes bloodstained.

Label buckets with tape indicating the date and time when the solution was prepared and when it needs to be changed.

0.5% solution is also used to prepare 1:100 bleach solution.

#### 1:100 bleach solution (containing 0.05% chlorine)

This is used for the following:

- disinfecting surfaces
- disinfecting bedding
- disinfecting reusable protective clothing before it is laundered
- rinsing gloves between contact with different patients (if new gloves are not available)
- rinsing gloves, aprons and boots before leaving a patient's room
- disinfecting contaminated waste before disposal.

To prepare 1:100 bleach solution, add one volume (e.g. 1 litre) of 1:10 bleach solution to nine volumes (e.g. 9 litres) of clean water.

Note that 1:100 bleach solution can also be prepared directly from household bleach by adding 1 volume of household bleach to 99 volumes of clean water (e.g. 100 mL of bleach to 9.9 litres of clean water), but making it up from 1:10 bleach solution is easier.

### Cleaning

This is often the most neglected of the three processes, and it must precede sterilisation and disinfection. When undertaken using a disinfectant detergent, cleaning alone will effectively reduce the number of microorganisms and make safe those items that come into contact with the intact skin (e.g. blood pressure cuffs, bed rails, intravenous poles).

#### Isolation of patients with specific infections

For isolation procedures to be effective they need to be instituted early. Two or more patients with the same infection can be isolated together. Different isolation techniques will be needed, and the use of gowns, gloves and masks will be necessary if the infection is very contagious and/or very serious. In some cases, nursing the patient in a cubicle or single room until medical tests are complete is all that is necessary. When there is a need for gowns, gloves and masks, these will require frequent changing or washing to ensure their efficacy, and must be used by everyone who comes into contact with the patient, including medical staff and carers. Ideally, they should be used only once and then removed and discarded or sent for laundering on leaving the isolation area. An area will need to be set aside for changing, with supplies of gowns, gloves, aprons and masks. Gowns made of cotton material will need to be worn with plastic aprons. Children's compliance with isolation techniques will improve if the element of fear is removed. This can be achieved by all medical staff allowing the child to see their face (through a window) before donning a mask. It is also essential that when children are in hospital, infection control policies do not interfere with the child's contacts with their parents.

#### Infection control measures following the death of a patient

When a patient dies, the amount of time that the parents

and other family members are able to spend with them will vary according to the facilities that are available. Rituals and beliefs concerning the death of an individual, and the management of the body, usually involve religious or cultural observance. There are many beliefs surrounding the distinction between physical and spiritual life, in particular the belief that something of the individual survives death, either to be reborn through reincarnation or to fulfil their spiritual destiny in the afterlife. It is important that the correct funerary procedures, if any, are followed in order to ensure that the bereaved are not distressed by any omission which they consider important.

All societies, whether religious or not, have to deal with the problem of the death of their patients and the bereavement of parents and other close family members. Like other transitions in an individual's life, death is usually marked by a rite of passage in which central values are restated and important social bonds re-emphasised. Precise customs vary in different religions and traditions, but common features include the washing and laying out of the corpse (which may be embalmed), and the wake, or watching over the dead body. These customs may need to be modified to prevent the spread of infection to other members of the community, or because of the need to perform post-mortem examinations to establish an exact cause of death. Effective hand-washing procedures remain of paramount importance.

In countries where the climate is characterised by extremes of temperature, refrigeration of dead bodies until they can be returned to the family is essential. Each hospital should have a mortuary building adjacent to, but separate from, the hospital. To prevent the spread of infection, staff working in the mortuary will need to be provided with separate clothing for use in that department. The use of two pairs of gloves, or thick rubber gloves and protective clothing, will be necessary for the post-mortem examination if there is suspected infection of the body with life-threatening bacteria or viruses.

The mortuary department will need to have facilities for families to see and spend time with their dead relative, and a separate comfortable area where documentation can be completed and any necessary interviews with local

government officials can be conducted. The mortuary department not only provides facilities for post-mortem examination, but also, in large centres, it can be part of the government facilities for forensic post-mortems, which may provide additional resources for the hospital. Having these centres within a hospital may improve services for families, but care needs to be taken that there is a culture of openness that involves families in the consent procedures for all examinations performed after the patient's death.

## Conclusion

Each member of the hospital has a role to play in the prevention of hospital-acquired infections. The greatest responsibility lies with the healthcare professionals, particularly nurses and doctors, who in the hospital setting are in contact with patients and their families 24 hours a day, and because of this are the main perpetrators of cross-infection. However, they can also demonstrate good practice by, for example, being the catalysts for change, and improving the education of other hospital staff and families.

# 1.3

## Continuing medical education for healthcare professionals

Continuing medical education takes many forms, including the following:

- on-the-wards training
- short courses on the management of emergencies
- use of a readily available pocketbook
- the availability of a postgraduate education centre with library and Internet facilities
- departmental meetings
- online websites and organisations
- local (Ministry of Health) guidelines and publications
- courses and conferences

- Internet-based membership organisations (e.g. HIFA 2015 and CHILD 2015).

Every healthcare professional needs to engage in continuing medical education in order to keep up with the pace of change. They may be a long way away from a university. They may have no library within reach. They may not be sent any journals to read. They may not be able to go away for further education. In resource-limited countries they may not be able to afford a computer or Internet access, or to print out the myriad of teaching materials available on the web.

### On-the-wards training

This is probably the most effective way of keeping front-line staff up to date, especially with regard to the management of emergencies such as eclampsia or the newborn infant who does not breathe at birth. For these mini-teaching sessions, as little as 1 to 2 hours a week can be very effective, and ideally a senior staff member who has been trained in medical education (e.g. through the Generic Instructor Course of the Advanced Life Support Group, ALSG) should lead. Manikins (e.g. of the newborn infant), in which the lungs expand only when the airway is positioned correctly and the face mask is properly applied, can be helpful. It can also be useful to include refreshments and to make the teaching sessions friendly and socially supportive so that staff look forward to them and are keen to participate and learn.

### Short courses on the management of emergencies

The ALSG in collaboration with Maternal and Childhealth Advocacy International (MCAI) has designed and made available for low-income countries 3- to 5-day courses in the emergency management of obstetric, neonatal and paediatric emergencies (see [www.alsg.org](http://www.alsg.org) and [www.mcai.org.uk](http://www.mcai.org.uk)). These courses, which are certified, consist of a combination of lectures, workshops, skill stations and clinical scenarios, undertaken by volunteer instructors who have been through a Generic Instructor Course (GIC) on medical education, and who are skilled in the clinical components of the course.

### Pocketbook

A pocketbook that is available at all times is one of the best ways of accessing up-to-date evidence-based information, and is particularly valuable for the management of emergencies when there is no time to go and look for a textbook.

The new edition of the WHO *Pocket Book of Hospital Care for Children* ([www.who.int/maternal\\_child\\_adolescent/documents/child\\_hospital\\_care/en/index.html](http://www.who.int/maternal_child_adolescent/documents/child_hospital_care/en/index.html)) is a valuable adjunct to the ward care of sick children in low-resource situations. A useful supplement to this pocketbook is the 2012 WHO publication 'Recommendations for management of common childhood conditions: Newborn conditions, dysentery, pneumonia, oxygen use and delivery, common causes of fever, severe acute malnutrition and supportive care' ([http://whqlibdoc.who.int/publications/2012/9789241502825\\_eng.pdf](http://whqlibdoc.who.int/publications/2012/9789241502825_eng.pdf)).

### Postgraduate education centre with library and Internet facilities

A postgraduate medical education centre that can be accessed by all healthcare staff is a good way of providing continuing medical education support. This education centre could, at the very minimum, consist of a reasonably sized, comfortable room containing a library and if possible at least one computer. This could function as the area where regular departmental meetings are held. All non-governmental organisations (NGOs) are concerned with sustainable development, and most of them regard education as a priority that requires major investment. If you are unable to obtain funding from your health service, cultivate a relationship with an NGO or similar organisation, and try to gain investment from them or other sources.

- The library should contain the basic textbooks, in editions that are as up to date as possible.

- If possible, subscriptions for the major obstetric and paediatric journals should be obtained or accessed online.
- It may be that none of the standard textbooks are published in your language. English is the major international scientific language, so it seems reasonable to focus on English language texts.
- If your centre has an electricity supply, if you are able to obtain a computer with CD-ROM, and if it is possible to install a telephone line or mobile Internet sticks are available, this will allow you to communicate by email with specialists in other countries, and to access the Internet in order to obtain up-to-date information on diseases and their treatment. The organisation Teaching-aids At Low Cost (TALC) ([www.talcuk.org](http://www.talcuk.org)) is useful in this regard. Computers are now being designed solely for Internet use, and these are less expensive than the standard personal computer (PC). This investment, for the price of perhaps six good books, can make available a vast amount of up-to-date information. In most countries a subscription is required for access to the Internet, and there will be telephone line usage charges, for which funding will be needed. Again, English is likely to be the language of choice for your global communication.
- Security may be a problem. The postgraduate education centre will need to be designed with this in mind, so that books and computers are not stolen.

### Departmental meetings

Many departments will need to hold regular meetings. Cases can be presented and discussed, and a journal club can be organised. Morbidity and mortality audit meetings are very useful for identifying areas where practice can be improved by the team. However, it is very important that this kind of meeting is supportive, non-judgemental, and does not to assign blame. It is a good idea for each department to hold one of their weekly meetings in English.

### Online websites and organisations

The Internet has many millions of pages. A number of websites are listed below, which will give you an introduction to online obstetric and paediatric information.

- **World Health Organization ([www.who.int](http://www.who.int))**. It is important to remember the WHO when working in low-resource settings. It is tempting to compare standards of care with those in the UK and other well-resourced countries. However, the WHO has produced numerous publications and guidelines on minimum standards of care and is a very valid resource.
- UNICEF: [www.unicef.org](http://www.unicef.org)
- UNFPA: [www.unfpa.org](http://www.unfpa.org)

UNICEF and UNFPA, like the WHO, can be an invaluable resource.

### Local (Ministry of Health) guidelines and publications

Some countries are beginning to develop professional bodies (e.g. paediatric societies, obstetric societies, groups for nurses and midwives). Some of these professional bodies are developing guidelines and have access to resources which will be useful.

In addition, some Ministries of Health are working with organisations such as the WHO, UNICEF, the Johns Hopkins Program for International Education in Gynecology and Obstetrics (Jhpiego) and Save the Children to develop programmes and guidelines to improve local healthcare. It is important for those working in low-resource countries to be aware of the activities of the relevant government.

### Courses and conferences

These will differ from one country to another, and will be linked with the Ministry of Health and professional bodies.

### Web-based membership organisations: HIFA 2015 and CHILD 2015

- HIFA 2015: [www.hifa2015.org](http://www.hifa2015.org) and <https://dgroups.org/groups/child2015/>
- CHILD 2015: [www.hifa2015.org/child2015-forum](http://www.hifa2015.org/child2015-forum)

The goal of these organisations is that, by 2015, every person worldwide will have access to an informed healthcare provider.

HIFA 2015 is a campaign and knowledge network with more than 5000 members representing 2000 organisations in 167 countries worldwide. Members include healthcare workers, publishers, librarians, information technologists, researchers, social scientists, journalists, policy makers and others – all working together towards the HIFA 2015 goal.

HIFA 2015 contributes to the broader goal of the Global Health Workforce Alliance: 'All people everywhere will have access to a skilled, motivated and supported healthcare worker, within a robust health system.'

Members interact via two email discussion forums: HIFA2015 and CHILD2015. Together these organisations are building the HIFA2015 Knowledge Base, a picture of information needs and how to meet them. Membership is free and open to all.

## 1.4 Essential imaging facilities

### Introduction

Despite the fact that the use of ionising radiation ('X-rays') for diagnostic purposes was discovered more than 100 years ago, up to two-thirds of the world's population still have no access to primary care diagnostic imaging services. Some rural clinics may be located in remote impoverished areas such that imaging equipment is impossible for the population to access. However, clinics in larger towns, and certainly **every institution that merits the title of 'hospital'**

**should have, at the very least, simple radiographic and ultrasound equipment available.** This will necessitate the training of healthcare workers to use the equipment appropriately and safely. Local healthcare workers will also interpret most of the examinations performed, and therefore need training in radiographic interpretation. Many African countries, for example, do not have a single radiologist. As most radiographic equipment is now digital, in the absence of a specialist opinion, teleradiology services are an option in

a few areas. Various teleradiology solutions exist in different regions and are expanding, but they are not widespread. For the under-resourced setting, charitable specialist opinions would need, of necessity, to be provided free of charge.

### A basic service

In the context of severely limited resources, health planners have to be selective in their choice of imaging technology. Some radiographic equipment can be so expensive that its purchase might be to the detriment of other important components of a basic health service. The radiographic equipment should nevertheless reflect the standard of care in each clinic or hospital. Albeit suboptimal, very basic orthopaedics can be carried out utilising plain radiographs alone. Proper fracture reduction necessitates that a C-arm fluoroscopy unit should ideally be available. A CT scanner should be on site at a regional centre where there are surgeons available with basic neurosurgical skills (e.g. capable of making burr holes for extradural haematoma evacuation).

- The majority of radiographic studies in hospitals everywhere are plain radiographic examinations. In a small rural or suburban hospital, plain radiography will account for approximately 90% of all the necessary examinations and, where available, ultrasound will meet the needs of much of the remaining 10%.
- Good diagnostic imaging frequently leads to less hospitalisation, allows for quicker and more accurate diagnosis, and results in less suffering and pain. The WHO recommends that even small hospitals and clinics with only one doctor should have imaging equipment.
- Access to most of the equipment described below should be available to all sick and injured children.

### Diagnostic radiographic equipment

- Radiographic equipment that is easy to operate and maintain, such as the World Health Imaging System for Radiography (WHIS-RAD). This is based on much practical experience, and is ideally suited to radiology departments in disadvantaged countries.
- WHIS-RAD was fully specified in 1995. A WHIS-RAD unit is easily applicable to children and small infants, is relatively inexpensive, is safe for patients and operators, and produces high-quality images.
- In recent years the cost of obtaining and processing X-ray film has become problematic, particularly in developing countries. Fortunately, WHIS-RAD is now available in digital format or retrofit. The use of computed radiography (CR) with reasonably priced liquid crystal display (LCD) monitors allows for easy data storage, archiving and retrieval, as well as the potential for utilising teleradiology resources.
- A CR plate has the added advantage of a large dynamic range such that repeat X-rays are seldom necessary.
- Radiation doses from a WHIS-RAD unit are typically lower than those from many conventional radiographic machines, which is particularly appealing where standards of radiation protection, the use of cones, lead protection and dosimetry may be variable and often non-existent.
- The X-ray generator specified for WHIS-RAD may be used with almost any power supply, however variable. WHIS-RAD batteries can operate for up to 3 weeks before they need to be recharged.

- Patients can be examined in a standing, sitting or recumbent position.
- The WHO has produced a range of radiology manuals for the developing world setting. The *WHO Manual of Diagnostic Imaging: Radiographic Techniques and Projections* provides a very clear explanation of how to use the equipment, even for those with no formal training in radiography. Operators can be trained in a matter of months. This and other useful information is available from the Diagnostic Imaging for Clinics and Small Hospitals website ([www.dicsh.info](http://www.dicsh.info)).
- The proposed publication of the *WHO Manual of Diagnostic Imaging: Paediatric Examinations* has unfortunately been severely delayed.
- Donations of old but functional radiographic equipment by well-resourced countries, although laudable, are often worthless. Bulky outdated equipment often cannot be installed, operated or maintained locally. The service manuals are often missing, obtaining spare parts is a major problem, and many of these machines break down irreparably.
- Portable X-ray equipment typically requires reliable power sources and expert radiography, such that its use is only practicable in larger centres.

A comprehensive list of the indications for diagnostic radiography is too long to include here. Suffice it to say that all children with a serious pneumonia, suspected tuberculosis or fractured limbs, to name a few examples, merit radiography. In practice, chest and skeletal examinations are the most frequent indications for diagnostic imaging worldwide. Where resources are less stretched, radiographic machines with slit-beam technology could be considered. These units, such as the LODOX Statscan, are also fully digital, have sufficiently low radiation doses to permit their use within a ward without special protective barriers, and offer flexibility for those with little radiographic positioning skill. In addition, they provide rudimentary CT information which is useful for head trauma patients, at a fraction of the price of CT scanners.

### Diagnostic ultrasound scanning equipment

**The wide range of applications of ultrasound in children and pregnant women, its versatility and its safety probably make it better suited to disadvantaged countries than any other imaging modality.** Sonography is harmless – it does not generate ionising radiation, and is thus particularly suitable for imaging children, adolescent girls in particular, and pregnant women.

- Ultrasound machines are simple to operate, but the images are also easy to misinterpret. It is therefore critically important that the person performing and interpreting an ultrasound study is suitably trained and competent. **Sonography must be taught on a supervised practical basis in a local environment.** The WHO recommends a 6-month minimum training period for diagnostic sonography.
- Initiatives such as that by Imaging the World (<http://imagingtheworld.org>) allow for alternative basic sonographic training to be shortened to as little as a few days. Reliance instead is placed on transmission of images over the Internet to a secure server, from which the images can be accessed and read anywhere in the world.

The WHO recommends minimum specifications for a general-purpose ultrasound scanner.

- The scanner should be able to operate from the local electrical power supply.
- Servicing should be available locally.
- It must be possible to store the unit safely under adverse conditions.
- When scanning children, at least two different MHz transducers (sector and linear array) are desirable.
- Doppler techniques are included on all modern ultrasound equipment, such that exclusion of a deep venous thrombosis, for example, should be possible.
- Some form of archived permanent hard-copy record is recommended for patient follow-up, and in the interests of teaching and training in general.

Additional points

- Mobile ultrasound scanners can be operated at the bedside or in the Emergency Department.
- Abdominal and pelvic ultrasound has a well-established role in the assessment of adolescent gynaecological conditions and paediatric emergencies.
- Sonography plays a major role in the management of pregnancy, from dating the age of the fetus to identifying multiple pregnancies, ascertaining the position of the

placenta and generally identifying potential problems, thus allowing the clinician to plan safe delivery.

- Sonography can quite simply resolve mass lesions from organomegaly.
- It is noteworthy that hydronephrosis is the commonest abdominal mass in the neonate and infant, and this is easily diagnosed with ultrasound scanning.
- Evaluation and drainage of pleural effusions or ascites is relatively straightforward, particularly with ultrasound guidance.
- Ultrasound scanning can be a useful tool for guiding other interventions, such as drainage of larger abscesses or an image-guided biopsy of a solid mass.
- Alternatively, evaluation of solid mass lesions and cysts should at least be possible, to aid patient referral to larger regional centres.
- Sonography of the infant brain is easily performed at the bedside, and can provide useful information in the infant who is febrile, unconscious or has seizures.
- In trauma patients, abdominal ultrasound scanning can prevent unnecessary surgery.
- Finally, ultrasound studies frequently reduce the need for plain abdominal radiographs and yield more diagnostic information.

## 1.5

## Essential operating-theatre resources

### Design of the operating theatre (OT)

- Ideally it should be located next to the labour ward.
- It should be of adequate size (minimum 7 m × 7 m) for the placement of essential equipment and the unobstructed movement of staff.
- It should not be used for storing purposes, for which a separate side room should be available which can also be used for hand washing.

### Essential equipment

- Ordinary OT table with a facility for the lithotomy position and lowering and raising the height of the table, preferably mechanically operated.
- A good focusing OT light is very important.
- A simple anaesthetic machine suitable for the resources available in the country (e.g. Diamedica-Glostavent, for resource-limited countries), with an uninterrupted oxygen and nitrous oxide supply, is the most essential item of equipment for the anaesthetist. Reserve cylinders for both oxygen and nitrous oxide should always be available. If nitrous oxide is not available, the patient can be maintained on ether or halothane, but the level of anaesthesia has to be deep, requiring more intensive post-operative monitoring.
- The suction machine (which should have both electrical and manual functions, in case of electrical failure) should

be periodically emptied and cleaned with antiseptic solution after every individual patient. It must be constantly checked.

- A fumigation machine is essential for the sterilisation of the OT.
- Anaesthetic equipment and supplies (see Section 1.22 for a list of essentials).
- All emergency drugs (e.g. lignocaine, adrenaline, atropine, sodium bicarbonate, 25% dextrose, morphine, etc.), with syringes, should be readily available in the OT (see Section 1.22).
- A boiler is essential for sterilisation if an autoclaving facility is not available. A heater of some kind is also essential for warming up crystalloid infusions to be used during surgery to prevent hypothermia.
- Monitoring equipment (see Section 1.22 for a list of essentials).
- Room heaters are essential, especially for surgery on infants. The OT temperature should be in the range 28–32°C to prevent hypothermia in babies. Hot-water bottles can provide heat for infants and are inexpensive, but it is essential to be vigilant about safety. Radiant warmers, incubators and electric blankets are helpful if they are available. Equally, air conditioning is also required in hot countries to ensure appropriate working temperatures for patient and OT staff.
- A cautery machine is useful for reducing blood loss

during surgery. An ordinary unipolar cautery will suffice for most procedures. A probe that has been heated with a Bunsen burner until it is red hot can provide thermocoagulation on touching the bleeding sites. This is a low-cost and effective method when a cautery machine is not available.

- Adequate supply of linen, towels, gowns and gloves.
- The minimum instruments required for minor surgery are as follows:

**Artery forceps:**

Mosquito	6
Kelly's	6

**Towel clips:**

Bulldog	6
---------	---

**Scissors:**

Metzenbaum	1
Mayo's	1

**Thumb forceps:**

Tooth	1
Non-tooth	1

**Intestinal clamps:**

Non-crushing	2 (4)
--------------	-------

**Martin artery forceps**

	2
--	---

**Right-angled forceps**

	1
--	---

Needle holders (paediatric) which can hold 3.5 to 5.0 sutures

	2
--	---

**Retractors:**

Right-angled	2
--------------	---

Zerneys	2
---------	---

Devers	2
--------	---

Malleable	2
-----------	---

<b>Suction tip</b>	1
--------------------	---

<b>Eye goggles for protection of staff from splashing</b>	3
---	---

Durbin (formally ECHO) ([www.durbin.co.uk](http://www.durbin.co.uk)) provides complete instrument kits, which are particularly relevant for Caesarean section and laparotomy.

- A whiteboard and pens with which to document the use of swabs and needles, aiming to ensure that none are left in the patient when surgery ends.

## Operating-theatre staff

Apart from the surgeon, an adequately trained doctor or nurse anaesthetist is essential.

- **Nursing staff** should be adequately trained in the care and handling of instruments and equipment in the OT. They should be made responsible for the proper functioning of all equipment, and trained in the sterilisation of the OT and the instruments used.
- **OT assistants** are important for transporting patients to and from the ward. They should be aware of the function of the equipment in the OT. They should also be counselled about the hazards of contact with blood and other patient body fluids, and especially made aware of the risks of infection with HIV and hepatitis B and C.
- **OT cleaners** should also be aware of the threat of these communicable diseases. It is essential to clean the OT between one case and the next to prevent nosocomial infections.

## Practices and procedures to reduce the risk of infection in the OT

- The floors, walls, table and all equipment in the OT should be cleaned and disinfected at least once a day, and also after every case involving infection.
- Autoclaving is the standard method of sterilisation, but if it is not available, boiling for 1 hour should be used instead.
- Spirit flaming of all the instruments (whereby the instruments are placed in a kidney tray, spirit is poured into the tray and a matchstick is used to flame it) can be undertaken where minimal equipment is available.
- There must be restricted entry to the OT, and this should only be permitted after a complete change of clean clothes (except for underwear) and shoes, and with the wearing of a proper clean head covering and mask (these items should be used once only before discarding or washing). Hand and forearm washing for at least 5 minutes before gowning and gloving up, using an antiseptic soap solution, will reduce the incidence of infection.
- The OT should be situated in the most inaccessible part of the hospital so that there is minimum encroachment by the general hospital patients.
- Ideally there should be an air-purifying/air-conditioning system in the OT.
- All tubing (suction, oxygen, anaesthetic) should be regularly cleaned and disinfected according to the individual manufacturer's instructions, in order to reduce the risk of nosocomial infection.
- Proper waste disposal bins for clinical and non-clinical waste from the OT are essential.

## Set-up of the recovery room

- The recovery room should be adjacent to the OT so that the surgeon and the anaesthetist have immediate access to the patient.
- Nursing care, oxygen, suction and emergency medicines should be available, as should resuscitation and monitoring equipment (see Sections 1.12 and 1.13).
- **An adequately trained doctor or nurse anaesthetist, who is proficient in resuscitative measures and critical care management, should be present whenever patients are in the recovery room.** Frequent evaluation and monitoring of surgical patients should be undertaken during the first 24 hours following a major operation. This should include observations/measurements of hydration, urine output, output from drains, soakage from the wound, pulse, respiratory rate and blood pressure. Post-operative pain management is most important, and a relatively 'pain-free' patient has a better outcome (see Section 1.15).

## 1.6 Drug and fluid administration

### Enteral fluids

- The best method of maintaining caloric intake is through enteral feeding.
- If the patient is unable to drink then pass a gastric tube (see Section 8.5).

When commencing feed by naso- or orogastric tube:

- 1 Fill the syringe to the required amount with feed.
  - 2 Draw the plunger back as far as possible.
  - 3 Attach the syringe to the tube.
  - 4 Kink the tube and remove the plunger.
  - 5 Allow feed to pass into the stomach using gravity.
  - 6 Observe the patient's colour and respiratory rate for any signs of aspiration.
- Breast milk is the best food for infants. It is always available at the correct temperature, no preparation is required, and no sterilising equipment is involved. If the infant is too ill to suck and is fed through a gastric tube, encourage the mother to express milk into a sterile receptacle.
    - 1 To encourage the release of milk and ease of expression, it may help if the mother expresses milk while holding the baby.
    - 2 Store excess milk in a in a refrigerator (<5°C) for up to 5 days or freezer (minus 20°C) for up to 6 months.
    - 3 Defrost the quantity needed for 4 hours of feeding at a time.
  - Oral rehydration solutions are used in gastroenteritis to maintain electrolyte balance. Prepare by **adding 1 sachet to 210 mL (7 oz) of clean water.** (One ounce = 30 mL.)

### Intravenous fluids

Intravenous (IV) fluids must only be used when essential and enteral feeds are not available or not absorbed. Always check the container before use, to ensure that the seal is not broken, the expiry date has not been passed, and the solution is clear and free of visible particles.

#### Choice of crystalloid fluid *Dextrose/glucose-only fluids*

It is clear that although glucose or dextrose is necessary to prevent or manage hypoglycaemia, fluids containing only dextrose which are hypotonic should never be used for IV

fluid replacement or maintenance, or for the emergency management of shock.

This is because the dextrose is rapidly metabolised, so the effect of a dextrose-only IV fluid on the child's body in shock may produce hyponatraemia, which could lead to brain damage or death. In addition, this solution is rapidly moved out of the circulation and into the cells, and the state of shock will not be resolved.

#### *Sodium-containing fluids*

The fluid traditionally infused into the circulation for the management of shock has been normal saline (0.9% NaCl). This fluid has increasingly been shown to be dangerous, especially in the sick patient. An infusion of normal saline causes a hyperchloraemic acidosis (a high chloride concentration leading to acidosis) which, in the shocked patient, who is already acidotic, causes a deterioration in the health of cells in vital organs even though perfusion of the cells has been improved by the increased circulating volume.

There are sodium-containing alternatives to normal saline which are safer because they approximate more closely to human serum/plasma in content (see Table 1.6.1), although they are slightly more expensive. We recommend the use of either of these alternatives – **Ringer-lactate and Hartmann's solution**, which are widely available – for all fluid replacement. Hospitals are advised to change their standard crystalloid from 0.9% ('normal') saline to Ringer-lactate or Hartmann's solution as soon as possible. Not all hospitals will have access to these solutions immediately, so there may sometimes be no alternative but to start fluid replacement with normal saline. However, if more than 20 mL/kg needs to be given, one of the safer alternatives should be used in very sick children if at all possible.

#### *Putting dextrose into Ringer-lactate or Hartmann's solution*

A crystalloid containing approximately 5% dextrose can be obtained by adding 50 mL of 50% dextrose to a 500-mL bag of Ringer-lactate or Hartmann's solution.

A crystalloid containing approximately 10% dextrose can be obtained by adding 100 mL of 50% dextrose to a 500-mL bag of Ringer-lactate or Hartmann's solution.

(It will therefore be necessary to remove 50–100 mL of fluid from the 500-mL bag first.)

Ensure that the above process is performed with a

**TABLE 1.6.1** Comparison of electrolytes, osmolality and pH levels in IV fluids with those in human serum

Fluid	Na <sup>+</sup> (mmol/L)	K <sup>+</sup> (mmol/L)	Cl <sup>-</sup> (mmol/L)	Ca <sup>2+</sup> (mmol/L)	Lactate or bicarbonate (mmol/L)	Osmolality (mOsmol/L)	pH
Human serum	135–145	3.5–5.5	98–106	2.2–2.6	22–30	276–295	7.35–7.45
Ringer-lactate/ Hartmann's solution	131	5.0	111	2.0	29	279	6.0
0.9% normal saline	154	0	154	0	0	310	5.4

sterile no-touch technique, swabbing the entry point to the bag with an alcohol swab.

**Dextrose/glucose solutions that are not in Ringer-lactate or Hartmann's solution are dangerous for replacing fluid losses.**

**Never infuse plain water IV: this causes haemolysis and will be fatal.**

**Always specify the concentrations of dextrose and saline solution to be infused.**

### Maintenance requirement of electrolytes

#### Daily sodium and potassium requirements in IV fluids:

- sodium (Na<sup>+</sup>): 3–4 mmol/kg/24 hours in children; 150 mmol/24 hours in pregnancy
- potassium (K<sup>+</sup>): 2–3 mmol/kg/24 hours in children; 100 mmol/24 hours in pregnancy.

Crystalloids containing a similar concentration of sodium to plasma (Ringer-lactate or Hartmann's solution) are used to replace vascular compartment losses. When infused IV, only around 25% remains inside the vascular compartment; the rest passes into the extracellular space.

All fluids should be prepared and administered using an aseptic technique. It is important to observe the cannula site directly (by removing the dressing) for redness and swelling before each IV injection. Observe the patient for pain or discomfort at the IV site. If there are any signs of inflammation, stop all fluids, reassess the need for continuing IV fluid drugs, and resite the cannula if necessary.

**The rate of administration of fluids can be calculated in drops per minute as follows:**

**In a standard giving set with a drop factor of 20 drops = 1 mL, then mL/hour divided by 3 = drops/minute.**

- Record that rate of fluid intake per hour on a fluid balance chart.
- Ensure that the IV site is kept clean.
- Flush the cannula with 0.9% saline or Ringer-lactate or Hartmann's solution 4-hourly if continuous fluids are not being given.

### Prescribing practice and minimising drug errors

#### Introduction

- Oral administration is safer and less expensive, if it is tolerated and if the condition is not life-threatening.
- The following antibiotics are as effective when given orally as when administered intravenously, although initial IV doses will increase the blood levels more quickly:
  - amoxicillin, ampicillin, chloramphenicol, ciprofloxacin, co-trimoxazole, erythromycin, flucloxacillin, fluconazole, metronidazole, sodium fusidate.
- If a drug is given down an orogastric or nasogastric tube, flush the tube through afterwards so that the drug does not remain in the tube.
- Rectally administered drugs are less reliably absorbed than those given orally.
- Liquid formulations are better than suppositories for rectal administration of drugs in infants.

#### Prescribing

- Use approved names.
- Dosages should be in grams (g), milligrams (mg) or

micrograms. **Always write micrograms in full.** Volumes should be in millilitres (mL).

- Avoid using numbers with decimal points if at all possible (e.g. write 500 mg, not 0.5 g). If decimal points are used, they should be preceded by a zero (e.g. write 0.5 mL, not .5 mL).
- Write times using the 24-hour clock.
- Routes of administration can be abbreviated to IV (intravenous), IM (intramuscular), PO (orally), SC (subcutaneous), NEB (nebuliser) and PR (rectally).
- 'As-required' prescriptions must be specific with regard to how much, how often and for what purpose the drug is being given (also indicate the maximum 24-hour dose).
- 'Stop dates' for short-course treatments should be recorded when the drug is first prescribed.

#### Measuring drug doses

- Multiple sampling from drug vials increases the risk of introducing infection, as the vials do not contain preservatives or antiseptic.
- Dilute drugs so that volumes can accurately be measured. For example do not use doses of less than 0.1 mL for a 1-mL syringe without diluting sufficiently for you to be able to give an accurate amount of the drug.
- Do not forget to consider the dead space in the hub of the syringe for small volumes.
- For dilutions of more than 10-fold, use a small syringe to inject the active drug, connected by a sterile three-way tap to a larger syringe, and then add diluent to the large syringe to obtain the desired volume.

#### Delivery

- All IV solutions, including drugs, must be given aseptically.
- Give IV drugs slowly in all cases.
- After injecting into the line (e.g. through a three-way tap), use the usual rate of the IV infusion to drive the drug slowly into the patient.
- If there is no ongoing infusion, give sufficient follow-up (flush) of 0.9% saline, Ringer-lactate or Hartmann's solution or 5% dextrose to clear the drug from the cannula or T-piece.
- Repeat flushes of 0.9% saline can result in excess sodium intake in infants, so use Ringer-lactate or Hartmann's solution if possible.
- Flush over a period of 2 minutes to avoid a sudden surge of drug (remember the hub).

#### Infusions

- These must be given aseptically.
- Adjust the total 24-hour IV fluid intake so that additional infusions for drugs do not alter the total fluid volume.
- Never put more drug or background IV into the syringe or burette than is needed over a defined period of time.
- Check and chart the rate of infusion, and confirm this by examining the amount left every hour.
- Use a cannula, **not butterfly needles**, for infusions if available.
- **Do not mix incompatible fluids IV.**
- Do not add drugs to any line containing blood or blood products.
- Infusions of glucose higher than 10%, calcium salts and adrenaline, can cause tissue damage if they leak outside the vein.
- Most IV drugs can be given into an infusion containing

0.9% saline, Ringer-lactate or Hartmann's solution or up to 10% glucose (the exceptions include phenytoin and erythromycin).

- If you are using only one line, wait 10 minutes between each drug infused, or separate the drugs by infusing 1 mL of 0.9% saline or Ringer-lactate or Hartmann's solution.

### Safe IV infusions when no burettes are available

Mark the infusion bottle with tape for each hour of fluid to be given, and label each hour.

or

Empty the infusion bottle until only the exact amount of fluid to be given is left in the bottle.

## Intravenous lines

### Placement of the line

- Always place the cannula aseptically and keep the site clean.
- **Use sterile bungs, not syringes**, for closing off cannula/butterfly needles between IV injections.

### Care of the line

- Change the giving set every 3 or 4 days.
- Change the giving set after blood transfusion, or if a column of blood has entered the infusion tubing from the vein, as this will be a site of potential bacterial colonisation.
- Always inspect the site of the cannula tip before and during drug injection. Never give a drug into a drip that has started to tissue. Severe scarring can occur, for example, from calcium solutions.
- Always use luer lock connections to minimise extravasation.

### Sampling from the line

- Clear the dead space first (by three times its volume).
- Glucose levels cannot be accurately measured from any line through which a glucose solution is infused.
- Blood cultures should always be taken from a separate fresh venous needle or stab sample.
- After sampling, flush the line. **Remember that repeat flushes of 0.9% saline can result in excess sodium intake in infants.**

## Complications

### Infection

- Local infection can become systemic, especially in neonates or the immunosuppressed (e.g. HIV-infected patients).
- If there is erythema in the tissue, remove the cannula.
- If lymphangitis is present, remove the cannula, take a blood culture from a separate vein and start IV antibiotics.

### Air embolism

- Umbilical or other central venous lines are particularly high risk.
- Another source of air embolus is through the giving set, especially when infusion pumps are used. **Infusion pumps must not be used if there are not enough nurses to closely monitor the infusion.**
- Always use a tap or syringe on the catheter, especially during insertion.

- If air reaches the heart it can block the circulation and cause death.

### Haemorrhage

- In neonates this can occur from the umbilical stump.
- All connections must be luer locked.
- The connections to the cannula and its entry must be visualised at all times.

### Minimising errors with IV infusions

- Prescribe or change infusion rates as infrequently as possible.
- Always have the minimum possible number of IV infusions running at the same time.
- Use a burette in which no more than the prescribed volume is present (especially in infants and young children, or with drugs such as quinine or magnesium sulphate in pregnancy).
- Record hourly the amount given (from the burette, syringe or infusion bag) and the amount left.
- Check the infusion site hourly to ensure that fluid has not leaked outside the vein.
- Ensure that flushes are only used if they are essential, and are given slowly over a period of at least 2 minutes.
- Be careful with potassium solutions given IV (use the enteral route when possible).
- Check and double check the following:
  - Is it the right drug? Check the ampoule as well as the box.
  - Is it at the right concentration?
  - Is the shelf life within the expiry date?
  - Has the drug been constituted and diluted correctly?
  - Is it being given to the right patient?
  - Is the dose correct? (Ideally two healthcare workers should check the prescription chart.)
  - Is it the correct syringe? (Deal with one patient at a time.)
  - Is the IV line patent?
  - Is a separate flush needed? If so, has the flush been checked?
  - Are sharps disposed of (including glass ampoules)?
  - Has it been signed off as completed (ideally countersigned)?
  - If the drug has not been received, is the reason stated?

## Intramuscular (IM) injections

- **IM injections are unsafe for patients in shock**, especially opiates, where a high dose can be released once recovery of the circulation occurs.
- To avoid nerve damage, only the anterior aspect of the quadriceps muscle in the thigh is safe in infants.
- Use alternate legs if multiple injections are needed.
- Do not give IM injections if a bleeding tendency is present.
- **Draw back the plunger to ensure that the needle is not in a vein before injecting** (especially if administering adrenaline or lidocaine).

In very resource-limited situations, the IM route might be preferred because the drug may reach the patient sooner than if the patient had to wait in a queue to have an IV line sited. It also requires less nursing time and is less expensive;

venous cannulae are often in short supply. The IM route is as effective as the IV route in many situations.

### Storage of drugs

Hospitals have struggled for many years to ensure that appropriate medicines are available when needed, while at the same time avoiding the problems of controlling the abuse and illegal use of these substances. Medicines that are of most concern in this respect are narcotics and sedatives. Supplies of these drugs must be available for the treatment of acutely ill patients, at the point of admission, in high-dependency care and post-surgical areas, and in all areas involved in the care of patients with terminal illness. Tragically, many care settings have solved the problem of storage by refusing to have stocks of these drugs readily available, either in the belief that patients, especially children, due to their physiological immaturity, do not feel pain, or due to fear of abuse by the patients and their families or healthcare staff.

The responsibility for the safe custody and storage of all medicines and drugs on a ward or department is that of the nurse in charge at any one time. Designated cupboards for the different types of drugs should be available. All cupboards, which should be permanently fixed to an inside wall, should have secure locks that make them inaccessible to unauthorised staff and visitors. Drug cupboards should be kept locked at all times, the keys being the responsibility of the nurse in charge.

Correct storage of drugs is paramount for prolonging the shelf life of the drug, as well as for complying with safety and legal requirements.

Due to the shelf life of some drugs, they need to be stored in a refrigerator, with the temperature set to store the drugs at between 2°C and 8°C. Drugs that need to be stored under these conditions include the following:

- reconstituted oral antibiotics
- eye drops
- rectal paracetamol
- some vaccines
- insulin (although this can be stored for up to 1 month at room temperature)
- oral midazolam
- pancuronium/vancuronium
- ergometrine
- oxytocin.

### Calculating and giving the correct dose

Children should be weighed naked and their weight (in kg) recorded on the prescription chart. The use of a drug formulary should be considered when calculating the therapeutic dose. To ensure that the correct amount of drug is given from the stock bottle or vial, the following calculation should be used:

**(prescribed dose divided by concentration of the stock solution) × (volume of stock dose).**

$$\begin{aligned} &\text{For example, } 125 \text{ mg (the amount prescribed) divided} \\ &\text{by } 250 \text{ mg/5 mL (concentration of the stock solution)} \\ &\quad \times 5 \text{ mL (volume of stock dose)} \\ &= 125/250 \times 5 \text{ mL} = 2.5 \text{ mL.} \end{aligned}$$

So the amount given would be 2.5 mL.

Medical staff should change the prescribed dose if after

using the above calculation the dose is not easily measurable (e.g. 1.33 mL, 2.46 mL). To ensure that the calculated dose is given accurately, a pre-marked syringe should be used. The smaller the required dose, the smaller the syringe that should be used, as it will give a more accurate measurement (i.e. a 1- or 2-mL syringe should be used, not a 10-mL syringe).

Other forms of measurement can be used for larger doses, such as 5 or 10 mL. These include a pre-measured medicine pot or a 5-mL pre-measured medicine spoon. For safety, the calculation should ideally be done by two trained nurses, and the amount dispensed checked by the same two nurses. Although it is recognised in some hospitals that one trained nurse can check oral medication on their own, ideally IV and IM drugs should be checked by two trained nurses or a nurse and a doctor.

### Safe use of morphine in hospital

Narcotic drugs, which may be controlled by law within the country concerned, should have a separate cupboard permanently fixed to the wall and locked. The keys to drug cupboards should be kept separately to all other keys and be carried by a qualified nurse for the period of each shift, and then handed over to the nurse taking over the next shift.

A logbook is necessary for recording the ordering and use of narcotic drugs. It is completed to order stocks, using one page for each order. It also records the use of each ampoule, tablet or dose of liquid. The name of the patient, hospital identification, date and time when the drug was given, and whether or not any portion of the drug was discarded is entered in the register (see Figure 1.6.1). Then each entry is signed by two staff members. Ideally, both must hold a nursing, medical or pharmacology qualification, and one must be a member of the ward or unit staff.

In addition, two members of unit staff must check the stock levels once in every 24-hour period and sign to confirm that the stocks are correct. Any discrepancy must be reported immediately to the senior nurse manager for the hospital.

Each hospital should have a policy for dealing with unauthorised use of narcotic drugs, and in some countries this will involve national law enforcement agencies.

When new drug stocks are required, the order book is sent to the central pharmacy, ideally in a container with a tamper-proof seal. Once the pharmacist has placed the order in the container, it is sealed and must not be opened until its arrival in the receiving ward or department.

When the stock arrives in the unit, the seal is broken in the presence of the messenger and the contents are checked against the order book, which is then signed by both. Drugs are then entered in the drug register, with two staff members checking and signing. The drugs are placed in the appropriate cupboard, which is then relocked.

In most hospital wards and units, these precautions will both ensure that adequate narcotic drugs are available when they are needed by patients, and prevent provision of supplies to those who may abuse them.

### Use of morphine

- Morphine is a safe drug if administered by doctors and nurses who know how to use it and how to monitor patients who have been given it. It is not addictive if used only in the short term for severe pain.

## 1.7

## Safe blood transfusion practice

**Introduction**

**Blood or blood products should be transfused only when they are needed to save life or to prevent major morbidity.**

The risk of transmission of infection is a major concern in countries with limited resources and poorly organised blood transfusion services.

Blood must be stored safely, or a bank of adequately screened donors must be available 24 hours a day, especially for obstetric emergencies or major trauma.

When giving a blood transfusion, care must be taken to ensure that the blood is compatible with that of the recipient, is infection free and is given safely.

**Clinical situations that require blood transfusion**

Normal haemoglobin (Hb) levels (after the neonatal period) are around 129 g/L (12.9 g/dL). Children with severe anaemia have Hb levels of 50 g/L or less. An Hb level of 50 g/L is widely accepted as the level at which transfusion might be indicated, and less than 40 g/L if there is severe malnutrition. Note: g/L divided by 10 = g/dL.

The WHO defines anaemia as any Hb level below 110 g/L. However, in pregnancy, normal haemodilution means that a cut-off value of less than 10 g/dL is more appropriate. In a pregnant woman, transfusion may be considered at an Hb level of 60–70 g/L, taking into account other factors.

In addition to Hb level, the following factors must be taken into account when considering transfusion.

- **Heart rate.** If it is rapid, this will favour the decision to transfuse. Remember that normal values for heart rate and respiratory rate vary with the age of the child.
- **Respiration rate.** If it is rapid, this will favour the decision to transfuse.
- **Is the patient grunting?** If so, this will favour the decision to transfuse.
- **Is the patient already in circulatory collapse (shock)?** If so **the need for transfusion is very urgent.**

Some patients will not show any of these features, and it might then be justifiable to delay transfusion and use haematinics (i.e. iron and folic acid). Some patients may show the above features and have an Hb level higher than 50 g/L. It will also be necessary to transfuse such patients if their symptoms are caused or significantly worsened by the anaemia and not an alternative pathology only (e.g. heart failure).

After birth, the haemoglobin level drops to less than 100 g/L in term infants at 8–12 weeks of age, but in premature infants it can drop to 70–100 g/L even earlier, at 6 weeks. (Oxygen delivery is well maintained because of rising levels of haemoglobin A, which releases oxygen more freely than haemoglobin F, which is found in the fetus.)

**Causes of anaemia in neonates**

- Hypovolaemic shock can result from acute blood loss,

as for example in premature separation of the placenta or feto–maternal haemorrhage, twin-to-twin transfusion, and other causes of fetal or neonatal haemorrhage.

- Neonates may lose a considerable blood volume as a result of sampling for laboratory tests. Therefore samples should be minimised.
- Reduce the need for transfusion in neonates by providing adequate antenatal care, to reduce the risks of premature delivery and when possible prevent nutritional anaemia in the mother.
- Encourage breastfeeding.
- Ensure that there is early provision of vitamin K prophylaxis, iron, vitamins and other haematinics, especially in premature babies.

**Causes of anaemia in children**

These include the following:

- surgery
- haematological malignancies
- malaria
- sickle-cell disease
- congenital haemolytic anaemias (thalassaemia, glucose-6-phosphate dehydrogenase deficiency)
- burns
- major trauma.
- malnutrition (see Section 5.10.B).

**Causes of anaemia in pregnancy**

These include the following:

- obstetric emergencies such as antepartum and postpartum haemorrhage
- severe anaemia that is untreated or unresponsive to haematinics
- major trauma.

**Transfusion policies and guidelines**

- In hypovolaemic shock, erythrocyte-free volume expanders may be used to maintain tissue **perfusion**. Oxygen and top-up blood transfusion (10–20 mL/kg. over 5–10 minutes) may be required when tissue **oxygenation** is compromised.
- Transfuse for anaemia only when there are clinical signs, such as tachycardia, tachypnoea, recurrent apnoea, failure to thrive or early signs of anaemia-induced heart failure.
- When possible, provide malaria prophylaxis, particularly in pregnant women and children (see Sections 2.8.D and 6.3.A.d) with sickle-cell disease. Early treatment of clinical malaria reduces the profound haemolysis that is a major reason for transfusion in endemic areas.
- Anaemia due to malaria responds to treatment with antimalarial drugs and folic acid.
- Blood transfusion is not required for sickle-cell disease in the steady state. It may be indicated in severe anaemia with incipient or established cardiac failure,

acute splenic enlargement, sequestration crisis with rapidly falling haemoglobin levels, aplastic crisis, acute chest syndrome, stroke, and sometimes as exchange transfusion for severe priapism (see Section 5.11.B on sickle-cell disease).

- National programmes for thalassaemia and other congenital haemolytic disorders, such as glucose-6-phosphate dehydrogenase deficiency, help to reduce transfusion requirements.

In situations where blood transfusion is unavailable or potentially unsafe, the following recommendations have been made:

- Transfusion is not necessary if the Hb level is more than 50 g/L.
- Transfusion may be necessary if the Hb level is less than 50 g/L and there is incipient cardiorespiratory distress (air hunger, hypotension, tachycardia and oedema).
- Transfusion may be necessary if the Hb level is less than 40 g/L and complicated by malaria or bacterial infection, even without incipient cardiac failure.
- Transfusion may be necessary if the Hb level is less than 30 g/L, with no apparent complications.

In situations where blood transfusion is safe and available, recommendations for its use are as follows.

#### Neonates and infants less than 4 months old

- Blood loss of more than 15% over 2 days.
- Haemoglobin level of less than 70 g/L with clinical manifestations of anaemia.

#### Infants aged 4 months or older

- Acute blood loss that is unresponsive to crystalloid and colloid infusions.
- Intra-operative blood loss of more than 15% of total blood volume and post-operative haemoglobin level of less than 80 g/L with clinical symptoms.
- Haemoglobin level of less than 110 g/L with severe pulmonary disease.
- Acute haemolysis with haemoglobin level of less than 80 g/L with signs of anaemia.
- To suppress endogenous haemoglobin in sickle-cell disease crises and thalassaemic syndrome.

#### Red-cell-free components

- Fresh frozen plasma (FFP) is only recommended when a specific haemostatic defect has been identified. In the absence of specific testing, consider administering FFP to a patient with signs of disseminated intravascular coagulation who is acutely unwell, as it may be life-saving.
- Freeze-dried plasma is now available, and its advantages include a long shelf life and the lack of need for refrigeration.
- Platelets are prepared from fresh blood using a special, simple centrifugation method, and the remaining blood can be given back to the donor. Once extracted by this method, platelets can last for up to 5 days at room temperature (around 23°C). Platelets should not be stored in a refrigerator. Transfused platelets survive only briefly, and repeated infusion may be required for active bleeding, or before essential procedures such as a lumbar puncture in a child with severe thrombocytopenia.

#### Blood donation and provision

- Ideally blood is obtained by routine whole blood collection from an established panel of blood donors with quality standards for testing, processing and distribution.
- Most transfusions are required and given as an emergency procedure. Ideally, emergency collection of blood for paediatric use should not be necessary (see below).
- Safe transfusion is enhanced by the following measures:
  - collection of blood from repeat regular donors screened using a standard health-check questionnaire, and who are found negative for all markers for transfusion-transmissible infection
  - collection in a multi-pack which allows each donation to be divided into small volumes, in a closed sterile system to reduce wastage and donor exposure
  - multiple, small-volume packs can be used for multiple transfusions in one child or neonate without having to repeat the pre-transfusion tests.
- Group O rhesus-negative small-volume packs facilitate transfusion across the ABO barrier. They must be checked for high-titre anti-A or anti-B by a suitable antiglobulin method.
- Establish a routine procedure for collection, testing and processing which should cover routine and emergency transfusions.
- Maternal blood is not recommended for transfusing into the newborn infant, even in an emergency, although theoretically it can be used after compatibility testing with the recipient's serum.

#### Pre-transfusion testing

##### *Minimum acceptable tests on blood prior to transfusion*

- 1 ABO and Rhesus D grouping.
- 2 Screening for hepatitis B antigen and antibodies to HIV-1 and -2, hepatitis C virus and syphilis.
- 3 Additional tests for locally prevalent infections, such as malaria and Chagas disease.
  - 0.1–0.2 mL blood in an EDTA bottle is required for grouping, and 2 mL of clotted blood in a plain bottle for compatibility testing.
  - In infants under 4 months of age, maternal blood testing for compatibility is always required: 4 mL of EDTA plus 5 mL of clotted blood.
  - Blood group the neonate using a cord, capillary or small venous sample (2–3 drops and specific standard reagents Anti-A, Anti-B, Anti-A+B and Anti-RhD). Red cells only are used, because antibody levels in the sera of neonates are too low to be of significant value.
  - The inclusion of control A, B, O, RhD-positive and RhD-negative cells in the procedure is part of good laboratory practice, and should be part of the testing method.
  - If possible, two methods should be used for grouping, to ensure reliability.
  - For neonates and infants up to 4 months of age, compatibility testing is not required if the mother's serum is negative for allo-antibodies. Compatibility between the mother's serum and red cells to be transfused is required only if the mother has antibodies or if there is a previous history of haemolytic disease of the newborn.

The most suitable method for compatibility is the anti-human globulin technique at 37°C for 1 hour. Agglutination should be read before and after the addition of the anti-human globulin reagent.

## Blood groups

There are four major blood groups: A, B, AB and O. To avoid ABO incompatibility, the blood group of both the donor and the receiver must be known. Blood can only be donated in the direction of the arrows shown in Figure 1.7.1.

**FIGURE 1.7.1** Safe transfusion of ABO blood groups.

- Donors with blood group O can donate to patients (receivers) with blood group A, B, AB or O.
- Donors with blood group A can donate to patients with blood group A or AB.
- Donors with blood group B can donate to patients with blood group B or AB.
- Donors with blood group AB can donate only to patients with blood group AB.

Blood is also categorised according to its rhesus status. Therefore:

- Rhesus-negative donors can give to Rhesus-positive and Rhesus-negative patients.
- Rhesus-positive donors can only give to Rhesus-positive patients.

If the blood group is unknown and blood is required before a cross-match can be performed, give O-Rhesus-negative blood if this is available.

## Exchange transfusion

- This is used for haemolytic disease of the newborn with severe anaemia and/or severe hyperbilirubinaemia (see Section 3.4). Exchange of double the neonate's blood volume is often required using 160–180 mL/kg of whole blood and/or plasma reduced red cells. The latter are prepared by removing approximately 100 mL of plasma to create a haematocrit of 0.5–0.6.
- Patients with sickle-cell anaemia and acute chest syndrome or impending cerebrovascular episodes may benefit from exchange transfusion (see Section 2.5.B).
- Blood should be fresh (less than 5 days old), and also screened for HbS if it is issued for sickle-cell disease.

Use Rhesus-negative blood, group O or the same ABO group as the infant compatible with maternal and infant serum.

The blood should be warmed with a heating coil or stood for 1 hour at room temperature or under the mother's clothing.

## Exchange transfusion: indications and technique

### Indications

- Severe haemolytic anaemia: use double volume exchange.
- Severe hyperbilirubinaemia: use double volume exchange.
- Polycythaemia: use partial exchange with Ringer-lactate or Hartmann's or 0.9% saline (see Section 3.4).

$$\text{Double volume exchange (mL)} = 2 \times 80 \times \text{weight (kg)}$$

$$\frac{80 \times \text{weight (kg)} \times (\text{actual haematocrit} - \text{desired haematocrit})}{\text{actual haematocrit}}$$

### Technique

- 1 Exchange transfusion should preferably be through umbilical or peripheral venous and arterial catheters so that simultaneous withdrawal and transfusion of blood/volume occurs. If this is not possible, a single large-bore venous cannula may be used with a three-way tap to allow alternate withdrawing and transfusing of aliquots. An aseptic technique must be maintained.
- 2 Use a 5- or 10-mL syringe to draw 5- or 10-mL aliquots (depending on the baby's weight) from the baby via the arterial line over a 3-minute cycle, and discard them. Simultaneously infuse 5- or 10-mL aliquots through the venous line over a 3-minute cycle.
- 3 The baby's temperature, pulse, respiratory rate and blood pressure must be monitored as for transfusions, and in addition blood glucose levels must be monitored every 30 minutes.
- 4 Use a nasogastric tube to evacuate the stomach contents, and keep the patient nil by mouth.
- 5 Use a separate IV line to administer dextrose solution to maintain blood glucose levels and hydration.
- 6 Check the baby's haemoglobin, bilirubin, glucose and calcium levels at the beginning and end of the procedure.
- 7 Check a blood film, Coombs' test, and if possible coagulation and arterial or capillary blood gas at the beginning of the procedure.

Potential complications include hypoglycaemia, electrolyte disturbance, thrombocytopenia, coagulopathy, sepsis, air embolus, circulatory overload and gastrointestinal complications (e.g. acute dilation of stomach, intestinal ischaemia).

### Bedside transfusion

A child's body contains 80 mL of blood for every kg of body weight. For example, a 3-year-old weighing 12 kg will have 960 mL of blood in their body.

A pregnant mother's body contains 100 mL of blood for every kg of body weight.

- Venous access for bedside transfusion should be chosen with no smaller than a 22- to 24-gauge vascular catheter, and a much larger one in pregnant mothers.
- Blood is usually cleaned and filtered in the lab, so when transfusing it to a patient the only filter that needs to be used is the usual on-line filter in a standard giving set.
- Blood should be treated like any other IV fluid, and given using an accurate measurement of rate and time. **A burette should be used for infants or in children for whom**

**too rapid an input could be dangerous (e.g. in incipient or actual heart failure).**

## Blood transfusion reactions

Blood transfusion can be life-saving and provides great clinical benefit to many patients. However, it is not without risks, which include the following:

- immunological complications
- errors and 'wrong blood' episodes
- infections (bacterial and viral).

### Causes of acute complications of transfusion

#### **Acute haemolytic transfusion reaction**

- Incompatible transfused red cells react with the patient's own anti-A or anti-B antibodies or other alloantibodies (e.g. anti-rhesus (Rh) D) to red cell antigens. Complement can be activated and may lead to **disseminated intravascular coagulation (DIC)**.
- Infusion of ABO-incompatible blood is almost always a result of errors in labelling sample tubes and/or request forms, or inadequate checks at the time of transfusion. When red cells are mistakenly administered, there is about a 1 in 3 risk of ABO incompatibility and a 10% risk of mortality, with the most severe reaction seen in a group O individual receiving group A red cells.
- Non-ABO red cell antibody haemolytic reactions tend to be less severe.

#### **Infective shock**

- Bacterial contamination can be fatal.
- Acute onset of tachycardia, low pulse pressure, hypotension, rigors and collapse rapidly follows the transfusion.

#### **Transfusion-related acute lung injury (TRALI)**

- TRALI is a form of acute respiratory distress due to donor plasma containing antibodies against the patient's leukocytes.
- Transfusion is followed within 6 hours of transfusion by the development of a prominent non-productive cough, breathlessness, hypoxia and frothy sputum. Fever and rigors may be present.
- Chest X-ray if available shows multiple perihilar nodules with infiltration of the lower lung fields.

#### **Fluid overload**

- This occurs when too much fluid is transfused or it is transfused too quickly, leading to **pulmonary oedema** and **acute respiratory failure**.
- Patients at particularly high risk are those with severe or chronic anaemia, or severe malnutrition and who have normal blood volumes (i.e. who are not bleeding), and those with symptoms of **cardiac failure** prior to transfusion.
- These patients should receive packed cells rather than whole blood via slow transfusion, with diuretics if required.

#### **Non-haemolytic febrile reactions to transfusion of platelets and red cells**

- Fevers (more than 1°C above baseline) and rigors may develop during transfusion due to the patient's antibodies to transfused white cells.

- This type of reaction affects 1–2% of patients.
- Multiparous women and those who have received multiple previous transfusions are most at risk. Reactions are unpleasant but not life-threatening. Usually symptoms develop towards the end of a transfusion or in the subsequent 2 hours. Most febrile reactions can be managed by slowing or stopping the transfusion and giving paracetamol.

#### **Severe allergic reaction or anaphylaxis**

- Allergic reactions occur when patients have antibodies that react with proteins in transfused blood components.
- Anaphylaxis occurs when an individual has previously been sensitised to an allergen present in the blood, and subsequently, on re-exposure, releases immunoglobulin E (IgE) or IgG antibodies. Patients with anaphylaxis become acutely dyspnoeic due to bronchospasm and laryngeal oedema, and may complain of chest pain, abdominal pain and nausea.
- Urticaria and itching are common within minutes of starting a transfusion.
- These symptoms are usually controlled by slowing the transfusion and giving antihistamine, and the transfusion may be continued if there is no progression at 30 minutes.
- Pre-treatment with an antihistamine should be given if the patient has experienced repeated allergic reactions to transfusion.
- For treatment of anaphylaxis, see Sections 2.7.C and 5.1.B.

#### **Presentation**

Symptoms or signs may occur after only 5–10 mL of transfusion of incompatible blood, so **patients should be observed very closely at the start of each blood unit transfused**.

#### **Symptoms**

These include the following:

- a feeling of apprehension or that 'something is wrong'
- flushing
- chills
- pain at the venepuncture site
- muscle aches
- nausea
- pain in the abdomen, loins or chest
- shortness of breath.

#### **Signs**

These include the following:

- fever (a rise in temperature of 1.5°C or more) and rigors
- hypotension or hypertension
- tachycardia
- respiratory distress
- oozing from wounds or puncture sites
- **haemoglobinaemia**
- **haemoglobinuria**.

#### **Investigations and management**

- If a serious acute transfusion reaction is suspected, **stop the transfusion**, take down the donor blood bag and giving set, and send the donor bag back to the blood bank with notification of the event. Set up a new giving set with Ringer Lactate, Hartmann's or 0.9% saline solution.
- To detect a haemolytic reaction, send post-transfusion

blood (for full blood count and clotting, repeat typing and cross-matching, antibody screen and direct Coombs' test) and a urine specimen (if available, for detection of urinary haemoglobinuria) from the transfusion recipient.

- Where bacterial contamination is suspected, send blood cultures from the patient and also bag remnants.
- If the patient is dyspnoeic, obtain a chest X-ray if possible and check for fluid overload and pulmonary oedema.

**TABLE 1.7.1 Investigations for blood transfusion reactions**

Type of reaction	Investigation findings
Acute haemolytic reactions	<ul style="list-style-type: none"> <li>• Visual inspection of centrifuged plasma: pink-red discoloration (haemoglobinaemia) indicates significant intravascular haemolysis</li> <li>• Visual inspection of centrifuged urine: red discoloration indicates haemoglobinuria</li> <li>• Retyping of donor and recipient red blood cells (RBCs): any discrepancy suggests that the transfusion has been mismatched and blood samples have been mixed up</li> <li>• Direct antiglobulin ('Coombs') test (DAT): ABO-related acute transfusion reactions usually cause a positive DAT test</li> <li>• Evidence of increased RBC destruction (e.g. a fall in haemoglobin and/or rise in bilirubin levels)</li> <li>• There may be evidence of DIC</li> <li>• Negative blood cultures</li> </ul>
Febrile non-haemolytic reactions	<ul style="list-style-type: none"> <li>• Visual inspection of the recipient's plasma and urine is normal</li> <li>• Retyping shows no incompatibility</li> <li>• DAT test is negative</li> </ul>
Allergic and anaphylactic reactions	<ul style="list-style-type: none"> <li>• Urticaria, itching and dyspnoea (for symptoms and signs of anaphylaxis, <i>see</i> Section 2.7.C)</li> </ul>
TRALI	<ul style="list-style-type: none"> <li>• Pulse oximeter shows hypoxaemia</li> <li>• Chest X-ray (if available) shows bilateral lung infiltrates</li> <li>• Full blood count frequently shows low white blood cell count and high eosinophil count</li> </ul>
Transfusion-transmitted bacterial infection	<ul style="list-style-type: none"> <li>• Blood cultures are positive and congruent for both donor and recipient blood</li> </ul>

### Management

- Where the only feature is a rise in temperature of less than 1.5°C from baseline, or urticaria, recheck that the correct blood is being transfused, give paracetamol and antihistamine, reset the transfusion at a slower rate and observe the patient more frequently.
  - Although fever or rigors are not uncommon in response to a transfusion and may represent a non-haemolytic febrile reaction, they may also be the first sign of a severe adverse reaction.
  - Where the reaction is more severe:
    - Stop the transfusion and call a doctor urgently to review the patient.
    - Vital signs (temperature, blood pressure, pulse, respiratory rate and oxygen saturation levels) and respiratory status (dyspnoea, tachypnoea, wheeze and cyanosis) should be checked and recorded. Look for signs of heart failure (basal lung crepitations and enlarged liver).
    - Check the patient's identity and recheck against details on the blood unit and compatibility label or tag.
  - Initial management if **ABO incompatibility** is suspected is as follows:
    - Take down the blood bag **and** the giving set with blood in it.
    - Keep the IV line open with Ringer-lactate or Hartmann's solution.
    - Give oxygen and fluid support.
    - Monitor urine output, usually following catheterisation, and maintain it at more than 2 mL/kg/hour in infants, > 1 mL/kg/hour in children and > 30 mL/hour in pregnancy, giving furosemide if it falls below this.
    - Consider inotropic support if hypotension is prolonged.
    - Treat DIC by giving fresh new blood fully matched to the recipient.
    - Inform the hospital transfusion department immediately.
  - If **another haemolytic reaction or bacterial infection of blood unit** is suspected:
    - Send haematological and microbiological samples for investigations as outlined above.
    - General supportive management is as for ABO incompatibility.
    - Start broad-spectrum IV antibiotics if bacterial infection is considered likely.
  - If **anaphylaxis or severe allergic reaction** is suspected:
    - Follow the anaphylaxis protocols for women and children (*see* Section 2.7.C and Section 5.1.B).
  - If **TRALI** is suspected:
    - Give high-concentration oxygen, IV fluids and inotropes (as for acute respiratory distress syndrome).
    - Ventilation may be urgently required; discuss this with an anaesthetist.
- TRALI improves within 2–4 days in over 80% of cases if there is adequate management and respiratory support.
- If **fluid overload** is suspected:
    - Give IV furosemide and high-concentration oxygen.

### Delayed complications of transfusion Delayed haemolysis of transfused red cells

- In those who have previously been immunised to a red cell antigen during pregnancy or by transfusion, the level of antibody to the blood group antigen may be so low as to be undetectable in the pre-transfusion sample.
- However, after transfusion of red cells bearing that antigen, a rapid secondary immune response raises the

antibody level dramatically, leading to the rapid destruction of transfused cells.

- At 5–10 days post-transfusion, patients present with fever, falling haemoglobin levels (or an unexpectedly poor rise in haemoglobin levels), jaundice and haemoglobinuria.
- A rise in bilirubin levels and positive direct antiglobulin test (DAT) will also be present.

#### **Development of antibodies to red cells in the patient's plasma (alloimmunisation)**

- Transfusion of red cells of a different phenotype to that of the patient will cause alloimmunisation (e.g. development of anti-RhD in RhD-negative patients who have received RhD-positive cells).
- This is dangerous if the patient later receives a red cell transfusion, and can cause **haemolytic disease of the newborn (HDN)**.

#### **Iron overload**

- Each unit of blood contains 250 mg of iron, and those receiving red cells over a long period of time may develop iron accumulation in cardiac and liver tissues.
- Chelation therapy (with **desferrioxamine**) is used to minimise iron accumulation in those most at risk.

#### **Infection**

- The risk of becoming infected with HIV, hepatitis B or hepatitis C from transfusion is now small. However, since there is always the potential for unrecognised or unknown infection to be spread via transfusion, **all non-essential transfusions should be avoided**.
- Blood must be stored at the correct temperature at all times (at 1–6°C for up to 35 days if using citrate-phosphate-dextrose adenine anticoagulant or up to 21 days if using citrate-phosphate-double dextrose). Ideally each blood bag should be labelled with a temperature-sensitive strip that changes colour when

the correct temperature for storage has been exceeded for a clinically significant period of time.

#### **Improving safety**

##### **Reducing transfusion errors**

- Introduce robust hospital transfusion protocols.
- Provide training for all staff involved in blood administration/taking samples for cross-matching.
- An understanding of transfusion medicine should be a core curricular component for all doctors in training.
- Improved information technology, such as use of a unique barcode on the patient's wristband/blood sample and prepared blood, is important.
- Appoint specialist transfusion practitioners.

##### **Reducing unnecessary transfusion**

- Transfusion risks related to the use of allogeneic blood can be eliminated by the use of autologous blood (whereby patients collect and store their own blood for use in planned surgery). However, this practice is not risk-free.
- Ensure that blood products are only used when the patient is judged more likely to benefit from than be harmed by a transfusion.
- Always record in the patient's notes the indication for giving blood.
- Adopt procedures such as checking for and correcting anaemia prior to planned surgery, stopping anticoagulants and antiplatelet drugs before surgery, minimising the amount of blood taken for laboratory samples, and using a simple protocol to guide when haemoglobin should be checked and when red cells should be transfused.
- Accept a lower haemoglobin concentration as a trigger for transfusion.
- Accept a lower post-transfusion target haemoglobin level.

## 1.8

## Essential laboratory services

### **Basic services provided in the laboratory and on the ward**

Whenever possible, the regional or central laboratory should procure the chemicals, prepare the reagents and standards, and distribute them with the necessary controls and approved testing procedure to district laboratories. Details on how to prepare the required reagents, standards and controls can be found in the 1995 WHO publication *Production of Basic Diagnostic Laboratory Reagents*.<sup>1</sup>

For all small hospitals, the WHO recommends six basic investigations as an absolute minimum:

- haemoglobin or packed cell volume
- blood smear for malaria
- blood glucose levels
- microscopy of cerebrospinal fluid (CSF) and urine

- blood grouping and cross-matching
- for newborn care, blood bilirubin levels.

### **Tests that can be performed on the wards**

These include the following:

- blood grouping
- rapid diagnostic test for *Plasmodium falciparum* (or urgent thick blood film for malarial parasites)
- urine microscopy (see Sections 5.6.A and 8.5)
- HIV rapid screening test
- HBsAg screening test
- 'hot stool' examination (for *Entamoeba histolytica*)
- rapid haemoglobin (WHO paper-based method)

- CSF/gland/chancere aspirate/wet preparation for trypanosomes.

### Tests to be performed in the laboratory

These include the following:

- thick and thin blood films for malaria and/or rapid diagnostic test for *Plasmodium falciparum*
- smears for *Leishmania amastigotes*
- rapid rk39 Ab test for *Leishmania* antibodies
- Ziehl-Neelsen sputum smears for TB
- Ziehl-Neelsen slit skin smears for leprosy
- Gram-stained smears
- haemoglobin estimation and platelets
- total and differential white cell count
- erythrocyte sedimentation rate (ESR)
- sickle-cell test
- HIV and hepatitis screening tests
- blood grouping and cross-matching
- urine deposits
- formol-ethyl acetate concentration and Kato-Katz thick smears for stool parasites.

### Essential equipment

A functioning **microscope** is essential, and also saves time and therefore salary costs. Ideally a binocular instrument should be available, with  $\times 10$  eyepieces and  $\times 10$ ,  $\times 40$  and  $\times 100$  (oil immersion) objectives with integral illumination. LED light sources and options for using solar-powered batteries are now available.

A robust **bench-top centrifuge** is also needed. Ensure that lidded conical tubes (15 mL) can be used, and that there is an inner safety lid. A built-in timer and variable rotor speed are also desirable.

### Haematological investigations

#### Haemoglobin

- **Haemoglobin colour scale** (WHO) filter paper 'matching method' (visual comparative technique): simple, cheap and portable, but is not suitable for use with artificial light. Available from WHO, Geneva.
- **Haemoglobinometer (BMS)** visual comparator method: a useful method for testing small numbers of sample. No dilution or measurement of sample is required, and standard is included. Available from Cascade HealthCare Products Inc., USA ([www.1cascade.com](http://www.1cascade.com)).
- **DHT Hb523 haemoglobinometer**: portable, battery-operated and requires 0.04% ammonia. Suitable when multiple investigations are required ([www.haemoglobinometer.co.uk](http://www.haemoglobinometer.co.uk)).
- **Microhaematocrit centrifugation**: if no other method is available this can be used for estimation. Note that there may be raised values caused by plasma loss (e.g. due to burns or dehydration).

#### White blood cell count

- **Improved Neubauer haemocytometer**: spare cover glasses, Turk's solution (white blood cell diluent), 20- $\mu$ L micropipette and hand tally counter are required.

#### Erythrocyte sedimentation rate (ESR)

- The **Westergren method** is recommended.

### Differential white cell counts

- Thin blood film stained with Leishman's/Rapayd Giemsa (pH 6.8). Tally counters are required.
- **Film may also be used to examine red cell morphology for cases of suspected nutritional anaemia (e.g. iron deficiency).**

### Sickle-cell test

- A simple slide test using 2% sodium metabisulphite (prepared daily) will enable the morphology of sickled red blood cells to be seen, but cannot differentiate between sickle-cell disease and trait. The HbS solubility filtration test can differentiate sickle-cell anaemia from sickle-cell disease.

### HIV test

- Rapid antibody tests are easy to use for blood transfusion screening purposes and for diagnostic screening. Many brands are available, their sensitivities and specificities vary, and brand use may depend on local availability.

### Hepatitis B and C testing

- Rapid tests are available to detect HBsAg and anti-HCV antibody (refer to **WHO Blood Safety Unit** for details of appropriate tests).

### Blood groups

- **Blood grouping/cross-matching sera should be available.**

### Biochemical investigations

Low-cost, easily maintained equipment is urgently required in low-resource settings to measure plasma sodium and potassium levels. Hyponatraemia and hypokalaemia are common and dangerous conditions that need early detection and management.

Important biochemical investigations include the following:

- Tests on whole blood, serum or plasma:
  - urea, creatinine and electrolytes
  - glucose
  - albumin
  - bilirubin
  - amylase
  - AST (aspartate aminotransferase).
- In specialised hospitals, the following can be measured:
  - alkaline phosphatase
  - ALT (alanine aminotransferase)
  - calcium
  - cholesterol
  - cholinesterase
  - iron
  - triglycerides.
- Urine clinical chemistry tests:
  - protein
  - glucose
  - bilirubin and urobilinogen
  - ketones
  - haemoglobin
  - nitrite
  - specific gravity.

- Faecal clinical chemistry tests:
  - occult blood
  - lactose
  - excess fat.
- Cerebrospinal fluid clinical chemistry tests:
  - protein (c. 1 mL of CSF)
  - glucose (0.5 mL into a fluorite oxalate bottle).

### Investigations for specific diseases

#### Malaria

- Thick blood film stained with Field's/Giemsa) stain; use finger prick or venous blood.
- Using Field's the film can be stained within 20 seconds (compound stain powders 'A' and 'B' are available to mix with water).
- To confirm diagnosis of the species, a methanol-fixed thin blood film (hand stained at pH 7.2) using Rapyd Giemsa/Leishman's or reverse Field's stain may be useful.
- Thick blood films may also reveal *Borrelia*, microfilariae and trypanosomes.
- The WHO has recommended the use of rapid diagnostic tests (RDTs) as a parasite-based diagnosis **where good-quality microscopy cannot be maintained** (for guidance on choosing the most appropriate RDT, visit [www.who.int/tdr](http://www.who.int/tdr)).

#### African trypanosomiasis

- Immediate examination of a wet preparation and/or thick blood film stained as described above is the simplest way of diagnosing *Trypanosoma brucei rhodesiense* (if a chancre is present, a sample may be taken from between the edge and the centre of the lesion and examined as for blood).
- Gland fluid from a swollen posterior cervical gland may be examined (this is particularly useful in *T.b. gambiense*), with immediate examination for motile trypanosomes or stained as for blood.
- If these tests are negative, up to four microhaematocrit (MHCT) tubes of blood should be taken. These are centrifuged for 5 minutes, stuck to microscope slides and the buffy coat area examined for motile trypanosomes (Woo test).
- All samples must be examined as soon as possible to avoid parasite lysis.
- If the blood is positive for trypanosomes, or it is suspected that the patient has late-stage (stage II) CNS disease, a lumbar puncture must be taken and CSF examined microscopically **within 30 minutes of the procedure in order to visualise trypanosomes**. The number of white blood cells should be counted using a haemocytometer.

#### Leishmaniasis

- For cutaneous leishmaniasis, a smear taken from the raised red edge of a lesion may be taken and stained with rapid Giemsa/Leishman's (diluted with buffered water at pH 7.2) to demonstrate amastigotes.
- For suspected visceral leishmaniasis, haematological investigations plus an antibody detection test such as the Rapyd Leishman's which utilises rk39 antigen are the most useful and safe investigations. Note that in HIV-positive individuals false-negative antibody test results are common.

### TB and leprosy

#### For suspected TB

- If possible, up to three consecutive morning sputum samples should be examined.
- The Ziehl–Neelsen (ZN) method of staining should be used.
- The addition of bleach to liquefy the sample may improve sensitivity, and lowers the risk of laboratory infection.

#### For suspected leprosy

- The ZN method of staining should be used on slit skin smears.

### Diarrhoeal diseases

#### For suspected parasitic cause

- Direct microscopy using saline smears (plus iodine to aid identification of cysts) should be used. A concentration technique such as formol-ether (or ethyl-acetate/petrol) concentration or the Kato–Katz cellophane technique (WHO) is particularly useful when looking for parasites such as *Schistosoma mansoni*, where the female worm only produces around 200 eggs per day.

#### For suspected bacteriological cause

- Ideally the specimen should be sent for culture and sensitivity testing.
- Culture may not be possible due to the need for sterile facilities and supplies of media.
- If possible, samples should be sent to a reference laboratory for culture.
- Supplies of the following transport media and sterile swabs should be available:
  - Stuart's medium or Amies medium for suspected *Salmonella typhi* and *Shigella*
  - alkaline peptone water and Cary-Blair medium for *Vibrio cholerae*.
- If microscopy of a fluid stool containing blood shows red blood cells, white blood cells/macrophages and numerous bacteria, **bacterial dysentery** is likely.
- If the sample is loose with blood and mucus, then a 'hot stool' (examined within 30 minutes of voiding) should be examined for motile *Entamoeba histolytica* trophozoites.

### Urinary infections and renal diseases

#### Urine examination

- Urine 'dipstick' tests are useful for detecting blood, protein, glucose, bilirubin, urobilinogen, infection, nitrites and white blood cells.
- A midstream urine (MSU) sample may be examined microscopically for the following:
  - *Schistosoma haematobium* ova (or terminal urine)
  - pus (white blood cells)
  - erythrocytes
  - casts
  - bacteria (suspected urinary tract infection).
- The addition of a drop of 1% methylene blue in physiological saline may aid microscopical examination.
- If urine is to be sent for culture, 20 mL of an MSU sample should be mixed with 3 mg of boric acid (a preservative).
- It is important to give instructions to ward staff on how to obtain an MSU sample, bag urine and suprapubic aspirate.

**Ulcers and exudates**

- For suspected bacterial (and fungal) infections, a smear of the pus or exudate should be stained with Gram stain.

**Meningitis**

- A Gram-stained CSF deposit may be useful in cases of suspected meningitis.
- The India ink stain is used for cryptococcal meningitis.

**1.9****Records, history taking and examination****Records**

- Records can be held by patients or parents, or by the hospital, or both.
- If they are patient or parent held, they can be developed into health booklets containing advice on how to manage illnesses (possibly in the form of pictures for illiterate parents). Immunisation information, if included, should comply with national immunisation programmes.
- Hospital records need to be kept confidentially in a logical system for audit purposes, with easy access to previous notes.
- Discharge information and advice should be entered in the patient- or parent-held booklet.
- If possible, diagnoses should be coded and entered according to the International Classification of Diseases (ICD) or in accordance with local policy and coding.

**History taking**

- The medical history should, when age appropriate, include the child's own input. The source of the information may be the mother, the father or the child him- or herself, and the source should be documented.
- It is important to listen, especially to the mother's worries about her child, taking into account her general frame of mind, her experience with previous children and her ability to communicate.
- Time can be a restricting factor due to the workload, but it is important to ask about the following:
  - pregnancy and previous deliveries (including stillbirths)
  - infant or young child feeding history
  - the immunisation record (best kept by the parents)
  - previous admissions or visits to hospital
  - existing medical problems
  - social circumstances at home, and the family history
  - the family's cultural beliefs and their religion and/or tribe
  - medication taken by the patient, and any allergies
  - the patient's presenting complaints and current treatment, if any.
- Most patients and their families are anxious. They need reassurance, kindness and understanding.

**Examination**

The following basic equipment is required:

- stethoscope
- otoscope (if available)
- ophthalmoscope (if available)
- tendon hammer
- bright torch light (or mobile phone light)
- thermometer
- Pinard's stethoscope or Sonicaid (a hand-held Doppler)
- microscope (if available).

**Conducting the examination**

- A triage nurse (see Section 1.10) can be helpful for making a preliminary assessment of patients. They can assess each patient and use the recorded body temperature, weight, general condition and pain score of the patient to decide how urgently he or she should be seen by the doctor.
- Do not rush the examination. A thorough examination is often needed, and taking time can help to gain the confidence of the patient and their family.
- If the patient is critically ill, quick action is required and questions can be asked later.
- Try to be gentle and avoid palpating a painful body part before everything else has been done. You want to avoid having a crying patient whom you cannot examine or auscultate.
- Small children and infants are best examined on the parent's lap; older ones can be asked to lie down.
- In general, the examination of a child will follow the same systematic approach as in adults. However, you may need to be more opportunistic.

**Essential emergency examination checklist**

Always check the following in the order shown:

- **A**irway
- **B**reathing
- **C**irculation
- **D**isability
- **E**xposure.

**In the case of a critically ill patient, proceed to basic and/or advanced life support using the structured approach (see Section 1.11).**

### Patients who are not in need of immediate resuscitation

- **Introduce yourself to the patient and parent, if present.**
- **Interact with any child throughout the examination.**
- **General inspection:** document dysmorphism, skin rashes or bruises, nutritional status, weight and height for age, jaundice, pallor, clubbing, (for child) relationship with parent, and state of consciousness.
- **Respiratory system:** document chest wall expansion (is it symmetrical? is there recession?), respiratory rate, cyanosis, palpation, percussion, and auscultation.
- **Cardiovascular system:** remember to feel all of the pulses, particularly the femoral pulses. Measure the blood pressure (the cuff **must** cover two-thirds of the upper arm circumference), examine the jugular venous pressure, palpate the cardiac impulses (i.e. for left and right ventricles), and auscultate the apex, left sternal edge, pulmonary and aortic areas and carotids and over the back.
- **Abdominal system:** if the patient is pregnant, assess the size of the uterus, the presentation of the fetus and listen for the fetal heart. In an infant check the genitals for cryptorchidism, hernias and gender. Rectal examinations are occasionally necessary but need to

be explained to the patient, parent and child (where appropriate). Inspect the mouth and teeth.

- **Neurological system:** use the AVPU or Glasgow Coma Scale score (see Section 1.11). Observe infants for their degree of responsiveness and rapport appropriate for age, social and motor skills, and look for neurocutaneous stigmata. Test for age-appropriate reflexes and saving reactions when assessing developmental delay. Leave sensation testing until last. Ideally, fundoscopy needs mydriatics, a dark room and (occasionally) sedation.
- **Motor system:** Always examine infants for dislocated/dislocatable hips. Check the gait.
- **Urine:** Test for protein, glucose and blood, and ideally for infection using a microscope or appropriate stick tests.

Patients and parents have the right to be told any abnormal findings, and the actual process of the examination should be explained to the patient in age-appropriate language.

The history and examination findings, including the patient's weight and height, should be recorded, with daily entries on management and progress. (Be aware of the local guidelines on nutritional assessments, especially in settings where malnutrition is common.) When the patient is discharged they should be given discharge information about the admission and any further treatment and advice that needs to be shared with their primary care healthcare workers.

See Section 9 (Appendix) for examples of various charts, including those for vital signs, fluid balance, growth and body mass index (BMI).

## 1.10 Triage: seeing the sickest first

Triage involves **determining the priority of a patient's treatment based on the severity of their condition, not on when they arrived or their place in a queue.**

### Introduction

The word 'triage' comes from the French word 'trier' (meaning 'to sort'). It is the process by which patients presenting to a health facility with an illness or injury are assigned a clinical priority. It is an essential step in clinical risk management, as it means that, if done correctly, those patients who are most in need of care receive it first. Triage should have a robust mechanism to ensure that patients at imminent risk of death or who are seriously ill or injured, requiring immediate resuscitation or emergency management, are provided with treatment before patients with conditions that are less critical, who can wait for further assessment and treatment.

Triage divides patients into the following three categories:

- 1 those who are at imminent risk of death, and require immediate resuscitation
- 2 those who are seriously ill or injured, and who need timely emergency management
- 3 those who have conditions which can wait before further assessment and possible treatment.

Of course, it is not always immediately apparent which category a patient is in, so most methodologies are based on a rapid physiological assessment of vital functions (airway and breathing, circulatory status and conscious level).

The models of decision making, of which there are many, require three steps:

- 1 rapid initial assessment
- 2 determination of the appropriate categories
- 3 selection of the most appropriate category.

### Triage scheme for children and pregnant women

#### Rapid initial assessment

When a woman or girl who is or might be pregnant presents to a health facility she is of immediate concern and should be given priority through triage without disadvantaging seriously affected men or older women. Infants and children can also become dangerously ill quickly, and therefore need urgent triage.

This process requires the ability to recognise, first, those patients who need resuscitation (**immediate management, group 1, 'red'**), and, second, those who need **urgent treatment (group 2, 'orange')** (see Table 1.10.1). This process must take only a few seconds, as any delay can be fatal.

**TABLE 1.10.1 A possible triage scale (adapted from the Advanced Life Support Group)**

Triage number	Type of action	Colour	Maximum target time to action (minutes)
Category 1	Immediate	Red	0
Category 2	Urgent	Orange	15
Category 3	Non-urgent	Green	60 (1 hour)

From the moment of arrival at the health facility (some information may be given before arrival, by contact between the ambulance crew and the facility), a decision on those who need resuscitation must be made. The decision making is based on the clinical signs listed in the second column of Tables 1.10.2 and 1.10.3.

Once a triage category has been identified, the patient should have observations of respiration rate and characteristics (e.g. wheeze, stridor, recession), pulse rate,

blood pressure, temperature and a rapid measure of conscious level, such as AVPU score (Alert, responds to Voice, responds to Pain, Unconscious; see Sections 1.11 and 1.12), measured and recorded.

Table 1.10.2 (for pregnant women) and Table 1.10.3 (for infants and children) show those features which, on rapid examination, determine that immediate resuscitation is required.

**TABLE 1.10.2 Clinical signs on simple observation or from the history which indicate the need for immediate resuscitation in pregnant mothers**

Underlying mechanism	What does the healthcare worker undertaking triage see in the patient or hear from the relatives?
A problem that is obstructing, or might obstruct, the upper airway A: AIRWAY	The patient is unconscious The patient is fitting or has been fitting There is major trauma to the face or head, including burns There is severe stridor or gurgling in the throat
Any problem producing apnoea, severe respiratory distress or cyanosis B: BREATHING	The patient is not breathing The patient is gasping The patient is cyanosed The patient is having so much difficulty breathing that they cannot speak
Any problem producing cardiac arrest, shock or heart failure C: CIRCULATION	The patient has heavy vaginal bleeding The patient has suffered major trauma The patient appears shocked (very pale/white, cannot sit up, has a reduced conscious level)

**TABLE 1.10.3 Clinical signs on simple observation or from the history which indicate the need for immediate resuscitation in infancy and childhood**

Underlying mechanism	What does the healthcare worker undertaking triage see in the patient or hear from the parents?
A problem that is obstructing, or might obstruct, the upper airway A: AIRWAY	The patient is unconscious The patient is fitting or has been fitting There is major trauma to the face or head, including burns There is severe stridor or gurgling in the throat The child has inhaled a foreign body which is still in the throat
Any problem producing apnoea, severe respiratory distress or cyanosis B: BREATHING	The patient is not breathing The patient is gasping The patient is cyanosed The patient is having so much difficulty breathing that they cannot speak or vocalise (cry)
Any problem producing cardiac arrest, shock or heart failure C: CIRCULATION	The patient has suffered major trauma The patient appears shocked (very pale/white, cannot sit up, weak, very rapid or absent pulse, and has a reduced conscious level)

Tables 1.10.4 and 1.10.5 list those features which indicate the need for urgent management (orange) within 15 minutes.

**TABLE 1.10.4 Clinical signs on simple observation or from the history in a pregnant mother which indicate the need for urgent management but not resuscitation**

Underlying mechanism	What does the healthcare worker undertaking triage see or hear from the patient or the relatives?
A problem that might obstruct the upper airway in the future A: AIRWAY	There is trauma to the face or head, or burns to this area, but the patient is conscious and able to speak Ingestion or accidental overdose of drugs which may alter the conscious level?
A problem producing respiratory distress B: BREATHING	The patient has difficulty breathing but can speak, and there is no cyanosis
Any problem that might, unless rapidly treated, lead to shock or heart failure C: CIRCULATION	The patient has vaginal bleeding which is heavy*, but is not yet shocked (they are able to stand or sit up and speak normally) The patient has suffered major trauma and is not yet shocked, but may have internal bleeding (they are able to stand or sit up and speak normally) Any burns covering more than 10% of the body The patient has fainted and has abdominal pain (this includes possible ruptured ectopic pregnancy) but they are now able to stand or sit up and speak normally The patient has passed products of conception and is still bleeding, but is not shocked (they are able to stand or sit up and speak normally) The patient has severe abdominal pain, but is not shocked (they are able to stand or sit up and speak normally) The patient is extremely pale, but is not shocked (severe anaemia) (they are able to stand or sit up and speak normally)
Possible severe pre-eclampsia and impending eclampsia	The patient is complaining of a headache and/or visual disturbance
Severe dehydration	The patient is complaining of severe diarrhoea/vomiting and is feeling very weak, but is not shocked (they are able to stand or sit up and speak normally)
Possible complication of pregnancy	The patient has abdominal pain not due to uterine contractions of normal labour
Possible premature labour	The patient is not yet due to deliver, but has had ruptured membranes (with or without contractions)
Infection that might become dangerous	The patient has a high fever > 38°C (they are hot to touch or shivering, but are able to stand or sit up and speak normally)
Possible intrauterine death	After 24 weeks of pregnancy the patient has not felt fetal movements for 24 hours or more
Prolapsed cord	The patient says that her membranes have ruptured and she can feel the umbilical cord

\*Heavy bleeding is defined as a clean pad or cloth becoming soaked within less than 5 minutes.

**Note that a low blood pressure in a pregnant woman or a child is a late and ominous sign.**

## Helping to ensure that triage works well

The following actions will help to prevent life-threatening delays:

- 1 Train all staff (including clerks, guards, door keepers and switchboard operators) to recognise those who need resuscitation.
- 2 Practise triage and the structured approach to emergencies with all staff in the facility.
- 3 Ensure that access to care is never blocked. Emergency equipment must always be available (not locked away) and in working order. This requires daily checks and the keeping of logbooks. Essential emergency drugs must be constantly available.
- 4 Give proper training of appropriate staff in the use of the equipment and drugs required.
- 5 A special trolley containing equipment and drugs for emergencies must be available at all times.

- 6 Protocols on the structured approach to emergencies (see below) must be available. Pathways of emergency care should be prominently displayed on the walls in areas where emergencies are managed.
- 7 Implement systems by which patients with emergencies can be exempted from payment, at least temporarily. These include local insurance schemes and health committee emergency funds. This exemption must be made known to all gatekeepers and security staff.

## Special priority signs Haemorrhage

Haemorrhage is a feature of many presentations, particularly in pregnancy and following trauma.

**Category 1 patients (red) are those who are exsanguinating. Death will occur quickly if the bleeding is not arrested.**

A haemorrhage that is not rapidly controlled by the application of sustained direct pressure, and which continues to bleed heavily or soak through large dressings quickly, should also be treated **immediately (Category 1, red)**.

**TABLE 1.10.5 Clinical signs on simple observation or from the history in an infant or child which indicate the need for urgent management but not resuscitation**

Underlying mechanism	What does the healthcare worker undertaking triage see or hear from the patient or relatives?
A problem that might obstruct the upper airway in the future A: AIRWAY	There is trauma to the face or head, or burns to this area, but the patient is conscious and able to speak/cry An overdose of respiratory depressant substance has or may have been taken
A problem producing respiratory distress B: BREATHING	The patient has difficulty in breathing but can speak/cry and there is no cyanosis
Any problem that might, unless rapidly treated, lead to shock or heart failure C: CIRCULATION	The patient has suffered major trauma and is not yet shocked, but may have internal bleeding (they are able to stand or sit up and speak/cry normally) Any burns covering more than 10% of the body The patient has fainted and has abdominal pain (a post-pubertal girl might have a ruptured ectopic pregnancy) but they are able to stand or sit up and speak/cry normally The patient has severe abdominal pain but is not shocked (they are able to stand or sit up and speak/cry normally) The patient is extremely pale but not shocked (severe anaemia) (they are able to stand or sit up and speak/cry normally)
Severe dehydration	The patient has severe diarrhoea/vomiting and is feeling very weak, but is not shocked (they are able to stand or sit up and speak/cry normally); the eyes may be sunken and a prolonged skin retraction time will be present
Infection that might become dangerous	The patient has a high fever > 38°C (they are hot to touch or shivering, but are able to stand or sit up and speak/cry normally)
The child shows evidence of severe malnutrition	Any child with visible severe wasting (especially of the buttocks), and swelling (oedema) of both feet, who is unwell or considered unwell by their parents, but is able to stand or sit up
Any neonate or young infant (less than 2 months old) who is unwell	<b>This indicates a possibility of dangerous sepsis</b>

**Conscious level**

**Category 1 or immediate priority (red) includes all unconscious patients (U or P on the AVPU scale).**

In patients with a history of unconsciousness or fitting, further dangerous events are possible. Those who respond to voice are categorised as **Category 2 urgent (orange)**.

**Pain**

Patients with severe pain should be allocated to **Category 1 immediate (red)**, and those with any lesser degree of pain should be allocated to **Category 2 urgent (orange)**.

For patients who have sustained **significant trauma or other surgical problems**, anaesthetic and surgical help is required **urgently**.

If there is an **urgent referral** from another healthcare facility or organisation, the patient must be seen **immediately** or **urgently**, depending on the circumstances.

**Importance of regular reassessment**

Triage categories may change as the patient deteriorates or gets better. It is important, therefore, that the process of triage (clinical prioritisation) is dynamic rather than static.

To achieve this, all clinicians involved in the pathway of care should rapidly assess priority whenever they encounter the patient. Changes in priority must be noted, and the appropriate actions taken.

All patients with symptoms or signs in the **immediate (red)** or **urgent (orange)** categories represent emergencies or potential emergencies, and need to undergo the structured approach to emergencies as outlined in Section 1.1.1.

**Non-urgent cases**

Proceed with assessment and further treatment according to the patient's needs once the immediate and urgent patients have been stabilised.

# 1.11 Structured approach to managing emergencies in pregnancy and childhood

## Approach to emergencies

### Training

Members of the clinical team must know their roles. They will ideally have trained together in:

- clinical situations and their diagnoses and treatments
- drugs and their use, administration and side effects
- emergency equipment and how it functions.

**The ability of a facility to deal with emergencies should be assessed and reinforced by the frequent practice of emergency drills.**

### Initial management

- Stay calm.
- **Do not leave the patient unattended.**
- Have a team leader in charge to avoid confusion.
- **Shout for help.** Ask one person to go for help and another to get emergency equipment and supplies (e.g. oxygen cylinder and emergency kit). Ideally resuscitation equipment and drugs should be available on one dedicated trolley.
- Assess and resuscitate in sequence using the structured approach – **Airway, Breathing, Circulation, Disability (Neurological Status)** (see below).
- If the patient is conscious, ask what happened and what symptoms they have.
- **Constantly reassess the patient**, particularly after any intervention.

## Structured approach to any pregnant woman, infant or child presenting as an emergency

**Approach emergencies using the structured ABCD (Airway, Breathing, Circulation, Disability) approach, which ensures that all patients with a life-threatening or potentially life-threatening problem are identified and managed in an effective and efficient way whatever their diagnosis or pathology.**

The structured approach to the seriously ill patient, which is outlined here, allows the health worker to focus on the appropriate level of diagnosis and treatment during the first hours of care. Primary assessment and resuscitation are concerned with the maintenance of vital functions and the administration of life-saving treatments, whereas secondary assessment and emergency treatment allow more specific urgent therapies to be started.

Secondary assessment and emergency care require a system-by-system approach in order to minimise the risk of significant conditions being missed.

Following cardiac and/or respiratory arrest, the outcome both for pregnant women and for children is poor. Earlier recognition and management of potential respiratory, circulatory or central neurological failure which may progress rapidly to cardiac and/or respiratory arrest will reduce mortality and secondary morbidity. The following

section outlines the physical signs that should be used for the rapid primary assessment, resuscitation, secondary assessment and emergency treatment of pregnant women, and of babies and children.

**Primary assessment and resuscitation** involves sequential assessment and resuscitation of vital functions – Airway, Breathing and Circulation.

If there are no life-threatening signs, the primary assessment can be completed within about 1 minute. If life-threatening signs are identified, resuscitation procedures are required.

If you are working on your own and have been unable to summon help, you must resuscitate Airway before Breathing, and Breathing before Circulation. This is because oxygen cannot be carried around in the blood to the vital organs if the blood is not oxygenated first, and the lungs cannot oxygenate the blood if there is no airway to allow air containing oxygen to enter the lungs.

If assistance is available, one person can deal with Airway, another with Breathing and a third with Circulation, all working simultaneously, but there must be a 'team leader' to take overall control.

During resuscitation, interventions that are either life-saving or designed to prevent the patient reaching a near-death situation are performed (see below). These include such procedures as basic airway opening procedures, suction, oropharyngeal airway insertion, intubation, assisted ventilation, venous cannulation and fluid resuscitation (when safe and appropriate). At the same time, oxygen is provided to all patients with life-threatening Airway, Breathing or Circulatory problems, vital signs are recorded, and essential monitoring is established.

This sequential primary assessment and any necessary resuscitation occur **before** any illness-specific diagnostic assessment or treatment takes place. Once the patient's vital functions are working safely, secondary assessment and emergency treatment can begin.

After each intervention, its effects should be tested by reassessment. Regular reassessments are a key component of the structured approach.

During **secondary assessment**, illness-specific pathophysiology is sought and emergency treatments are instituted. Before embarking on this phase, it is important that the resuscitative measures are fully under way. During the secondary assessment, vital signs should be checked frequently to detect any change in the patient's condition. If there is deterioration, primary assessment and resuscitation should be repeated in the 'Airway, Breathing, Circulation' sequence.

### Primary assessment and resuscitation

**Assessment and resuscitation occur at the same time.** The order of assessment and resuscitation enables identification of immediately life-threatening problems, which are treated as they are found.

A rapid examination of vital ABC functions is required. **If at any stage a life-threatening A, B, or C problem is identified: CALL FOR HELP.**

After ABC, always assess for neurological problems, and resuscitate their components (sometimes referred to as 'D' for disability of the ABC approach).

### Primary assessment and resuscitation of airway

**The first priority is establishment or maintenance of airway opening. If there is a need for resuscitation in a patient who is bleeding (e.g. in cases of massive postpartum haemorrhage or trauma), try to stop this at the same time as you are opening the airway.**

#### PRIMARY ASSESSMENT

LOOK – for chest or abdominal movement.

LISTEN – for breath sounds.

FEEL – for breath.

Talk to the patient.

A patient who can speak or cry has a clear airway.

Signs associated with airway obstruction may include any of the following:

- an absence of breathing
- stridor, snoring, or gurgling in the throat
- cyanosis
- chest wall recession
- agitation, reduced consciousness, or coma.

Be alert for foreign bodies (see Section 1.12 on choking).

**Airway obstruction is most commonly due to obstruction by the tongue in an unconscious patient.**

### Resuscitation

**Open the airway and keep it open.**

If there is no evidence of air movement, open the airway using the following:

- a head tilt, chin lift or jaw thrust manoeuvre (see Section 1.12 on basic life support). If this opens the airway and breathing starts, keep the airway open manually until it can be secured. Be careful when using head tilt if the cervical spine is at risk, but **opening the airway is always the priority**
- suction/removal of blood, vomit or a foreign body.

If there is no improvement after adjusting the airway manually and trying different techniques, place **an oropharyngeal airway**, which may be helpful **if the patient is unconscious and has no gag reflex**. Avoid using a nasopharyngeal airway if there is any suspicion of base of skull injury.

If the airway is still obstructed, a definitive airway by intubation or surgical airway may be needed.

**Give oxygen to all patients.**

**Be careful not to distress young children with partial upper airway obstruction due to infections such as epiglottitis and severe croup, as this may precipitate acute worsening of their airway obstruction. Having a parent or other known adult present will help to keep the child calm.**

### Identify the 'at-risk' airway

Reassess the airway after any airway-opening manoeuvres. If there continues to be no evidence of air movement, then airway opening can be assessed by performing an airway-opening manoeuvre while giving rescue breaths. Proceed to Breathing (see below).

### Advanced airway management

Advanced airway management techniques for securing the airway by **intubation** may be required in patients with any of the following:

- persistent airway obstruction
- altered level of consciousness, with failure to protect the airway, especially from vomiting
- facial trauma, including burns, penetrating neck trauma with expanding haematoma, and severe head injury (see Section 7).

This should be performed by skilled professionals such as an anaesthetist (if available) (see Section 1.24 for details). The following sequence should be followed:

- 1 pre-oxygenation with 100% oxygen with manual lung inflation if required
- 2 administration of a carefully judged, reduced dose of an anaesthetic induction agent
- 3 application of cricoid pressure
- 4 suxamethonium 1–2 mg/kg
- 5 intubation with a correctly sized tracheal tube.

### Confirmation of correct placement of the tube

Signs such as chest movement and auscultation remain helpful, but are occasionally misleading, especially in inexperienced hands. The most important point is to see the tube pass through the vocal cords. The correct size is a tube that can be placed easily through the cords with only a small leak. Intubation of the right main bronchus is best avoided by carefully placing the tube only 2–3 cm below the cords and noting the length at the teeth before checking by auscultation (best in the left and right lower axillae). Capnography, if available, is a useful adjunct for helping to confirm correct tube placement.

If it is not possible to provide an airway using intubation, a **surgical airway** may be required.

**NOTE: It is extremely risky to proceed to Circulation (and IV/IO cannulation) when partial upper airway obstruction is present in young children (e.g. due to epiglottitis, severe croup or a foreign body), as invasive procedures can precipitate complete airway closure. Stabilise the airway first. This will require help from an anaesthetist.**

### Emergency treatment situations

- 1 For **severe croup**, nebulised adrenaline can be helpful (5 mL of 1 in 1000). Always give oral steroid as soon as possible (150 micrograms/kg of dexamethasone or 1 mg/kg of prednisolone).
- 2 For upper airway obstruction due to **anaphylaxis**, nebulised adrenaline (5 mL of 1 in 1000) and IM adrenaline (1 mg IM in pregnancy and 10 micrograms/kg in children).
- 3 **Inhaled foreign body** (see Section 1.12).
- 4 For **severe bronchiolitis**, clear the nasal airways by using gentle suction.

**If the patient has major trauma or postpartum haemorrhage and is obviously bleeding rapidly, to the point of exsanguination (see Section 7.3.A), measures to stop the exsanguination must be instituted at the same time as Airway resuscitation.**

Throughout primary assessment and resuscitation, protect the cervical spine with a collar, sand bags and tape if the patient is likely to have an unstable cervical spine and if subsequent surgical stabilisation is possible (see Section 7.3.A.).

### Primary assessment and resuscitation of breathing

An open airway does not guarantee adequate ventilation. The latter requires an intact respiratory centre and adequate pulmonary function augmented by coordinated movement of the diaphragm and chest wall.

#### Primary assessment

Assess whether breathing is adequate by:

- assessing **effort**:
  - recession
  - rate
  - added noises
  - accessory muscles
  - alar flaring
- assessing **efficacy**:
  - listening for reduced or absent **breath sounds**, or any wheezing, with a stethoscope or ear on chest wall
  - **chest and/or abdominal expansion** (symmetrical or asymmetrical)
  - abdominal excursion
  - SaO<sub>2</sub> if available
- assessing effects on **heart rate**
- assessing effects on **skin colour** (check the possibility of cyanosis)
- assessing effects on **mental status**.

#### Evidence of life-threatening respiratory difficulty

This includes the following:

- 1 absence of breathing (apnoea)
- 2 very high or very low respiratory rates
- 3 gasping, which is a sign of severe hypoxaemia, and may indicate impending respiratory arrest and death
- 4 severe chest wall recession, usually with increased respiratory rate, but pre-terminally with a fall in rate
- 5 severe hypoxaemia (cyanosis)
- 6 signs of tension pneumothorax (respiratory distress with hyper-resonant percussion) (see Section 7.3.A)
- 7 major trauma to the chest (e.g. tension pneumothorax, haemothorax, flail chest) (see Section 7.3.A)
- 8 signs of severe asthma (severe respiratory distress with wheezing, but a silent chest in severe asthma can be a near-fatal situation).

#### Evidence of respiratory difficulty which can progress if not treated

This includes the following:

- 1 increased respiratory rate
- 2 inspiratory stridor
- 3 reduced or absent breath sounds on auscultation
- 4 expiratory wheezing
- 5 chest expansion (most important), and reduced abdominal excursion

- 6 pulse oximetry showing oxygen saturation (SaO<sub>2</sub>) of less than 94% (normal SaO<sub>2</sub> in a patient at sea level is 94–100% in air).

**Fast breathing** is caused by either an airway problem, lung disease or metabolic acidosis.

**TABLE 1.11.1** Respiratory rates 'at rest' for different age groups

Age (years)	Respiratory rate (breaths/minute)
< 1	30–40
1–2	25–35
2–5	25–30
5–12	20–25
> 12	15–20
In pregnancy	15–20*

\* In pregnancy, respiratory rate does not change although tidal volume increases resulting in approximately 50% increase in minute ventilation.

The WHO suggests a breathing rate of 30 per minute or more in pregnancy as evidence of shock.

Care should be taken when interpreting single measurements. Infants can show rates of between 30 and 90 breaths/minute depending on their state of activity. It is more useful to use trends in measurements as an indicator of improvement or deterioration.

WHO definitions of fast breathing in young children are as follows:

- < 2 months: ≥ 60 breaths/minute
- 2–12 months: ≥ 50 breaths/minute
- 12 months to 5 years: ≥ 40 breaths/minute

Slow breathing rates may result from fatigue or raised intracranial pressure, or may immediately precede a respiratory arrest due to severe hypoxaemia.

#### Other signs of breathing difficulty

##### Chest wall recession

- Intercostal, subcostal or sternal recession reflects increased effort of breathing, which is seen in particular in infants, who have more compliant chest walls.
- The degree of recession indicates the severity of respiratory difficulty.
- In the patient with exhaustion, chest movement and recession will decrease.

##### Inspiratory or expiratory noises

- Stridor, usually inspiratory, indicates laryngeal or tracheal obstruction.
- Wheeze, predominantly expiratory, indicates lower airway obstruction.
- Volume of noise is not an indicator of severity.

##### Grunting

- This is observed in infants and children with stiff lungs to prevent airway collapse (it represents the noise made by closure of the larynx during expiration, which is the body's attempt to increase lung volume).
- It is a sign of severe respiratory distress.

**Accessory muscle use**

- In infants, the use of the sternocleidomastoid muscle creates 'head bobbing' and does not help ventilation.
- Flaring of the alae nasi is also seen in infants with respiratory distress.

**Exceptions**

**Increased effort of breathing does not occur in three circumstances:**

- 1 exhaustion
- 2 central respiratory depression (e.g. from raised intracranial pressure, poisoning or encephalopathy)
- 3 neuromuscular disease (e.g. poliomyelitis).

**Effects of breathing failure on other physiology**

**Heart rate: this is increased with hypoxia, but decreases when hypoxia is severe, when bradycardia is a sign of impending cardiorespiratory arrest.**

**Skin colour: hypoxia first causes vasoconstriction and pallor. Cyanosis is a late sign and may indicate impending cardiorespiratory arrest. In an anaemic patient it may never be seen, however hypoxic the patient is.**

**Mental status: hypoxia causes initial agitation, then drowsiness, followed by loss of consciousness.**

**Resuscitation of breathing**

**In the patient with absent or inadequate breathing, it is essential to breathe for the patient using:**

- mouth-to-mouth or mouth-to-mouth-and-nose ventilation, or
- bag-valve-mask ventilation: if using oxygen, add a reservoir to increase the oxygen concentration.

**Intubate (if skilled professionals are available) and provide assisted ventilation through the tube if long-term ventilation is needed or bag-mask ventilation is ineffective.**

**However, do not persist with intubation attempts without ventilating the patient intermittently with a bag and mask as necessary to prevent hypoxaemia during the intubation process.**

**Give high-flow oxygen to all patients with respiratory difficulty.**

**Give as much oxygen as possible through a mask with a reservoir bag to any patient who is breathing but has respiratory difficulty or the other signs of hypoxia (e.g. cyanosis).**

**Situations in which emergency treatment is given**

- 1 Perform **needle thoracocentesis** if the diagnosis is tension pneumothorax (see Figure 8.3.1). This should be followed by a chest drain.
- 2 Consider inserting a chest drain if there is major trauma to the chest (see Figure 8.3.2).
- 3 Give **nebulised salbutamol** if the patient has severe, life-threatening asthma (2.5 mg for children < 5 years of age, or 5 mg for children > 5 years of age and pregnant mothers). If a nebuliser is not available, use a spacer and

metered-dose inhaler (100 micrograms/puff; 10 puffs initially for all age groups).

- 4 Give **nasal continuous positive airway pressure (CPAP)** if a neonate has severe respiratory distress (see Section 8.3).
- 5 Give **IM adrenaline** (1 mg in pregnancy and 10 micrograms/kg in children) and **nebulised salbutamol** (see above) if wheezing is due to anaphylaxis.
- 6 Give **anticoagulant** (IV unfractionated heparin) if pulmonary embolus is diagnosed in pregnancy or post delivery (see Section 2.5.H).
- 7 Give **calcium gluconate** (10 mL 10% IV over 10 minutes) if respiratory arrest is due to magnesium toxicity in a patient treated for eclampsia with magnesium sulphate.

**Primary assessment and resuscitation of circulation****Primary assessment**

The circulatory system is more difficult to assess than airway and breathing, and individual measurements must not be over-interpreted.

If there is no palpable pulse, a very slow heart rate (< 60 beats/minute in an infant, or < 40 beats/minute in a child or pregnant woman) or no 'signs of life' (e.g. movements, coughing, normal breathing), cardiac arrest or near-cardiac arrest is likely, and basic life support must be started (see Section 1.12).

Agonal gasps (irregular, infrequent breaths) do not provide adequate oxygenation and are not for these purposes a 'sign of life'.

In addition to cardiac arrest or near-arrest, shock and heart failure are additional life-threatening issues that it is important to identify.

**Shock**

The following clinical signs can help to identify shock (inadequate circulation) (see Sections 2.5.A and 5.5.A).

**TABLE 1.11.2 Heart rates 'at rest' at different ages**

Age (years)	Heart rate (beats/minute)
< 1	110–160
1–2	100–150
2–5	95–140
5–12	80–120
> 12	60–100
Pregnancy	70–115*

\* The heart rate in pregnancy increases by 10–15 beats per minute.

**Heart rate**

- Heart rate increases in shock and heart failure.
- Severe bradycardia due to hypoxaemia may be a sign of near cardiorespiratory arrest.

The **WHO definition of tachycardia** is a heart rate of > 160 beats/min in children aged under 1 year, and > 120 beats/minute in those aged 1–5 years.

The WHO defines a heart rate in pregnancy of 110 beats per minute or more as evidence of shock.

**Pulse volume**

Absent peripheral pulses or reduced strength of central pulses can signify shock.

**Capillary refill time (CRT)**

- Pressure on the centre of the sternum or fingernail for 5 seconds should be followed by return of the circulation to the skin within 3 seconds or less. CRT may be prolonged by shock, cold environment, or the vasoconstriction that occurs as a fever develops.
- Prolonged CRT is not a specific or sensitive sign of shock, and should not be used alone as a guide to the need for or the response to treatment.

**Blood pressure**

- The cuff should cover at least 80% of the length of the upper arm, and the bladder should be more than two-thirds of the arm’s circumference. In pregnant mothers, the largest possible cuff should be used to avoid missing a raised blood pressure.
- Korotkoff phase 5 (K5, disappearance of sound) should be used to measure diastolic pressure. Korotkoff phase 5 (K5A, muffling or softening of sound) should only be used if the sound does not disappear until near to zero cuff pressure.
- In pregnancy the patient should ideally be sitting or lying in the lateral tilt positions when pressure is measured. In both of these positions, the cuff must be level with the heart.
- Hypotension is a late sign of circulatory failure in both children and pregnant mothers, and will be rapidly followed by cardiorespiratory arrest unless it is treated urgently.

**TABLE 1.11.3 Systolic and diastolic blood pressure in children**

Age (years)	Systolic blood pressure (mmHg) 5th centile	Systolic blood pressure (mmHg) 50th centile
< 1	65–75	80–90
1–2	70–75	85–95
2–5	70–80	85–100
5–12	80–90	90–110
> 12	90–105	100–120

Blood pressure may be difficult to measure and interpret, especially in infants and children under 5 years of age. The following formula can be used to calculate average systolic blood pressure in children (50th centile):

$$85 + (2 \times \text{age in years})$$

WHO defines normal adult BP as 120/80mmHg. Blood pressure falls early in pregnancy due to a decrease in systemic vascular resistance. It is usually 10mmHg below baseline and reaches a lowest mean value of 105/60mmHg in the second trimester. During the third trimester it gradually returns to the pre-pregnancy level at term.

The normal systolic blood pressure in pregnancy is in the range 95–135mmHg. The normal diastolic blood pressure is in the range 60–85mmHg.

The WHO suggests a systolic BP of < 90mmHg in pregnancy as evidence of shock. A systolic BP < 95mmHg should prompt a search for other possible indicators of developing shock.

The cardiovascular system in children and pregnant mothers compensates well initially in shock.

**Hypotension is a late and often sudden sign of decompensation and, if not reversed, will be rapidly followed by death. Serial measurements of blood pressure should be performed frequently.**

**Effects of circulatory failure on other organs**

**Respiratory system:** tachypnoea and hyperventilation occur as a result of the acidosis caused by poor tissue perfusion.

**Skin:** pale or mottled skin indicates poor perfusion.

**Mental status:** circulatory failure causes initial agitation, then drowsiness, followed by unconsciousness.

**Urine output:** a reduction in urine output to < 2 mL/kg/hour in infants, < 1 mL/kg/hour in children or < 30mL/hour in pregnant mothers indicates inadequate renal perfusion.

**In pregnancy:** fetal compromise can be the first sign of shock in the mother.

The **WHO definition of shock** is cold hands, *plus* CRT of > 3 seconds, *plus* a weak and rapid pulse.

Life-threatening shock is usually associated with:

- severe tachycardia
- a weak-volume pulse (ideally assess centrally: brachial, femoral or carotid)
- low blood pressure (this is a late sign, and very difficult to measure in young children)
- extreme central pallor (if due to severe anaemia)
- raised respiratory rate (due to acidosis)
- poor skin circulation, with a CRT of > 3 seconds
- reduced conscious level.

Remember that anaphylaxis is one cause of shock, and typically there is a relevant history and other signs such as angio-oedema and urticaria.

**Remember that if shock is due to heart failure, fluid overload will be fatal (for information on how to recognise and manage shock caused by heart failure, see Section 2.7.A).**

**Resuscitation in shock**

For cardiac arrest or near arrest, **chest compressions** should be undertaken (for information on basic and advanced life support, see Sections 1.12 and 1.13).

Ensure that there is an open and secure airway.

Give **high-flow oxygen** to any patient who has an inadequate circulation (whether due to shock or to heart failure). This should be administered via a face mask with a reservoir bag (or an endotracheal tube if intubation has been necessary).

Venous or intra-osseous access should be obtained and blood for essential tests taken (haemoglobin, cross-matching, blood clotting factors, and urea and electrolytes if possible).

**Lateral tilt**

**In pregnancy and after 20 weeks’ gestation (whenever the uterus can be palpated abdominally), place the patient in the left lateral tilt position to prevent uterine pressure on the abdominal and pelvic veins stopping blood return to the heart.**

In all patients with shock, lie them flat (or tilted) and **elevate the legs**.

**Fluids in shock**

In most cases of shock, if obvious bleeding is the cause then

the first priority must be to stop this. IV or IO fluids are then required as the immediate resuscitation treatment, once the airway has been opened and secured and oxygen is being given. However, different causes of shock require different approaches to treatment, as described below.

- If loss of fluid causing **hypovolaemia** is the cause of shock: for infants and children give an immediate **IV/IO bolus of 10–20 mL/kg of crystalloid (usually Ringer-lactate or Hartmann’s solution)** as appropriate for weight (see below), provided that heart failure is not present (see above). For pregnant women and girls, give an IV bolus of **500–1000 mL of crystalloid**.

For a child, weight can be estimated on the basis that birth weight doubles by 5 months, triples by 1 year, and quadruples by 2 years.

After 12 months of age, the following formula can be applied, but it needs to be modified according to whether the child is small or large compared with the average:

$$\text{weight (kg)} = 2 \times (\text{age in years} + 4)$$

- If the loss of fluid causing shock is due to **severe gastroenteritis**, there will usually be evidence of severe dehydration and a history of profound or long-standing diarrhoea. Give **20 mL/kg of Ringer-lactate or Hartmann’s solution as an initial IV or IO bolus** as rapidly as possible, reassess, and then repeat if necessary. In cases of cholera, up to 60 mL/kg might be required in children, and 3 litres in pregnant mothers. Additional potassium will usually be required (see Section 5.12.A).
- If the loss of fluid causing shock is due to **bleeding**, which is **one of the commonest causes in pregnancy**, give crystalloid immediately and then try to obtain blood for transfusion as rapidly as possible, ideally fresh blood. Give O-negative blood if this is available.

The concept of **targeted crystalloid fluid resuscitation** is important and requires urgent research into management if the cause of hypovolaemic shock is haemorrhage due to penetrating injury in trauma or to obstetric haemorrhage such as ruptured ectopic pregnancy. Here the initial boluses of IV crystalloids required to treat shock would only be given to keep the vital organs (especially the brain, heart and kidneys) perfused before surgery and/or specific medical treatments to stop the bleeding have started to take effect. Fresh blood is particularly useful to combat the coagulopathy that occurs in major blood loss if specific coagulation components such as platelets are unavailable.

Giving too much IV crystalloid can increase the blood pressure and theoretically increase bleeding by disrupting early clot formation. IV crystalloid also dilutes the red cells (and coagulation factors) in the circulation, but whether or not this could reduce oxygen-carrying capacity requires further research.

We suggest that when giving boluses of crystalloid in **shock due to bleeding (before blood is available and before procedures undertaken to stop haemorrhage are effective)** in patients with penetrating major trauma or obstetric haemorrhage, only the amount needed to maintain the blood pressure at a level sufficient to perfuse the vital organs is given. There is no clear evidence to indicate the precise blood pressure that should be achieved in pregnant women or in children who are in

shock due to haemorrhage. **Adequate perfusion of vital organs may best be indicated by a radial pulse that can be palpated and a conscious level of A or V on the AVPU scale (i.e. the woman or child is either awake or will respond by opening their eyes when spoken to). During pregnancy, the adequacy of the fetal heart rate may also be helpful.**

In children under 2–3 years of age, the radial pulse may be difficult to feel and the presence of a palpable brachial pulse may be the best available indicator at present.

In this situation, therefore, and to maintain a palpable radial pulse in pregnancy, start with IV boluses of 500 mL of crystalloid or ideally blood, and reassess after each bolus.

In children, in order to maintain a radial or brachial pulse give 10 mL/kg IV boluses of crystalloid or ideally blood, and reassess after each bolus.

In situations where there is brisk active blood loss and delay in obtaining blood or effective intervention to halt the bleeding, several boluses of crystalloids may be required. The importance of undertaking measures to halt the bleeding and obtaining blood for transfusion rapidly cannot be overstated.

- If shock is due to **septicaemia with purpura** (meningococcus or dengue), give IV or IO boluses of Ringer-lactate or Hartmann’s or 0.9% saline as fast as possible, 20 mL/kg in children and 1 litre in pregnant mothers, and then reassess. Usually at least 40 mL/kg in children and 2–3 litres in pregnant mothers will be required to overcome shock (see Section 2.5.A). In this situation, **inotropes** may be valuable if they are available and safe to use (see Section 2.5.A).
- If shock is due to **anaphylaxis**, give **adrenaline**, 10 micrograms/kg (0.1 mL/kg of 1 in 10 000) IM in children and 1 mg (1 mL of 1 in 1000) IM in pregnant mothers, in addition to IV or IO fluid.
- If shock is due to **diabetic ketoacidosis**, there will usually be evidence of severe dehydration and coma. Give **10 mL/kg of 0.9% saline (or Ringer-lactate or Hartmann’s solution) as an initial IV bolus** as rapidly as possible, reassess, and then repeat if necessary. Once shock has been initially managed, give fluid more cautiously, as overloading can cause cerebral oedema and death in patients with this condition.
- If shock is due to **severe anaemia**, IV crystalloid boluses such as Ringer-lactate or Hartmann’s solution must be given with extreme care (due to the risk of heart failure). As soon as possible, give blood carefully (10 mL/kg in children and 50 mL in pregnant mothers, over 15 minutes) and then reassess and repeat if it is safe to do so.

Partial exchange transfusion may be helpful in this situation, especially if it is possible to access a large superficial vein in the antecubital fossa. Successively remove 20-mL aliquots of the patient’s blood and replace each 20 mL with 40 mL of packed donor red blood cells until shock has resolved.

### Heart failure

This life-threatening situation can be seen in severe anaemia, after fluid overload, in the presence of structural heart disease and with severe hypertension (usually in pregnancy). It is important to distinguish heart failure from

shock, as the resuscitation required is different. Some of the following signs will be present in heart failure:

- tachycardia out of proportion to respiratory difficulty
- severe palmar pallor (if anaemia is the cause)
- raised jugular venous pressure
- gallop rhythm on auscultation of the heart
- some heart murmurs (if structural heart defect is responsible)
- an enlarged, sometimes tender, liver
- crepitations on listening to the lung bases
- cyanosis that does not respond to oxygen in the case of infants with cyanotic congenital heart disease.

In pregnancy, **severe hypertension** can cause heart failure (check the blood pressure; patients with values above 170/110 mmHg can present with heart failure).

### Resuscitation for heart failure

- 1 **Sit the patient up.**
- 2 Give **oxygen**.
- 3 Give **furosemide** 1–2 mg/kg by IV/IO injection in children and 40 mg IV in pregnant mothers.
- 4 Consider giving **morphine** (50 micrograms/kg in children and 3 mg in pregnant mothers), and reassess. Morphine should be used with caution, especially in patients with altered mental status and impaired respiratory drive.
- 5 If the patient has severe anaemia, consider **exchange transfusion**.

### Situations where emergency treatment is given in heart failure with shock

- 1 **Supraventricular tachycardia (usually in a child)** can cause both shock and heart failure. The heart rate will be > 180 beats/minute, and in infants can reach > 220 beats/minute. If available, ECG will confirm tachycardia. Treat by **vagal manoeuvres**, defibrillation if available, or adenosine if rapid IV access is available (see Section 5.4.C).
- 2 In **ventricular tachycardia**, defibrillation is needed if shock is present (see Section 1.13).
- 3 If **congenital or rheumatic heart disease** or **cardiomyopathy** is the cause of heart failure, inotropes or digoxin may be appropriate, but specialist advice will be needed.
- 4 If cyanotic congenital heart disease in the newborn is the cause of shock, give prostaglandin E<sub>2</sub>, but specialist paediatric advice will be necessary (see Section 5.4.A).

### Primary assessment and resuscitation of neurological failure (disability)

**Always assess and treat Airway, Breathing and Circulation problems before undertaking neurological assessment.**

#### Primary assessment

##### Conscious level: AVPU

**Alert** is the normal state for an awake person. If the patient does not respond to **Voice** (i.e. being spoken to and asked 'Are you all right?'), it is important that assessment of the response to **Pain** is undertaken next. A painful central stimulus can be delivered by sternal pressure, by supra-orbital ridge pressure or by pulling frontal hair. A patient who is **Unresponsive** or who only responds to pain has a significant degree of coma which can seriously interfere with vital Airway and Breathing functions.

#### Fits

Generalised convulsions, also known as 'fits' or 'seizures', can seriously interfere with vital Airway and Breathing functions, both during the fit itself and immediately afterwards, when lowered levels of consciousness may be present.

#### Posture

Many patients who have a serious illness in any system are hypotonic. Stiff posturing, such as that shown by decorticate (flexed arms, extended legs) or decerebrate (extended arms, extended legs) posturing, is a sign of serious brain dysfunction. **These postures can be mistaken for the tonic phase of a convulsion.** Alternatively, a painful stimulus may be necessary to elicit these postures.

Severe extension of the neck due to upper airway obstruction can mimic the opisthotonus that occurs with meningeal irritation. In infants, a stiff neck and full fontanelle are signs that suggest meningitis.

#### Pupils

Many drugs and cerebral lesions have effects on pupil size and reactions. However, the most important pupillary signs to seek are dilatation, unreactivity and inequality, which suggest possible serious brain disorders.

**Always check blood glucose levels or suspect hypoglycaemia in any unwell infant or young child, especially if they have impaired consciousness.**

**Hypoglycaemia with a blood glucose level of less than 2.5 mmol/L (45 mg/dL) can cause impaired consciousness, coma or fits.**

#### Respiratory effects of central neurological failure

The presence of any abnormal respiratory pattern in a patient with coma suggests mid- or hindbrain dysfunction.

#### Circulatory effects of central neurological failure

Systemic hypertension with sinus bradycardia (Cushing's response) indicates compression of the medulla oblongata caused by herniation of the cerebellar tonsils through the foramen magnum. **This is a late and pre-terminal sign.**

Raised intracranial pressure (ICP) may cause:

- hyperventilation
- slow sighing respirations
- apnoea
- hypertension
- bradycardia.

#### Resuscitation

- 1 If the patient is unconscious (P or U on the AVPU scale) but their airway and breathing are adequate, place them in the **recovery position**, so that if they vomit there is less likelihood of aspiration because when unconscious, the gag reflex may not be operative.
- 2 If the patient is unconscious or fitting, **always give oxygen**.
- 3 If **hypoglycaemia** is a cause of reduced consciousness (or a suspected cause, but immediate blood glucose measurements are not possible), treatment with glucose is urgently required. Give 2–5 mL/kg of 10% glucose IV or IO in children (see Section 5.8.B) and 100 mL of 25% glucose IV or IO in pregnant mothers. (Make 100 mL of 25% glucose by adding 50 mL of 50% glucose to 50 mL of Ringer-lactate or Hartmann's solution).

If IV or IO access is not immediately available in a

child, give sublingual sugar, 1 teaspoonful moistened with 1 to 2 drops of water. **Children should be monitored for early swallowing which leads to delayed absorption, and in this case another dose of sugar should be given.** Continue to attempt IV or IO access, as parenteral glucose is a more reliable method of treating hypoglycaemia.

If sublingual sugar is given, repeat the doses at 20-minute intervals.

Recheck the blood glucose level after 20 minutes, and if the level is low ( $< 2.5$  mmol/litre or  $< 45$  mg/dL), repeat the IV/IO glucose (5 mL/kg) or repeat the sublingual sugar.

- 4 If fitting occurs in pregnancy, give **magnesium sulphate** (see Section 2.5.E).
- 5 If fitting occurs in an infant or child and continues in your presence for more than 5 minutes and there is no hypoglycaemia, give **IV or rectal anticonvulsants**. Always make sure that a bag and mask are available in case the patient stops breathing, which is a possibility. Commonly used anticonvulsants in this situation are diazepam or, if there is no IV access, rectal diazepam, rectal paraldehyde or buccal midazolam (see Section 5.16.E).
  - IV or IO diazepam: 250 micrograms/kg IV over 5 minutes
  - rectal diazepam: 500 micrograms/kg
  - rectal paraldehyde: 0.4 mL/kg
  - buccal midazolam: 300 micrograms/kg.
- 6 To gain time in **acutely raised intracranial pressure** (e.g. in cases of head injury), consider the use of **IV mannitol**, 250–500 mg/kg, which will draw fluid out of the brain for a short while, thereby temporarily reducing the ICP. Because the effect of mannitol is only short-lived (a matter of hours), it is used to gain time while definitive care is being set up (e.g. surgical intervention to drain an extradural or subdural haematoma).
- 7 In any case where **meningitis** or **encephalitis** is suspected, it is vital that suitable antibiotics and/or antiviral drugs are started IV or IO as soon as the condition is suspected (see Sections 2.7.E, 3.4, 5.16.B and 5.16.C). Antibiotic choices might include **cefotaxime** or **chloramphenicol**, **penicillin**, **amoxicillin** and **gentamicin** in the newborn. Consider adjunctive treatment with dexamethasone 150 micrograms/kg every 6 hours for 4 days starting before or with the first antibiotic dose. Do not use dexamethasone in cases where there is also septic shock (e.g. in meningococcal disease).

## Secondary assessment and emergency treatments

The secondary assessment takes place once vital functions have been assessed and the initial resuscitation of those vital functions has been started. Primary assessment and resuscitation can usually be undertaken in less than 1 minute if the patient does not have a life-threatening airway, breathing, circulation or neurological problem.

Secondary assessment includes a focused medical history, a focused clinical examination and specific investigations. It differs from a standard medical history and examination in that it is designed to establish which emergency treatments might benefit the patient. Time is limited, and a focused approach is essential. At the end of secondary assessment, the practitioner should have a

better understanding of the illness or component of injury likely to be affecting the patient, and may have formulated a differential diagnosis. Emergency treatments will be appropriate at this stage – to treat either specific disorders (e.g. asthma) or conditions (e.g. raised intracranial pressure). Emergency treatments will be undertaken at this stage in addition to those given as part of resuscitation/life-saving treatments, in order to manage specific components of serious illnesses or injuries (e.g. steroids for asthma, Caesarean section for antepartum haemorrhage). The establishment of a definite diagnosis is part of definitive care.

**The history often provides the vital clues.** In the case of infants and children, the history is often obtained from an accompanying parent, although a history should be sought from the child if possible. Do not forget to ask any health worker who has seen the patient about the initial condition and about treatments and the response to treatments that have already been given.

Some patients will present with an **acute exacerbation/complication of a known condition**, such as pregnancy, asthma or epilepsy. Such information is helpful in focusing attention on the appropriate system, but the practitioner should be wary of dismissing new pathologies in such patients. The structured approach avoids this problem. Unlike trauma (see Section 7), illness affects systems rather than anatomical areas. The secondary assessment must reflect this, and the history of the complaint should be sought with special attention to the presenting system or systems involved. After the presenting system has been dealt with, all of the other systems should be assessed and any additional emergency treatments commenced as appropriate.

The secondary assessment is not intended to complete the diagnostic process, but rather it aims to identify any problems that require emergency treatment.

An outline of a structured approach in the first hour of emergency management is given below. It is not exhaustive, but addresses the majority of emergency conditions that are amenable to specific emergency treatments in this time period.

The symptoms, signs and treatments relevant to each emergency condition are elaborated further in the relevant sections of the textbook.

## Secondary assessment of airway and breathing

TABLE 1.11.4 Airway and breathing: signs and symptoms

Common symptoms	Clinical signs	Emergency investigations
Breathlessness	Bubbly noises in throat	Oxygen saturation
Coryza	Cyanosis	Blood culture
Tachypnoea	Recession	(if infection is suspected)
Choking	Noisy breathing	Chest X-ray
Cough	– stridor	(selective)
Abdominal pain	Droping and inability to drink	
Chest pain	Wheeze	
Apnoea	Tracheal shift	
Feeding difficulties	Abnormal percussion note	

(continued)

Common symptoms	Clinical signs	Emergency investigations
Hoarseness Chest pain	Creptitations on auscultation Acidotic breathing Grunting	ECG (if pulmonary embolus is suspected) (selected and if available)

### Examples of emergency treatment for airway and breathing

- If in a young child there is a harsh stridor associated with a barking cough and severe respiratory distress, upper airway obstruction due to **severe croup** should be suspected. **Nebulised adrenaline** will already have been given as resuscitation, but now give **oral prednisolone** as emergency treatment (see Section 5.1.A).
- If there is a quiet stridor and drooling in a sick-looking child, consider **epiglottitis** or **bacterial tracheitis**. **Intubation** is likely to be urgently required, preferably by an anaesthetist, and is initial resuscitation if the airway is completely closed. Do not put the airway at risk by performing unpleasant or frightening interventions. **Give intravenous antibiotics as emergency treatment, but only after the airway has been secured** (see Section 5.1.A). A surgical airway may also be needed as emergency treatment or as resuscitation if intubation is not possible, so contact a surgeon.
- With a sudden onset and significant history of inhalation, consider a laryngeal foreign body. If the 'choking' protocol has been unsuccessful, the patient may require laryngoscopy (see Section 1.12). Do not put the airway at risk by performing unpleasant or frightening interventions, but contact an anaesthetist/ENT surgeon urgently. However, in extreme, life-threatening cases, immediate direct laryngoscopy as part of resuscitation to remove a visible foreign body with Magill's forceps may be necessary.
- Stridor following ingestion or injection of a known allergen suggests **anaphylaxis** (see Section 5.1.B). Patients in whom this is likely should have received IM and nebulised adrenaline (**10 micrograms/kg for a child and 1 mg for an adult**) as resuscitation treatment. IV or oral **steroids** would then be part of emergency treatment.
- Patients with a history of asthma or with wheeze, significant respiratory distress and/or hypoxia should receive inhaled salbutamol and oxygen as resuscitation, but then need **oral steroids and further inhaled bronchodilators** as emergency treatment (see Section 5.2.B).
- Infants with wheeze and respiratory distress are likely to have bronchiolitis, and require oxygen, as well as clearing of nasal secretions as resuscitation, and **IV or NG fluids** as emergency treatment (see Section 5.2.A).
- In acidotic breathing, measure blood glucose levels to confirm diabetic ketoacidosis. A bolus of IV Ringer-lactate or Hartmann's solution will already have been given as resuscitation for any shock due to dehydration, and **insulin** can now be given as emergency treatment (see Section 5.8.A).
- In clinically suspected pulmonary embolus in pregnancy, IV **unfractionated heparin** should be given as resuscitation, and subcutaneous **low-molecular-weight heparin** should be given as emergency treatment (see Section 2.5.H).

## Secondary assessment of circulation

TABLE 1.11.5 Circulation: signs and symptoms

Common symptoms	Signs	Emergency investigations
Haemorrhage	Tachycardia or bradycardia	Oxygen saturation
Breathlessness	Abnormal pulse volume or rhythm	Blood culture (if infection is suspected)
Palpitations	Abnormal skin perfusion or colour	Chest X-ray (selective)
Feeding difficulties	Haemorrhage or hidden haemorrhage	ECG (selective and if available)
Abdominal pain	Severe malnutrition	Haemoglobin
Chest pain	Fever	Urea and electrolytes (if available)
Apnoea	Hypotension or hypertension	Clotting studies (if available)
Feeding difficulties	Cyanosis	Malarial parasites
Hoarseness	Pallor	
Drowsiness	Enlarged liver	
	Lung creptitations	
	Reduced urine output	
	Cardiac murmur	
	Peripheral oedema	
	Raised jugular venous pressure	
	Gallop rhythm on auscultation of the heart	
	Dehydration	
	Purpuric rash	

### Examples of emergency treatment for circulation

- Further IV/IO **boluses of fluid** should be considered in shocked patients with hypovolaemia from gastroenteritis or with sepsis who have not shown a sustained improvement in response to the first bolus given at resuscitation (see Sections 2.5.A, 5.5.B and 5.5.C).
- However, in trauma, if there is uncontrolled internal bleeding, **early surgical intervention** has priority, and too much IV fluid may be harmful. **Continued blood transfusion** is an emergency treatment after the initial resuscitation (see Section 7.3.A).
- Consider **inotropes, intubation and central venous pressure monitoring**, if available, as emergency treatment for shock (see Section 2.5.A).
- Consider **IV broad-spectrum antibiotics** as emergency treatment for shock in patients with no obvious fluid loss, as sepsis is likely. Antibiotics are essential if purpura is present, as a diagnosis of meningococcal infection is likely (see Section 6.1.G).
- If a patient has a cardiac arrhythmia, the appropriate protocol should be followed after initial resuscitation (see Section 5.4.C).
- If anaphylaxis is suspected, IM adrenaline 10 micrograms/kg in children, or 1 mg in pregnant mothers, in addition to fluid boluses, should be given as resuscitation treatment, and **steroids and antihistamines** should be given as emergency treatment (see Sections 5.1.B and 2.7.C).
- Targeted treatment is needed for obstetric emergencies

that are known to cause shock. These include sepsis (for which **antibiotics** are needed), and antepartum or postpartum haemorrhage (for which specific treatment including **medication** and **urgent surgery** is needed together with **replacement of lost blood** (see Sections 2.5.D.i, iii and iv).

- Surgical advice and interventions for certain gastrointestinal emergencies such as volvulus would constitute emergency treatment. The following symptoms and signs may suggest intra-abdominal emergencies: vomiting, abdominal pain, abdominal tenderness and/or rigidity, lack of bowel sounds, rectal bleeding, abdominal mass (see Section 5.19).

### Secondary assessment of neurological failure (disability)

TABLE 1.11.6 Neurological failure: signs and symptoms

Common symptoms	Signs	Emergency investigations
Headache	Altered conscious level	Blood glucose
Drowsiness	Convulsions	Oxygen saturation
Vomiting	Bradycardia	Blood culture (if infection is suspected)
Behavioural changes	Altered pupil size and reactivity	Haemoglobin
Visual disturbance	Abnormal postures	Urea and electrolytes (if available)
	Meningism	Malarial parasites
	Fever	
	Papilloedema or retinal haemorrhage	
	Altered deep tendon reflexes	
	Hypertension	

### Examples of emergency treatment for neurological failure

- If hypoglycaemia with a blood glucose level of less than 2.5 mmol/L (45 mg/dL) is a possible diagnosis, it will have been treated as part of resuscitation, but the prevention of further hypoglycaemia by IV glucose infusion represents emergency treatment. Remember that there will be a reason for the hypoglycaemia, so further monitoring and treatment are needed until the child is drinking appropriate fluids or has an IV infusion in place through which dextrose can be given.

- If convulsions persist after initial anticonvulsant drugs, treatment with further doses of anticonvulsants (see Sections 2.5.E, 2.7.E and 5.16.E) represents emergency treatment.
- If there is evidence of raised intracranial pressure (i.e. decreased conscious level, abnormal posturing and/or abnormal ocular motor reflexes), the patient should receive oxygen and bag-valve-mask ventilation as resuscitation, if they have apnoea or slow or poor breathing. Emergency treatment could include:
  - nursing with head in-line and 20–30 degrees head-up position (to aid cerebral venous drainage)
  - repeat IV infusion with mannitol 250–500 mg/kg over 15 minutes; however, the treatment becomes less effective with each dose (see Section 7.3.C)
  - in more long-standing raised ICP, caused by tumours in the brain, dexamethasone will help to reduce raised ICP for a few days while specialist neurosurgical intervention is sought, or as palliation (see Section 5.14). The initial dose is 25 mg for patients over 35 kg and 20 mg for patients less than 35 kg, followed by a sliding scale of 4 mg every 3 hours for 3 days, then every 6 hours for 1 day, and continuing to decrease by 1–2 mg per day.
- In patients with a depressed conscious level or convulsions, antibiotics are urgently required, but then consider encephalitis and give acyclovir as appropriate, as emergency treatment (see Sections 2.7.E and 5.16.C).
- In unconscious patients with pinpoint pupils, consider the possibility of opiate poisoning. After supporting breathing if necessary, a trial of naloxone should be given as emergency treatment (see Section 1.15).

### Developmental and family history

Particularly in a small child or infant, knowledge of the child's developmental progress and immunisation status may be useful. The family circumstances may also be helpful, and asking about these may sometimes prompt parents to remember other details of the family's medical history.

### Drugs and allergies

Any medication that the patient is currently taking, or has taken, should be recorded. In addition, if poisoning is a possibility, ask about any medication in the home that a child might have had access to. A history of allergies should be sought.

## 1.12 Basic life support for children and pregnant mothers

### Introduction

Basic life support (BLS) is a technique that can be employed by one or more rescuers to support the respiratory and circulatory functions of a collapsed patient using no or minimum equipment.

### Resuscitation from cardiac arrest in pregnant women and in children

The international guidelines for resuscitation from cardiac arrest (European Resuscitation Council, 2010) detail two approaches to basic life support. One is for adults and the other for children.

The 'adult' programme is predicated on resuscitation from a sudden cardiac event (e.g. ventricular fibrillation from a coronary occlusion) in a patient who was ventilating before the event and therefore has oxygen in their blood. In this group, chest compressions to move the oxygenated blood into the coronary and cerebral arteries are of prime importance, and therefore the rescuer's sequence of actions after assessment starts with chest compressions, not rescue breaths.

The sequence of actions in the 'child' programme is predicated on a hypoxic event (including any respiratory failure or obstruction, or hypoxia at a cellular level as seen in shock). In this type, re-establishing oxygenation is of prime importance, and moving the oxygenated blood to the coronary and cerebral arteries is the second step. Therefore the rescuer's sequence of actions after assessment starts with rescue breaths and then moves on to chest compressions.

The 'child'-type cardiac arrest is seen in almost all children (excluding those rare arrhythmic events in children with congenital or acquired heart disease and those in whom sudden, unexpected collapse is preceded by apparent normal respiratory and circulatory function), and in adults who have a terminal acute illness involving respiratory or circulatory pathology. This includes patients who have had convulsions, trauma (including drowning), poisoning, bleeding, sepsis, etc.

In addition, international guidelines on resuscitation from cardiac arrest agree that, where possible, guidelines should be simplified as there is evidence that complex guidelines cause 'provider paralysis', resulting in no or poor life-saving effort being made.

In view of the above, the Advanced Life Support Group

(ALSG)/Maternal Childhealth Advocacy International (MCAI) programme for resource-limited countries teaches a programme of basic life support for infants, children and pregnant mothers which reflects the known pathologies in these groups (i.e. respiratory and circulatory causes of cardiac arrest) and recognises that the clinicians who provide resuscitation attend patients of all ages.

The sequence taught therefore includes five preliminary rescue breaths and a subsequent ratio of 15:2.

Because of minor differences in technique based on anatomical differences between the groups, children are classified into two groups:

- infants (< 1 year of age)
- children between 1 year of age and puberty.

### Basic life support for infants, children and pregnant mothers (see Figures 1.12.1 and 1.12.2)

#### The initial approach: the three S's

**Safety:** it is essential that the rescuer does not become a second victim. Therefore they should approach the patient with care, and remove the patient from any continuing source of danger if necessary.

**Stimulate:** ask the question 'Are you all right?' in order to establish the state of consciousness of the patient.

**Shout:** this is essential because help will be needed. If more than one rescuer is present, one person should start basic life support. The second person should activate the Emergency Medical Services (EMS) system and then returns to assist in the basic life support effort.

If the patient is an infant or pre-pubertal child, and there

**FIGURE 1.12.1** Algorithm for basic life support in infants and children. CPR, cardiopulmonary resuscitation; VF, ventricular fibrillation; VT, ventricular tachycardia; PEA, pulseless electrical activity.

FIGURE 1.12.2 Algorithm for basic life support in pregnant women.

is only one rescuer and no help has arrived, the rescuer should open the airway, deliver the five rescue breaths and give 1 minute of cardiopulmonary resuscitation (CPR), and then activate the EMS system (if one is available) using a mobile phone if available so as to continue CPR. If a mobile is not available and the patient is a baby, the rescuer will probably be able to carry them to a telephone while continuing CPR.

Similarly, if the patient is a pregnant mother, and there is only one rescuer, they should activate the EMS system, where one is available, if no help has arrived in response to the initial shout for help after opening the airway, delivering the five rescue breaths and giving 1 minute of CPR.

**‘Are you all right?’**

An initial simple assessment of responsiveness consists of asking the patient ‘Are you all right?’ and gently shaking them by the shoulder. Infants may make some noise or open their eyes.

In cases associated with trauma, or possible trauma, the cervical spine should be immobilised during this procedure by placing one hand firmly on the forehead while one of the patient’s shoulders is shaken.

**Airway-opening actions**

An obstructed airway may be the primary problem, and correction of the obstruction can result in recovery without the need for further intervention. If the patient is unconscious but breathing, the recovery position should be used. For pregnant mothers the left lateral position must be adopted (see Section 2.5).

FIGURE 1.12.3 Head tilt with chin lift in neutral position for the infant.

FIGURE 1.12.4 Head tilt with chin lift in ‘sniffing’ position for the child and mother.

If the patient is not breathing, this may be because the airway is blocked by the tongue falling back and obstructing the pharynx. Attempt to open the airway using the **head tilt/chin lift manoeuvre**. The rescuer places their nearest hand on the patient's forehead, and applies pressure to tilt the head back gently. The correct positions are **'neutral' in the infant (0–1 year of age)** (see Figure 1.12.3) or **'sniffing' (nose up in the air) in the child or pregnant mother** (see Figure 1.12.4).

The fingers of the other hand should then be placed under the chin, and the chin of the supine patient should be lifted upwards. As this action may close the patient's mouth, it may be necessary to use the thumb of the same hand to part the lips slightly.

As an alternative to the head tilt/chin lift, the **jaw thrust manoeuvre** can be very effective, but requires more training and experience.

**FIGURE 1.12.5** Jaw thrust to open airway.

Jaw thrust is achieved by placing two or three fingers under the angle of the mandible bilaterally, and lifting the jaw upward (see Figure 1.12.5). This is potentially safer than the head tilt/chin lift if there is a history of major trauma, as the latter manoeuvre may exacerbate a cervical spine injury.

**BUT airway opening is always the most important action which must be achieved, and should always take precedence over concerns about a possible cervical spine injury.**

Patency of the airway should then be assessed by:

- **looking** for adequate chest movements
- **listening** for breath sounds
- **feeling** for breaths.

This is best achieved by the rescuer placing their face above that of the patient, with the ear over the nose, the cheek over the mouth, and the eyes looking along the line of the chest. They should take no longer than 10 seconds to assess breathing.

If there is anything obvious in the mouth and it is easy to reach, remove it.

**Do not perform a blind finger sweep in the mouth.** A blind finger sweep can damage the soft palate, and foreign bodies may be forced further down the airway and become lodged below the vocal cords.

### Breathing actions

If airway-opening techniques do not result in the resumption of adequate breathing within 10 seconds, and a self-inflating bag-mask system is not available, then the rescuer should commence mouth-to-mouth or mouth-to-mouth-and-nose exhaled air resuscitation.

### Definition of adequate breathing

A patient may have very slow or shallow breathing, or take infrequent, noisy, agonal gasps. Do not confuse this with normal breathing.

### Rescue breaths

*If in doubt about the adequacy of breathing, five initial rescue breaths should be given.* While the airway is held open, the rescuer breathes in and seals their mouth around the patient's mouth or mouth and nose (in the case of infants) (see Figures 1.12.6 and 1.12.7). If the mouth alone is used, the nose should be pinched using the thumb and index finger of the hand maintaining head tilt. Slow exhalation, 1–2 seconds, by the rescuer should result in the patient's chest rising. The rescuer should take a further breath him- or herself before the next rescue breath.

**FIGURE 1.12.6** Mouth-to-mouth and nose breaths in neutral position for an infant.

**FIGURE 1.12.7** Mouth-to-mouth breaths with pinched nose in sniffing position for a child or mother.

As children and mothers vary in size, only general guidance can be given regarding the volume and pressure of inflation (see Box 1.12.1).

**BOX 1.12.1 General guidance for exhaled air resuscitation**

- The chest should be seen to rise.
- Slow breaths at the lowest pressure reduce gastric distension.
- Firm gentle pressure on the cricoid cartilage may reduce gastric distension with air.

If the chest does not rise, the airway is not clear. The usual cause is failure to correctly apply the airway-opening techniques discussed earlier. The first step is to readjust the head tilt/chin lift position and try again. If this is not successful, jaw thrust should be tried. If two rescuers are present, one should maintain the airway while the other breathes for the patient.

Failure of both head tilt/chin lift and jaw thrust should lead to suspicion that a foreign body is causing the obstruction (see below).

While performing rescue breaths, the presence of a gag reflex or coughing is a positive sign of life (see below).

**Circulation actions**

Once the initial five breaths have been given successfully, circulation should be assessed and managed.

**Check signs of life and/or pulse (take no more than 10 seconds)**

Even experienced health professionals can find it difficult to be certain that the pulse is absent within 10 seconds, so the absence of 'signs of life' is the best indication for starting chest compressions. 'Signs of life' include movement, coughing, gagging or normal breathing (but not agonal gasps, which are irregular, infrequent breaths). Thus the absence of evidence of normal breathing, coughing or gagging (which may be noticed during rescue breaths) or any spontaneous movement is an indication for chest compressions.

Inadequacy of circulation is also indicated by the absence of a central pulse for up to 10 seconds, but it can be difficult and therefore time wasting to be certain about this – hence the current emphasis on assessing the presence of 'signs of life'.

In babies and young children, if a slow pulse (less than 60 beats/minute) is felt, this is still an indication for chest compressions. In children and pregnant mothers, the carotid pulse in the neck can be palpated. However, infants generally have a short fat neck, so the carotid pulse may be difficult to identify. The brachial artery in the medial aspect of the antecubital fossa or the femoral artery in the groin should be felt in infants. If there are no signs of life and/or a pulse is absent for up to 10 seconds, **start chest compressions**. Compressions should also be started if in an infant or young child there is an inadequate heart rate (less than 60 beats/minute), **but only if this is accompanied by signs of poor perfusion**, which include pallor, lack of responsiveness and poor muscle tone.

Start chest compressions if:

- there are no signs of life *or*
- there is no pulse *or*
- there is a slow pulse (less than 60 beats/minute in an unconscious infant or young child with poor perfusion).

'Unnecessary' chest compressions are almost never damaging. It is important not to waste vital seconds before starting chest compressions after oxygenating the patient with the rescue breaths. If there are signs of life and the pulse is present (and has an adequate rate, with good perfusion), but apnoea persists, exhaled air resuscitation must be continued until spontaneous breathing resumes.

**Chest compressions**

For the best output, the patient must be placed on their back, on a hard surface. The chest should be compressed by a third of its depth. Children vary in size, and the exact nature of the compressions given should reflect this. In general, infants (less than 1 year of age) require a different technique from pre-pubertal children, in whom the method used in adults can be applied with appropriate modifications for their size.

**FIGURE 1.12.8** Two-thumb method for chest compressions in an infant (two rescuers).

**FIGURE 1.12.9** Two-finger method for chest compressions in an infant (one rescuer).

**Position for chest compressions**

Chest compressions should compress the lower half of the sternum.

**Infants:** Infant chest compression can be more effectively achieved using the hand-encircling technique: the infant is held with both the rescuer's hands encircling or

**FIGURE 1.12.10** Chest compressions using one hand in a child.

partially encircling the chest. The thumbs are placed over the lower half of the sternum and compression is carried out as shown in Figure 1.12.8. This method is only possible when there are two rescuers, as the time needed to reposition the airway precludes the use of the technique by a single rescuer if the recommended rates of compression and ventilation are to be achieved. The single rescuer should use the two-finger method as shown in Figure 1.12.9, employing the other hand to maintain the airway position.

**Small children:** Place the heel of one hand over the lower half of the sternum. Lift the fingers to ensure that pressure is not applied over the child's ribs. Position yourself vertically above the child's chest and, with your arm straight, compress the sternum to depress it by approximately one third of the depth of the chest (Figure 1.12.10).

For **larger children or pregnant mothers**, or for small rescuers, compressions may be achieved most easily by using both hands with the fingers interlocked (Figure 1.12.11). The rescuer may choose one or two hands to achieve the desired compression of one third of the depth of the chest.

Once the correct technique has been chosen and the area for compression identified, **15 compressions should be given to 2 ventilations.**

#### Technique for giving chest compressions in larger children and pregnant mothers

- Kneel by the side of the patient, who must be positioned on a firm surface, the uterus having been displaced if appropriate (see below).
- Place the heel of one hand in the centre of the patient's chest.
- Place the heel of your other hand on top of the first hand.
- Interlock the fingers of your hands and ensure that pressure is not applied over the patient's ribs. Do not apply any pressure over the upper abdomen or the bottom end of the bony sternum (breastbone).
- Position yourself vertically above the patient's chest and,

**FIGURE 1.12.11** Chest compressions using two hands in a larger child or mother.

with your arms straight, press down on the sternum to a depth of 5–6 cm.

- After each compression, release all the pressure on the chest without losing contact between your hands and the sternum.
- Repeat at a rate of about 100–120 times a minute (a little less than 2 compressions a second).
- Compression and release should take an equal amount of time.

#### Technique for giving breaths in larger children and pregnant mothers (see Figure 1.12.12)

- After 15 compressions, open the airway again using the head tilt and chin lift (use the jaw thrust if you are experienced and capable of doing it properly and there are two rescuers).
- Pinch the soft part of the patient's nose closed, using the index finger and thumb of your hand on their forehead.
- Allow the patient's mouth to open, but maintain chin lift.
- Take a normal breath and place your lips around the patient's mouth, making sure that you have a good seal. If you have a bag-valve-mask, this can be used instead of mouth-to-mouth basic life support in all age groups.
- Blow steadily into the patient's mouth while watching for their chest to rise; take about 1 second to make their chest rise, as in normal breathing; this is an effective rescue breath.
- Maintaining the head tilt and chin lift, take your mouth away from the patient and watch for their chest to fall as air is exhaled.
- Take another normal breath and blow into the patient's mouth once more to give a total of two effective rescue breaths. Then return your hands without delay to the correct position on the sternum and give a further 15 chest compressions.
- Continue with chest compressions and rescue breaths in a ratio of 15:2.
- Stop to recheck the patient only if they start breathing **normally**; otherwise **do not interrupt resuscitation.**
- If your rescue breaths do not make the chest rise as in normal breathing, then before your next attempt:
  - check the patient's mouth and remove any visible obstruction
  - recheck that there is adequate head tilt and chin lift
  - try the jaw thrust if you are able to do this effectively.

**FIGURE 1.12.12** Giving breaths for a larger child or a mother.

- Do not attempt more than two breaths each time before returning to chest compressions.
- **If there is more than one rescuer present, a different person should take over CPR about every 2 minutes to prevent fatigue. Ensure that there is minimal delay during the changeover between rescuers.**

### **Continuing cardiopulmonary resuscitation**

The compression rate for all age groups is 100–120 compressions per minute. A ratio of 15 compressions to 2 ventilations is maintained irrespective of the number of rescuers. With pauses for ventilation there will be less than 100–120 compressions per minute, although the **rate** is 100–120 per minute. Compressions can be recommenced at the end of inspiration and may augment exhalation.

If no help has arrived, the emergency services must be contacted after 1 minute of cardiopulmonary resuscitation.

**Apart from this interruption to summon help, basic life support must not be interrupted unless the patient moves or takes a breath.**

Effective chest compressions are tiring for the rescuer. Continually check that the compressions and ventilations are satisfactory (they should be performed 'hard and fast') and, if possible, alternate the rescuers involved in this task.

Any time spent readjusting the airway or re-establishing the correct position for compressions will seriously decrease the number of cycles given per minute. This can be a real problem for the solo rescuer, and there is no easy solution. In infants and small children, the free hand can maintain the head position. The correct position for compressions does not need to be measured after each set of ventilations.

The cardiopulmonary resuscitation manoeuvres recommended for infants and children are summarised in Table 1.12.1.

**TABLE 1.12.1** Summary of basic life support techniques in infants and children

	Infants (< 1 year)	Children (1 year to puberty) and pregnant mothers
Airway		
Head-tilt position	Neutral	Sniffing
Breathing		
Initial slow breaths	Five	Five
Circulation		
Pulse check	Brachial or femoral	Carotid
Landmark	Lower half of sternum	Lower half of sternum
Technique	Two fingers or two thumbs	One or two hands
CPR ratio	15:2	15:2

### **Call emergency services (if available)**

If no help has arrived, the emergency services must be contacted after 1 minute of resuscitation has been delivered. A mobile phone can be used or an infant or small child may be carried to a static telephone or to get help while attempts are continued. Apart from any necessary interruption to summon help, basic life support must not be interrupted unless the patient moves or takes a breath, or you are exhausted.

If recovery occurs and signs of life return, place the patient in the recovery position and continue to reassess them and ensure that specialist help arrives.

### **Special circulation actions in the pregnant mother (see Figures 1.12.13 and 1.12.14)**

Place the patient on a hard surface in the left lateral tilt position to overcome vena caval compression. This can be achieved with a wedge placed under the right hip to displace the gravid uterus to the left, or it is possible to

improvise with a pillow or coat. If an assistant is available, they can displace the uterus to the left side of the vena cava. Effective chest compressions can be accomplished at a 15–30-degree tilt to the left, but displacement of the uterus is the more effective method.

Chest-compression-only CPR.

- If you either unable or unwilling to give rescue breaths, give chest compressions only. This is particularly relevant in countries where there is a high prevalence of HIV, hepatitis or TB (see below).
- If chest compressions only are given, these should be continuous at a rate of 100 compressions per minute.
- Stop to recheck the patient only if they start to breathe **normally**; otherwise do not interrupt resuscitation.

Continue resuscitation until:

- qualified help arrives and takes over or
- the patient starts breathing normally or
- you become exhausted.

**FIGURE 1.12.13** The supine hypotensive syndrome. On the left the mother is lying on her back, her uterus is occluding her inferior vena cava. On the right the mother is lying in a lateral position (the recovery position here) and the inferior vena cava is no longer compressed.

**FIGURE 1.12.14** Displacing the gravid uterus manually.

### Basic life support and infection risk

Few cases have been reported. The most serious concerns are meningococcus and TB. In the case of meningococcus, rescuers involved in the resuscitation of the airway in such patients should take standard prophylactic antibiotics.

There have been no reported cases of transmission of either hepatitis B or human immunodeficiency virus (HIV) through mouth-to-mouth ventilation. Blood-to-blood contact is the single most important route of transmission of these viruses, and in non-trauma resuscitation the risks are negligible. Sputum, saliva, sweat, tears, urine and vomit are low-risk fluids. Precautions should be taken, if possible, in cases where there might be contact with blood, semen, vaginal secretions, cerebrospinal fluid, pleural and peritoneal fluids, or amniotic fluid. Precautions are also recommended if any bodily secretion contains visible blood. Devices that prevent direct contact between the rescuer and the patient (such as resuscitation masks)

can be used to lower the risk. Gauze swabs or any other porous material placed over the patient's mouth is of no benefit in this regard.

Infection rates vary from country to country, and rescuers must be aware of the local risk. In countries where HIV/AIDS is more prevalent, the risk to the rescuer will be greater.

**If available, bag-valve-mask ventilation is preferable to mouth-to-mouth ventilation.**

### The recovery position

The patient should be placed in a stable, lateral position that ensures maintenance of an open airway with free drainage of fluid from the mouth, ability to monitor and gain access to the patient, security of the cervical spine and attention to pressure points (see Figure 1.12.15). The Resuscitation Council (UK) recommends the following sequence of actions when placing a patient in the recovery position:

- Remove the patient's spectacles (if present).
- Kneel beside the patient and make sure that both of their legs are straight.
- Place the arm nearest to you out at right angles to their body, elbow bent with the hand palm uppermost.
- Bring the far arm across the chest, and hold the back of the hand against the patient's cheek nearest to you.
- With your other hand, grasp the far leg just above the knee and pull it up, keeping the foot on the ground.
- Keeping their hand pressed against their cheek, pull on the far leg to roll the patient towards you on to their side.
- Adjust the upper leg so that both the hip and knee are bent at right angles.
- Tilt the head back to make sure the airway remains open.
- Adjust the hand under the cheek, if necessary, to keep the head tilted.
- Check the patient's breathing regularly.

If the patient has to be kept in the recovery position for **more than 30 minutes**, turn them to the opposite side in order to relieve the pressure on the lower arm.

FIGURE 1.12.15 The semi-prone or recovery position.

### Automatic external defibrillators (AEDs)

The use of the AED is now included in basic life support teaching for adults because early defibrillation is the most effective intervention for the large majority of unpredicted cardiac arrests in adults. As has already been stated, in children and young people and in pregnant and puerperal women, circulatory or respiratory causes of cardiac arrest predominate. However, in certain circumstances, in children and pregnant mothers there may be a primary cardiac cause of cardiac arrest, and the use of an AED may be life-saving.

An algorithm for AED use is shown in Figure 1.12.16. The standard AED can be used in children over the age of 8 years and in adults. For children aged 1–8 years, an AED can be used, but paediatric paddles are essential. An AED cannot currently be used for infants under 1 year old, as the devices are not accurate enough in this age group.

These devices are becoming much more widely available and are relatively inexpensive. They are life-saving in cases where there is a shockable rhythm, and are included in the training for basic rather than advanced life support, as they were designed for community use. If defibrillation is to be successful, it must be performed within 15 minutes of the onset of fibrillation (and the earlier it is performed, the greater the likelihood of success), so for cases of collapse that might produce fibrillation in the community, waiting until arrival at hospital would be too late.

However, AEDs are also now widely used in treatment of hospital cardiac arrests by first responders, and are therefore included here.

### Attach AED pads

Expose the chest and place one adhesive defibrillator pad on the patient's chest to the right of the sternum below the right clavicle, and one in the mid-axillary line, taking care to avoid breast tissue. Keep the axillary electrode vertical to maximise efficiency.

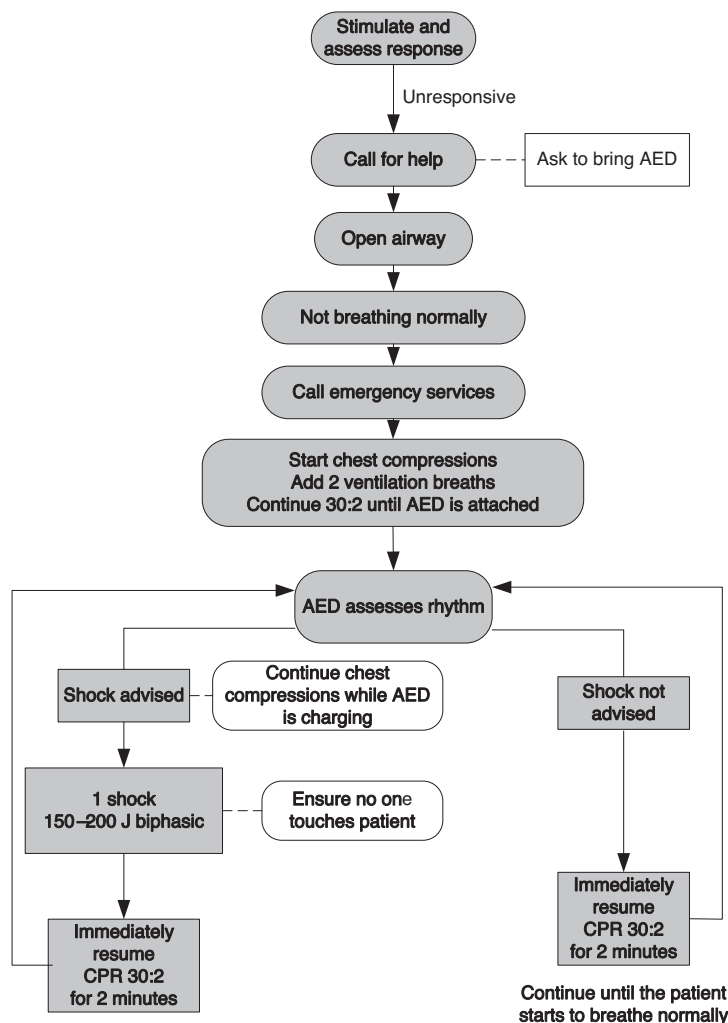

FIGURE 1.12.16 Algorithm for automatic external defibrillator (AED) use.

If a shock is indicated, most AED devices will do this automatically, but some will ask the operator to deliver the shock by pressing a button. Immediately after the shock, resume compressions for 2 minutes, after which there will be a further prompt for a rhythm analysis.

If defibrillation is **not** indicated, CPR should be continued for 2 minutes, at which stage the AED will prompt further analysis of the rhythm.

### Perimortem Caesarean section

The UK Resuscitation Council considers that prompt Caesarean delivery should be seen as part of resuscitation in cardiac arrest in advanced pregnancy. Delivery of the fetus will obviate the effects of aortocaval compression and significantly increase the likelihood of successful resuscitation. It will reduce maternal oxygen consumption, increase venous return, make ventilation easier and allow CPR in the supine position.

#### When to perform it

All the evidence suggests that a Caesarean delivery should begin within 4 minutes of cardiac arrest and be accomplished by 5 minutes. In practice this means that preparations for surgical evacuation of the uterus should begin almost at the same time as CPR following cardiac arrest. Pregnant women develop anoxia faster than non-pregnant women, and can suffer irreversible brain damage within 4–6 minutes of cardiac arrest. CPR should be continued throughout the Caesarean section and afterwards, as this increases the likelihood of a successful neonatal and maternal outcome.

#### Where to perform it

The woman should **not** be transferred to an operating theatre as this will merely waste time. She should be delivered at the site of collapse unless this is physically impossible. Diathermy will not be needed, as blood loss is minimal in patients with no cardiac output. If the mother is successfully resuscitated, she can be moved to theatre to be anaesthetised and to complete the operation.

#### How to perform it

A minimal amount of equipment is required in this situation. Sterile preparation and drapes are unlikely to improve survival. A surgical knife is sufficient.

No one surgical approach in particular is recommended, and the choice of approach should be based on operator preference. The classical midline abdominal approach is aided by the natural diastasis of recti abdomini that occurs in late pregnancy and the relatively bloodless field in this situation. However, many obstetricians are more familiar with a lower transverse abdominal incision and can deliver a baby in less than 1 minute.

Open cardiac massage during surgery is a possibility when the abdomen is already open and the heart can be reached relatively easily through the diaphragm (if a midline approach has been used).

An anaesthetist should attend at the earliest opportunity to provide a protected airway, ensure continuity of effective chest compressions and adequate ventilation breaths, and help to determine and treat any underlying cause (4 Hs and 4 Ts, see Section 1.13).

If resuscitation is successful and the mother regains a

cardiac output, appropriate anaesthesia and pain relief will be required and the woman should be moved to a theatre to complete the operation.

### Fetal outcome

It must be emphasised that Caesarean section is part of resuscitation and is performed to improve maternal survival, and it is worthwhile performing this procedure once the uterus has reached the level of the umbilicus (i.e. around 20 weeks' gestation). If done promptly, it can also improve fetal survival, although gestational age at the time of delivery also clearly influences the fetal outcome. In the UK, the 2006–2008 National Audit Report on maternal mortality (*'Saving Mothers' Lives': The Eighth Report of the Confidential Enquiries into Maternal Deaths in the United Kingdom*) there were no neonatal survivors among those delivered at less than 28 weeks. However, 47% of those delivered at more than 36 weeks did survive; all but one of the cases in this group involved CPR commenced in hospital, demonstrating the advantage of early evacuation of the uterus for the neonate as well as the mother.

Although uterine evacuation is a well-validated step in maternal resuscitation, there is still reluctance among some obstetricians to perform peri-arrest Caesarean section, due to concerns about neonatal neurological damage. However, in a comprehensive review of postmortem Caesarean deliveries between 1900 and 1985 by Katz and colleagues, 70% (42/61) of infants delivered within 5 minutes survived, and all of them developed normally. Only 13% (8/61) of those delivered at 10 minutes and 12% (7/61) of those delivered at 15 minutes survived. One infant in each of the groups of later survivors had neurological damage. Later series confirm the advantage of early delivery for intact fetal survival, although there are a few case reports of intact infant survival more than 20 minutes after maternal cardiac arrest.

The evidence suggests that if the fetus survives the neonatal period, the probability of normal development is high.

### The decision to abandon CPR if it is unsuccessful

CPR should be continued if the rhythm continues as ventricular fibrillation (VF)/ventricular tachycardia (VT). The decision to abandon CPR should only be made after discussion with senior clinicians.

### Medico-legal issues

No doctor has been found liable for performing a postmortem Caesarean section in the UK jurisdiction.

## Choking

### Introduction

The vast majority of deaths from foreign body airway obstruction (FBAO) occur in preschool children. Virtually anything may be inhaled, but foodstuffs predominate. The diagnosis may not be clear-cut, but should be suspected if the onset of respiratory compromise is sudden and associated with coughing, gagging and stridor.

Airway obstruction also occurs with infections such as acute epiglottitis and croup. In these cases, attempts to relieve the obstruction using the methods described below are dangerous. Children with known or suspected infectious causes of obstruction, and those who are still breathing and in whom the cause of obstruction is unclear, should be

taken to hospital urgently. The treatment of these children is dealt with in Section 4.

If a foreign body is easily visible and accessible in the mouth, remove it, but while attempting this take great care not to push it further into the airway. Do not perform blind finger sweeps of the mouth or upper airway, as these may further impact a foreign body and damage tissues without removing the object.

The physical methods of clearing the airway, described below, should therefore only be performed if:

- 1 the diagnosis of FBAO is clear-cut (witnessed or strongly suspected) and ineffective coughing and increasing dyspnoea, loss of consciousness or apnoea have occurred.
- 2 head tilt/chin lift and jaw thrust manoeuvres have failed to open the airway of an apnoeic child.

If the child is coughing, this should be encouraged. A spontaneous cough is more effective in relieving an obstruction than any externally imposed manoeuvre. An effective cough is recognised by the patient's ability to speak or cry and to take a breath between coughs. The child should be continually assessed and not left alone at this stage. No intervention should be made unless the cough becomes ineffective (i.e. quieter or silent), and the patient cannot cry, speak or take a breath, or becomes cyanosed or starts to lose consciousness. Then call for help and start the intervention.

These manoeuvres are then alternated with each other, and with examination of the mouth and attempted breaths as shown in Figure 1.12.17.

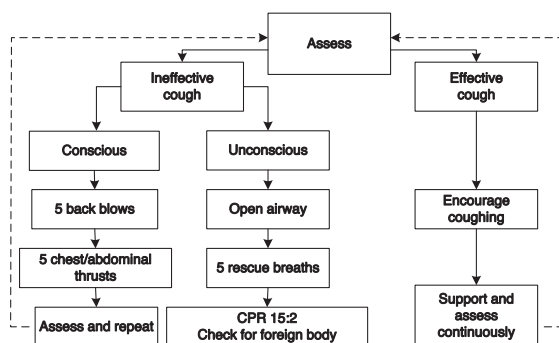

FIGURE 1.12.17 Algorithm for the management of choking.

### Infants

Abdominal thrusts may cause intra-abdominal injury in infants. Therefore a combination of back blows and chest thrusts is recommended for the relief of foreign body obstruction in this age group (see Figures 1.12.18 and 1.12.19).

The baby is placed along one of the rescuer's arms in a head-down position, with the rescuer's hand supporting the infant's jaw in such a way as to keep it open, in the neutral position. The rescuer then rests his or her arm along the thigh, and delivers five back blows with the heel of the free hand.

If the obstruction is not relieved, the baby is turned over and laid along the rescuer's thigh, still in a head-down position. Five chest thrusts are given using the same landmarks as for cardiac compression, but at a rate of one per second. If an infant is too large to allow use of the single-arm technique described above, then the same manoeuvres can be performed by lying the baby across the rescuer's lap.

FIGURE 1.12.18 Back blows in an infant.

FIGURE 1.12.19 Chest thrusts in an infant.

### Children

Back blows can be used as described for infants or, in the case of a larger child, with the child supported in a forward-leaning position (see Figure 1.12.20). In children the abdominal thrust (Heimlich manoeuvre) can also be used (see Figures 1.12.21 and 1.12.22). This can be performed with the patient either standing or lying down, but the former is usually more appropriate.

If this manoeuvre is to be attempted with the child standing, the rescuer moves behind the patient and passes his or her arms around the patient's body. Owing to the short height of children, it may be necessary for an adult to raise the child or kneel behind them to carry out the standing manoeuvre effectively. One hand is formed into a fist and placed against the child's abdomen above the umbilicus and below the xiphisternum. The other hand is placed

over the fist, and both hands are thrust sharply upwards into the abdomen. This procedure is repeated five times unless the object that is causing the obstruction is expelled before then.

To perform the Heimlich manoeuvre in a supine child, the rescuer kneels at the child's feet. If the child is large, it may be necessary to kneel astride him or her. The heel of one hand is placed against the child's abdomen above the umbilicus and below the xiphisternum. The other hand is placed on top of the first, and both hands are thrust sharply upwards into the abdomen, with care being taken to direct the thrust in the midline. This procedure is repeated five times unless the object that is causing the obstruction is expelled before then.

**FIGURE 1.12.20** Back blows in a small child.

Following successful relief of the obstructed airway, the child should be assessed clinically. There may still be some foreign material present in the respiratory tract. If abdominal thrusts have been performed, the child should be assessed for possible abdominal injuries.

Each time breaths are attempted, look in the mouth for the foreign body and remove it if it is visible. Take care not to push the object further down, and avoid damaging the tissues. If the obstruction is relieved the patient may still require either continued ventilations if they are not breathing,

**FIGURE 1.12.21** Heimlich manoeuvre in a standing child.

or chest compressions if there are no signs of a circulation. Advanced life support may also be needed.

**FIGURE 1.12.22** Heimlich manoeuvre using a chair.

If the child is breathing effectively, place them in the recovery position and continue to monitor them.

**Unconscious infant or child with foreign body airway obstruction**

- Call for help.
- Place the child in a supine position on a flat surface.
- Open the mouth and attempt to remove any visible object.
- Open the airway and attempt five rescue breaths, repositioning the airway with each breath if the chest does not rise.
- Start chest compressions even if the rescue breaths were ineffective.
- Continue the sequence for single-rescuer CPR for about 1 minute, then summon help again if none is forthcoming.
- Each time breaths are attempted, look in the mouth for the foreign body and remove it if it is visible. Take care not to push the object further down, and avoid damaging the tissues.
- If the obstruction is relieved, the patient may still require either continued ventilations if they are not breathing but are moving or gagging, or both ventilations and chest compressions if there are no signs of a circulation. Advanced life support may also be needed.
- If the child is breathing effectively, place them in the recovery position and continue to reassess them.

# 1.13 Advanced life support for children and pregnant mothers

## Introduction

As described in Section 1.12 on basic life support, the pregnant mother in cardiac arrest has usually suffered from the same deranged pathophysiology as the arrested child (i.e. respiratory or circulatory collapse rather than a primarily cardiac event).

The 'child' type of cardiac arrest is seen in almost all children (excluding those rare arrhythmic events in children with congenital or acquired heart disease, and those in whom sudden, unexpected collapse is preceded by apparent normal respiratory and circulatory function), and in adults who have a terminal acute illness involving respiratory or circulatory pathology. This includes patients who have had convulsions, trauma (including drowning), poisoning, bleeding, sepsis, etc.

In addition, there is international agreement that, where possible, guidelines on resuscitation of patients with cardiac arrest should be simplified, as there is evidence that complex guidelines cause 'provider paralysis', resulting in no or poor life-saving effort being made.

In view of this, the Advanced Life Support Group (ALSG)/Maternal Childhealth Advocacy International (MCAI) programme for resource-limited countries teaches a programme of basic life support (BLS) and advanced life support (ALS) for infants, children and pregnant mothers which reflects the known pathologies in these groups (i.e. respiratory and circulatory causes of cardiac arrest) and recognises that the clinicians who provide resuscitation attend patients of all ages.

## Airway and breathing

Management of the airway (A) and breathing (B) components of the ABC must take priority in all situations. Resuscitation will fail if effective ventilation does not occur.

Before effective resuscitation techniques can be applied, it is essential that the operator is able to:

- 1 understand the airway equipment available and how to use it
- 2 recognise respiratory failure and when it may occur
- 3 perform a systematic and prioritised approach (the structured ABC approach) to the management of the infant, child or mother who has a problem of the airway or breathing (see Section 1.11).

## Airway: equipment and skills for opening and maintaining the airway

**Essential airway and breathing equipment** includes the following:

- face masks (ideally with reservoirs)
- airways, including laryngeal mask airways (LMAs) if anaesthetic skills are available
- self-inflating bag-valve-mask devices
- tracheal tubes, introducers and connectors
- laryngoscopes

- Magill's forceps
- suction devices
- surgical airway packs for performing an emergency surgical airway.

This equipment should be available in all resuscitation areas, ideally on a resuscitation trolley. It is crucial to gain familiarity with it before an emergency situation occurs.

## Pharyngeal airways

There are two main types of pharyngeal airway, namely **oropharyngeal** (see Figures 1.13.1 and 1.13.2) and **nasopharyngeal**.

**FIGURE 1.13.1** Oropharyngeal airway, showing position when inserted.

**FIGURE 1.13.2** Oropharyngeal airway, showing sizing technique.

## Oropharyngeal airways

The oropharyngeal or Guedel airway is used in the unconscious or obtunded patient to provide an open airway channel between the tongue and the posterior pharyngeal wall.

In the awake patient with an intact gag reflex, it may not be tolerated and may induce vomiting.

The oropharyngeal airway is available in a variety of sizes. A correctly sized airway when placed with its flange at the centre of the incisors, then curved around the face, will reach the angle of the mandible. Too small an airway may be ineffective, and too large an airway may cause laryngospasm. Either may cause mucosal trauma or may worsen airway obstruction. Reassessment following placement is therefore a vital part of safe insertion of an airway device.

There are two methods for inserting an oropharyngeal airway in children, depending on whether the child is small or large. However, there is no specific age of transition from one to the other – the choice of method depends on practicality and the skills of the operator. The important point is not to push the tongue back by inserting the airway carelessly.

The twist technique is used for larger children and in pregnant mothers. With this technique the convex side of the airway is used to depress the tongue as the airway is pushed into the mouth. The airway should be inserted upside down until the tip has passed the soft palate, and then rotated through 180 degrees so that the natural curve of the Guedel airway follows the curve of the tongue and pharynx (see Figure 1.13.3).

**FIGURE 1.13.3** Oropharyngeal airway shown being inserted concave side up, then in place concave side down.

However, in infants and small children, as the tongue is larger relative to the size of the mouth, the airway cannot be rotated in the mouth without causing trauma. Therefore the tongue is depressed with a spatula and not by the convex side of the airway (see Figure 1.13.4).

**FIGURE 1.13.4** When inserting the airway without rotation, a tongue depressor can be helpful (not shown).

### Nasopharyngeal airways

The nasopharyngeal airway is often better tolerated than the Guedel airway. **It is contraindicated in fractures of the base of the skull.** It may also cause significant haemorrhage

from the vascular nasal mucosa if it is not inserted with care, preferably with lubrication. A suitable length can be estimated by measuring from the lateral edge of the nostril to the tragus of the ear. An appropriate diameter is one that just fits into the nostril without causing sustained blanching of the alae nasi. If small-sized nasopharyngeal airways are not available, shortened endotracheal tubes may be used.

**Ensure that insertion of one or other of these devices results in an improvement in the patient's airway and breathing. If it does not improve the airway as shown by improved breathing, then a reappraisal of the choice or size of airway is urgently required.**

In pregnant mothers, the nasopharyngeal tube is not commonly used, because of the tendency for nasal mucosal bleeding to occur in pregnancy.

### Laryngoscopes

There are two principal designs of laryngoscope, namely **straight bladed** and **curved bladed**.

The straight-bladed laryngoscope is usually employed to directly lift the epiglottis, thereby uncovering the vocal folds. The advantage of this approach is that the epiglottis is moved sufficiently so that it does not obscure the cords. The potential disadvantage is that vagal stimulation may cause laryngospasm or bradycardia.

The curved-bladed laryngoscope is designed to move the epiglottis forward by lifting it from in front. The tip of the blade is inserted into the mucosal pocket, known as the vallecula, anterior to the epiglottis, and the epiglottis is then moved forward by pressure in the vallecula. This may be equally effective for obtaining a view of the cords, and it has the advantage that less vagal stimulation ensues, as the mucosa of the vallecula is innervated by the glossopharyngeal nerve instead.

A laryngoscope blade appropriate for the age of the patient should be chosen. It is possible to intubate with a blade that is too long, but not with one that is too short.

Laryngoscopes are notoriously unreliable pieces of equipment which may develop flat batteries and unserviceable bulbs very quickly between uses. Therefore it is vital that a spare is available at all times, and equipment must be regularly checked to ensure that it is in good working order.

### Tracheal tubes

Uncuffed tubes should be used during resuscitation, by operators who do not have paediatric anaesthetic experience, for children up to approximately 10 years of age. If the operator is familiar with cuffed tube placement, both cuffed and uncuffed tubes are acceptable for infants and children undergoing emergency intubation, but not for neonates. Up until the age of around 10 years, the larynx is circular in cross section and the narrowest part of it is at the cricoid ring, rather than the vocal cords. An appropriately sized tube should give a relatively gas-tight fit in the larynx, but the fit should not be so tight that no leak is audible when the bag is compressed. Failure to observe this condition may lead to damage to the mucosa at the level of the cricoid ring, and to subsequent oedema following extubation.

The appropriate size of an uncuffed tracheal tube is estimated as follows:

$$\begin{aligned} \text{internal diameter (mm)} &= (\text{age in years}/4) + 4 \\ \text{length (cm)} &= (\text{age in years}/2) + 12 \text{ for an oral tube} \\ \text{length (cm)} &= (\text{age in years}/2) + 15 \text{ for nasal tube.} \end{aligned}$$

These formulae are appropriate for ages over 1 year. Neonates usually require a tube of internal diameter 3–3.5 mm, although preterm infants may need one of diameter 2.5 mm. Cuffed tubes should not be used in neonates.

For cuffed tracheal tubes, the appropriate internal diameter for children aged 2 years or older is estimated as follows:

$$\text{internal diameter (mm)} = (\text{age in years}/4) + 3.5.$$

For infants of weight over 3 kg and up to 1 year in age a size 3 cuffed tube is usually acceptable, and for those aged 1–2 years a size 3.5 cuffed tube can generally be used.

The size of tracheal tubes is measured in terms of their internal diameter in millimetres. They are available in whole- and half-millimetre sizes. The clinician should select a tube of appropriate size, but also prepare one a size smaller and one a size larger.

In the case of resuscitation in a young child where the lungs are very 'stiff' (e.g. in a cardiac arrest from severe bronchiolitis), a cuffed tube rather than an uncuffed tube may be used by a non-expert, but the risk of airway damage from the cuff must be balanced against the risk of failure to inflate the lungs.

In pregnant mothers, cuffed tubes must be used because of the high risk of gastric reflux in the pregnant patient causing aspiration of acidic gastric material and severe respiratory problems.

#### **Tracheal tube introducers**

Intubation can be facilitated by the use of a stylet or introducer, which is placed through the lumen of the tracheal tube. There are two types – either **soft and flexible** or **firm and malleable**.

The soft and flexible type can be allowed to project beyond the tip of the tube, so long as it is handled very gently. The firm and malleable type is used to alter the shape of the tube, but can easily damage the tissues if allowed to protrude from the end of the tracheal tube. Tracheal tube introducers should not be used to force a tracheal tube into position.

Bougies, which are flexible, deformable, blunt-ended gum elastic rods of different sizes, can be used to help to introduce a tracheal tube when access is difficult. A Seldinger-type technique is used. The bougie is introduced into the trachea using the laryngoscope, the endotracheal tube is then passed over it into the trachea, and finally the bougie is removed.

In pregnant mothers:

- 1 A 15 French bougie should be used for endotracheal tube sizes 6.0–11.0.
- 2 Lubricate the bougie with KY jelly.
- 3 Perform laryngoscopy. If the cords are not visible, identify landmarks to aid intubation.
- 4 Place the bougie into the pharynx and direct it into the larynx. If necessary, bend the bougie to negotiate the corner. Correct placement may be confirmed by detection of tracheal 'clicks' and 'hold-up' of the bougie (the absence of hold-up indicates oesophageal placement).
- 5 Hold the tube firmly in place and gently withdraw the bougie.
- 6 Remove the laryngoscope and confirm tube placement as usual.

#### **Tracheal tube connectors**

In pregnant mothers, the proximal end of the tube connectors is of standard size, based on the 15-mm/22-mm system, which means that they can be connected to a standard self-inflating bag.

The same standard system exists for children, including neonates.

#### **Magill's forceps**

Magill's forceps (see Figure 1.13.5) are angled to allow a view around the forceps when they are in the mouth. They may be useful to help to position a tube through the cords by lifting it anteriorly, or to remove pharyngeal or supraglottic foreign bodies.

**FIGURE 1.13.5** Magill's forceps.

#### **Suction devices**

These are used to remove blood, vomit and secretions from the mouth and throat, usually with a rigid suction tube (Yankauer suction tube; see below). In resuscitation areas, ideally the suction device should be connected to a central vacuum unit. This consists of a suction hose inserted into a wall terminal outlet, a controller (to adjust the vacuum pressure), a reservoir jar, suction tubing and a suitable sucker nozzle or catheter. In order to aspirate vomit effectively, it should be capable of producing a high negative pressure and a high flow rate, although these can be reduced in non-urgent situations, so as not to cause mucosal injury.

Portable suction devices are required for resuscitation when central suction is not available (as is the case in most resource-limited hospitals), and for transport to and from the resuscitation room. These are either manual, mains electrical or battery powered. A manual or battery-operated suction system must be available at all sites where resuscitation may be needed.

**To clear the oropharynx of debris (e.g. vomit), a rigid sucker (e.g. Yankauer sucker) should be used with care not to damage delicate tissue or induce vomiting. The Yankauer sucker is available in both adult and paediatric sizes. It may have a side hole, which can be occluded by a finger, allowing greater control over vacuum pressure.**

#### **Tracheal suction catheters (see Figure 1.13.6)**

These may be required after intubation to remove bronchial secretions or aspirated fluids. In general, the appropriate size in French gauge is numerically twice the internal diameter in millimetres (e.g. for a 3-mm tube the correct suction catheter is a French gauge 6).

FIGURE 1.13.6 Tracheal and oral or nasal suction catheters.

### Advanced airway techniques

Advanced airway techniques are used when the above techniques fail to maintain and protect an airway over the longer term, particularly if there is potential for it to become obstructed and thus prevent accurate control of oxygenation and ventilation. Advanced airway techniques (tracheal intubation, surgical cricothyroidotomy and surgical tracheostomy) are described in Section 8.2.

### Breathing: equipment and skills for helping the patient to breathe

The following equipment for oxygenation and ventilation should be readily available:

- an oxygen source
- masks for those who are spontaneously breathing
- close-fitting face masks (for artificial ventilation)
- self-inflating bag-valve systems to be used with close-fitting face masks
- T-piece and open-ended bag systems (only to be used by those with anaesthetic skills)
- mechanical ventilators
- chest tubes
- gastric tubes.

### Oxygen treatment

#### Indications

Give oxygen to patients:

- with respiratory distress (severe indrawing of the lower chest wall, also known as recessions, raised respiratory rate, gasping, grunting with each breath, nasal flaring, head bobbing, etc.)
- with cyanosis (blueness) that is central (around the lips and tongue, or inside the mouth in children with dark skin)
- who are shocked
- who are fitting
- who are unconscious, with abnormal oxygen saturation ( $\text{SaO}_2$ ) on a pulse oximeter.

Ideally, where the resources for this are available, oxygen therapy should be guided by pulse oximetry (see below). Give oxygen to children with an  $\text{SaO}_2$  of < 94%, and aim to keep  $\text{SaO}_2$  at 94–98% (except at high altitude, where normal oxygen saturation levels are lower). If pulse oximeters are not available, the need for oxygen therapy has to be guided by clinical signs, which are less reliable.

### Provision of oxygen

Oxygen must be available at all times. The two main sources of oxygen are cylinders and oxygen concentrators.

Oxygen cylinders contain compressed gas. A flow meter needs to be fitted to regulate flow. A hissing noise can be heard if gas is being delivered.

Flow meters are used to ascertain how much oxygen is being delivered. Take the reading of flow rate from the middle of the ball. Always switch off the flow when the source is not in use (ensure that the indicator ball is at the bottom of the flow meter and not moving).

**Do not leave anything inflammable near to the oxygen supply. Do not allow smoking near to the oxygen supply.**

At least once a day, check that an adequate oxygen supply is available (use a signed logbook). If a gauge indicating the amount left in the cylinder is not available, switch on the flow and listen for a hissing noise. Replace empty cylinders promptly. Ensure that cylinders are stored and secured in an upright position in suitable containers so that they cannot fall over and cause injury. Cylinder keys to permit changes of regulator should be tied to each cylinder.

Oxygen concentrators may be available. They produce more than 95% oxygen with a flow of 1–8 litres/minute but, unlike cylinders, they require a continuous electricity supply. For this reason, all areas where patients might need oxygen must have both cylinders and concentrators.

There are now small oxygen plants available that can provide oxygen for a defined area or even for the whole of a hospital or health facility. Some of them can be used to fill oxygen cylinders as well, thus providing a constant back-up ([www.ogsi.com](http://www.ogsi.com)).

### Oxygen delivery

A mask with a reservoir bag (see Figure 1.13.7) allows up to 100% oxygen to be delivered. Without a reservoir, it is only possible to deliver around 40% oxygen. If only low flow rates of oxygen are available, do not use a reservoir bag.

If an oxygen mask is being used, ensure that the mask is large enough to cover the mouth and nose. Both low- and high-flow oxygen (with a delivery rate of up to 15 litres/minute) can be given. Hold the mask in place using the

FIGURE 1.13.7 Reservoir bags.

elastic strap around the back of the head or, in the case of a young child, ask the mother to hold it as close as possible to the child's face.

Nasal cannulae (also known as nasal prongs) (see Figure 1.13.8) are the preferred method of delivery in most circumstances, as they are safe, non-invasive, reliable and do **not** obstruct the nasal airway. Head boxes are not recommended, as they use up too much oxygen and deliver a low concentration. Face masks can be used for resuscitation purposes, ideally with a reservoir attached to deliver 100% oxygen.

### Monitoring

Nursing staff must know how to place and secure the nasal cannulae correctly. Check regularly that the equipment is working properly, and remove and clean the cannulae at least twice a day.

Monitor the patient at least every 3 hours to identify and correct any problems, including:

- SaO<sub>2</sub> values measured by pulse oximeter
- nasal cannulae out of position
- leaks in the oxygen delivery system
- incorrect oxygen flow rate
- airway obstructed by mucus (clear the nose with a moist wick or by gentle suction).

### Pulse oximetry

Normal oxygen saturation at sea level in a child is 95–100%. Oxygen is ideally given to maintain oxygen saturation at 94–98%. Different cut-off values might be used at high altitude or if oxygen is scarce. The response to oxygen

**FIGURE 1.13.8** Nasal cannulae delivering oxygen and taped in place.

therapy in lung disease can be measured with the pulse oximeter, as the patient's SaO<sub>2</sub> should increase (in patients with cyanotic heart disease, SaO<sub>2</sub> does not change when oxygen is given). The oxygen flow can be titrated using the pulse oximeter as a monitor to obtain a stable SaO<sub>2</sub> of 94–98% without giving too much oxygen. This is especially important in pre-term babies with respiratory disease (see Section 3.4).

### Assessment of oxygenation at and above sea level

A systematic review in 2009 found an SpO<sub>2</sub> of 90% is the 2.5th centile for a population of healthy children living at an altitude of approximately 2500 m above sea level. This decreases to 85% at an altitude of approximately 3200 m.

**TABLE 1.13.1** SpO<sub>2</sub> levels at different altitudes<sup>a</sup>

Altitude	Location	n	Age	SpO <sub>2</sub> (%)	Author	Year
Sea level	UK	70	2–16 (mean, 8) years	Range, 95.8–100 Median, 99.5	Poets <i>et al.</i>	1993
Sea level	Peru	189	2 months to 5 years	Range, 96–100 Mean, 98.7	Reuland <i>et al.</i>	1991
1610 m	Colorado	150	< 48 hours 3 months	95% CI, 88–97 Mean, 93 95% CI, 86–97 Mean, 92.2	Thilo <i>et al.</i>	1991
1670 m	Nairobi	87	7 days to 3 years	Range, 89.3–99.3 Mean, 95.7	Onyango <i>et al.</i>	1993
2640	Bogota	189	5 days to 2 years	Range, 84–100 Mean, 93.3	Lozano <i>et al.</i>	1992
2800	Colorado	72	3–670 days	Range, 88–97 Mean, 91.7	Nicholas <i>et al.</i>	1993
3100	Colorado	14	6 hours to 4 months 1 week to 4 months	Range, 81–91 Mean, 80.6±5.3 Mean, 86.1±4.6	Niemeyer <i>et al.</i>	1993
3658	Tibet <sup>b</sup>	15	6 hours to 4 months	Immigrant, 76–90 Indigenous, 86–94	Niemeyer <i>et al.</i>	1995
3750	Peru	153	2–60 months	Range, 81–97 Mean, 88.9	Reuland <i>et al.</i>	1991

<sup>a</sup>Values given are those in quiet sleep.

<sup>b</sup>Ranges refer to those born to immigrant Chinese mothers and to those indigenous babies whose families have lived at that altitude for innumerable generations.

**Duration of oxygen therapy**

Continue giving oxygen continuously until the patient is able to maintain an SaO<sub>2</sub> of 94% or higher in room air. When the patient is stable and improving, take them off oxygen for a few minutes. If the SaO<sub>2</sub> remains in the range 94–98%, discontinue oxygen, but check again 30 minutes later, and 3-hourly thereafter on the first day off oxygen to ensure that the patient is stable. Where pulse oximetry is not available, the duration of oxygen therapy has to be guided by clinical signs, which are less sensitive.

**Breathing for the patient**

**Face masks with seal over nose and mouth for positive pressure ventilation (see Figure 1.13.9)**

These face masks are used for either mouth-to-mask or, more commonly, bag–mask ventilation. Masks are available in various sizes, and the appropriate size to cover the mouth and nose should be chosen.

Face masks for mouth-to-mouth or bag-valve-mask ventilation in infants are of two main designs. Some masks conform to the anatomy of the patient’s face and have a low dead space. Circular soft plastic masks give an excellent seal and are often preferred. Children’s masks should be clear so that the child’s colour or the presence of vomit can be seen.

A pocket mask is a single-size clear plastic mask with an air-filled cushion rim designed for mouth-to-mask resuscitation. It can be supplied with a port for attaching it to an oxygen supply, and can be used in adults and children. It can be used upside down to ventilate infants.

**FIGURE 1.13.9** Face masks with cushioned rim for a leak-proof fit, and round shape for infants.

**Self-inflating bags (see Figure 1.13.10)**

This is one of the most important pieces of equipment, allowing hand ventilation by face mask without a supply of gas. The two appropriate sizes are **500 mL** and **1600 mL (the smaller size for infants under 1 year of age, and the larger size for children and mothers)**. There is also a 250-mL version for small premature babies. These bags have pressure-limiting valves that operate at 30–45 cm H<sub>2</sub>O. Test the valve by placing the mask on a surface and pressing the bag and ensuring that the valve opens. It can be overridden if necessary for stiff, poorly compliant lungs by loosening the screw at the top.

The bag connects to the patient through a one-way valve to direct exhaled air to the atmosphere. The other end connects to the oxygen supply and can attach to a reservoir bag which allows high concentrations (up to 98%) of oxygen to be delivered. Without the reservoir bag, only

concentrations of up to 40% can be delivered. The bag itself is easily dismantled and reassembled. It is important to realise that this system **will operate without an attached oxygen supply**, allowing resuscitation to be initiated before oxygen is available. However, if resuscitation is failing, check that oxygen is being delivered into the bag and to the patient and that the oxygen supply has not been disconnected.

**Always use high-flow oxygen (if available) and a reservoir bag during resuscitation apart from at birth where room air is satisfactory for almost all babies (see Section 3.2).**

It is also important to clean the system after each patient.

**FIGURE 1.13.10** Two sizes of self-inflating bags and masks.

It is essential that the mask is properly sized and correctly placed over the mouth and nose of the patient (see Figures 1.13.11 and 1.13.12).

**FIGURE 1.13.11** (a) Correct placement of infant mask. (b), (c) and (d) Incorrect placement of infant mask.

**FIGURE 1.13.12** Two views of single-handed grip on mask.

**FIGURE 1.13.13** Two-handed grip on mask incorporating jaw thrust.

If the chest does not rise, the airway is not clear. The usual cause is failure to correctly apply the airway-opening techniques discussed previously. The first step to try is to readjust the head-tilt/chin-lift position and try again. If this is not successful, the jaw-thrust manoeuvre should be tried (see Figure 1.13.13). Failure of both the head-tilt/chin-lift and jaw-thrust manoeuvres should lead to suspicion that a foreign body is causing the obstruction.

Once breathing has restarted, replace the bag-valve-mask system with a simple face mask and reservoir. Because of the internal valves it is not possible to spontaneously breathe through the bag-valve-mask system.

**Chest tubes**

In cases with a significant haemothorax or pneumothorax (particularly tension pneumothorax), ventilation may be compromised and insertion of a chest drain is mandatory (see Section 8.3).

**Gastric tubes**

Insertion of a gastric tube is essential after intubation, and may also relieve respiratory distress in spontaneously breathing patients with abdominal emergencies or gastric stasis. It allows decompression of a stomach full of air from both bag and mask ventilation as well as air swallowed by a distressed patient. Without a gastric tube, the patient may vomit or there may be aspiration of stomach contents. In addition, venting of stomach gas will avoid diaphragmatic splinting. A nasogastric tube will increase airway resistance through the nose, which in a spontaneously breathing infant with respiratory failure can be significant. An orogastric tube has less effect on ventilation, but is less readily tolerated and less easily fixed in position.

**Further information**

Additional breathing procedures are described in Section 5.2.B (on spacers and nebulisers), Section 8.3

**FIGURE 1.13.14** Initial approach to cardiac arrest. CPR, cardiopulmonary resuscitation; VF, ventricular fibrillation; VT, ventricular tachycardia; PEA, pulseless electrical activity.

(on needle thoracocentesis) and Section 8.3 (on chest drain insertion).

## Circulation: equipment and skills for maintaining the circulation

Details of how to undertake the following procedures are covered in Section 8.4:

- peripheral venous cannulation
- blood sampling from an IV cannula
- intraosseous cannulation and infusion
- cutdown long saphenous venous cannulation
- insertion of central venous catheters
- needle pericardiocentesis.

## Management of cardiac arrest

Cardiac arrest occurs when there is no effective cardiac output. Before any specific therapy is started, effective basic life support must be established (see Figure 1.13.14).

Four cardiac arrest rhythms can occur:

- 1 asystole
- 2 pulseless electrical activity (including electromechanical dissociation)
- 3 ventricular fibrillation
- 4 pulseless ventricular tachycardia.

These are divided into two groups. Asystole and pulseless electrical activity, which do not require defibrillation, are called 'non-shockable' rhythms. Ventricular fibrillation and pulseless ventricular tachycardia, which do require defibrillation, are called 'shockable' rhythms.

### Non-shockable cardiac arrest

#### Asystole

This is the most common cardiac arrest rhythm in infants and children, and in pregnant mothers. The response of the heart to prolonged severe hypoxia and shock (which are the usual pathologies in these groups) is progressive bradycardia leading to asystole.

The ECG will distinguish asystole from ventricular fibrillation, ventricular tachycardia and pulseless electrical activity. The ECG appearance of ventricular asystole is an almost straight line; occasionally P-waves are seen (see Figure 1.13.15). Check that the appearance is not caused by an artefact (e.g. a loose wire or disconnected electrode). Turn up the gain on the ECG monitor.

FIGURE 1.13.15 ECG appearance of asystole.

#### Pulseless electrical activity (PEA)

This is the absence of a palpable pulse or other signs of life despite the presence on the ECG monitor of recognisable complexes that normally produce a pulse (see Figure 1.13.16). PEA is treated in the same way as asystole, and is often a pre-asystolic state.

PEA in children and pregnant mothers is often due to

major trauma, often with an identifiable and reversible cause such as severe hypovolaemia, tension pneumothorax or pericardial tamponade. PEA is also seen in hypothermic patients and in those with electrolyte abnormalities. It may be seen after massive pulmonary thromboembolus.

FIGURE 1.13.16 Pulseless electrical activity (PEA) in a child with no pulse or signs of life.

### Management of asystole/PEA in children and pregnant mothers

**The first essential step is to establish ventilations and chest compressions effectively.** Ensure a patent airway, initially using an airway manoeuvre to open the airway and stabilising it with an airway adjunct. Ventilations are provided initially by bag and mask with high-concentration oxygen.

Provide effective chest compressions at a rate of 100–120 per minute with a compression:ventilation ratio of 15:2. The depth of compression should be at least one-third of the antero-posterior diameter of the chest, and compressions should be given in the middle of the lower half of the sternum. Ideally a cardiac monitor is attached. Properly performed basic life support is key to any chance of successful resuscitation from cardiac arrest. Ensure that the person performing chest compressions is keeping the correct rate and depth of compression, and if possible change operator every 2 to 3 minutes, to avoid fatigue causing poor performance.

If asystole or PEA is identified, give **adrenaline 10 micrograms/kilogram** (0.1 mL of 1:10 000 solution/kg) **intravenously or intra-osseously in children and 1 mg IV in pregnant mothers.** Adrenaline increases coronary artery perfusion, enhances the contractile state of the heart and stimulates spontaneous contractions. The drug is best given through a central line, but if one is not in place it may be given through a peripheral line. Where there is no existing IV access, the IO route is recommended as the route of choice, as it is rapid and effective. In each case, the adrenaline is followed by a normal crystalloid flush (2–5 mL).

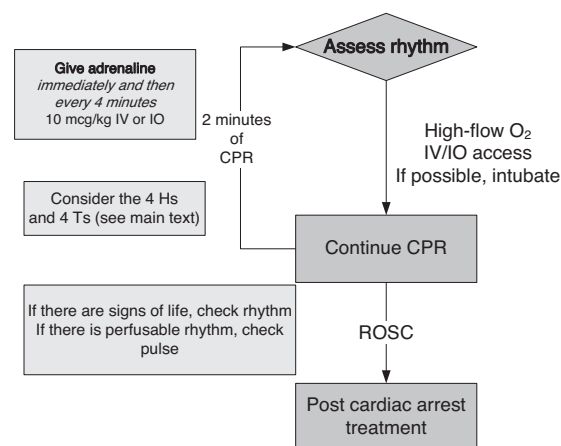

FIGURE 1.13.17 Algorithm for the treatment of non-shockable (asystole and PEA) rhythms in children. Doses of drugs used in pregnancy are given in the text above. CPR, cardiopulmonary resuscitation; IV, intravenous; IO, intra-osseous; ROSC, return of spontaneous circulation.

If available, and as soon as is feasible, a skilled and experienced operator should **intubate the patient's airway**. This will both control and protect the airway and enable chest compressions to be given continuously, thus improving coronary perfusion. Once the patient has been intubated and compressions are uninterrupted, the ventilation rate should be 10–12 breaths per minute. It is important for the team leader to check that the ventilations remain adequate when chest compressions are continuous. An algorithm for non-shockable rhythms is shown in Figure 1.13.17.

During and following adrenaline treatment, chest compressions and ventilation should continue. It is vital that chest compressions and ventilations continue uninterrupted during advanced life support, as they form the basis of the resuscitative effort. The only reason for interrupting compressions and ventilation is to shock the patient if necessary (see below), and to check the rhythm. A brief interruption may be necessary during difficult intubation. Giving chest compressions is tiring for the operator, so if enough personnel are available, change the operator frequently and ensure that they are achieving the recommended rate of 100–120 compressions per minute together with a depression of the chest wall by at least one-third of the antero-posterior diameter of the chest.

At intervals of about 2 minutes during the delivery of chest compressions, pause briefly to assess the rhythm on the monitor. If asystole persists, continue CPR while again checking the electrode position and contact.

- If there is an organised rhythm, check for a pulse and signs of life.
- If there is a return of spontaneous circulation (ROSC), continue post-resuscitation care, increasing the ventilation rate to 12–20 breaths per minute.
- If there is no pulse and no signs of life, continue the protocol.
- Give adrenaline about every 4 minutes at a dose of 10 micrograms/kg IV/IO in children and 1 mg IV in pregnant mothers.

In pregnant mothers, if there is asystole or a slow heart rate (< 60 beats/minute), give atropine 3mg IV just once to counteract any excessive vagal tone.

### Reversible causes of cardiac arrest

The causes of cardiac arrest in childhood and pregnancy are multifactorial, but the two commonest final pathways are through hypoxia and hypovolaemia.

All reversible factors are conveniently remembered as the **4Hs and 4Ts** (see below). Sometimes cardiac arrest is due to an identifiable and reversible cause, such as shock due to massive haemorrhage. In the trauma setting, cardiac arrest may be caused by severe hypovolaemia, tension pneumothorax or pericardial tamponade.

It is often appropriate to give an early IV bolus of Ringer-lactate or Hartmann's solution (10mL/kg in a child and 500mL to 1 litre in a mother, depending on her weight), as this will be supportive in cases related to severe hypovolaemia. In addition, however, a tension pneumothorax and/or pericardial tamponade require definitive treatment. Continuing blood replacement and the prevention of haemorrhage may also be required.

Rapid identification and treatment of reversible causes such as hypovolaemic shock, hypothermia, electrolyte

and acid–base disturbance, tension pneumothorax and pericardial tamponade are vital.

During CPR it is important to continually consider and correct reversible causes of the cardiac arrest based on the history of the event and any clues that are found during resuscitation.

### The 4Hs and 4Ts

- 1 **Hypoxia** is a prime cause of cardiac arrest in childhood, and its reversal is key to successful resuscitation.
- 2 **Hypovolaemia** may be significant in arrests associated with trauma, gastroenteritis, pregnancy-related haemorrhage, anaphylaxis and sepsis. It requires infusion of crystalloid, and in the case of haemorrhage, blood should be given.
- 3 **Hyperkalaemia, hypokalaemia, hypocalcaemia, acidaemia, hypermagnesaemia** (following excess magnesium sulphate in eclampsia) and other metabolic abnormalities may be suggested by the patient's underlying condition (e.g. renal failure, eclampsia), tests taken during the resuscitation or clues from the ECG. Intravenous calcium (0.2mL/kg of 10% calcium gluconate in children and 10mL of 10% calcium gluconate in pregnant mothers) is indicated in cases of magnesium overdose, hyperkalaemia and hypocalcaemia.
- 4 **Hypothermia** is associated with drowning incidents and requires particular care. A low-reading thermometer must be used to detect it (see Section 7.3.E).
- 5 **Tension pneumothorax and cardiac Tamponade** are especially associated with PEA and are often found in trauma cases.
- 6 **Toxic** substances, resulting either from accidental or deliberate overdose or from an iatrogenic mistake, may require specific antidotes.
- 7 **Thromboembolic** phenomena (pulmonary or amniotic fluid) in pregnancy.

### Shockable cardiac arrest

These arrhythmias are less common in children and in pregnant mothers, but either of them may be expected in patients with sudden collapse, hypothermia, poisoning by tricyclic antidepressants, or cardiac disease. The protocol for ventricular fibrillation (VF) (see Figure 1.13.18) and pulseless ventricular tachycardia (pVT) (see Figure 1.13.19) is the same, and is shown in Figure 1.13.20.

A sudden witnessed collapse is also suggestive of a VF/pVT episode.

FIGURE 1.13.18 An episode of ventricular fibrillation.

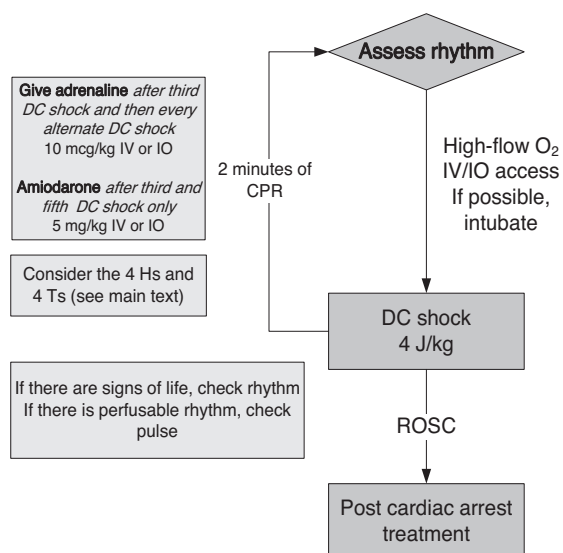

FIGURE 1.13.19 Ventricular tachycardia.

**FIGURE 1.13.20** Algorithm for the treatment of shockable (VF and pVT) rhythms in children. Doses of drugs and size of shock used in pregnancy are given in the text below. CPR, cardiopulmonary resuscitation; IV, intravenous; IO, intra-osseous; ROSC, return of spontaneous circulation.

If the patient is being monitored, the rhythm can be identified before significant deterioration occurs. With immediate identification of VF/pVT, asynchronous electrical defibrillation of 4 joules/kg in children and 200 joules in pregnant mothers should be undertaken immediately and the protocol continued as described below.

In unmonitored patients, basic life support will have been started in response to the collapse, and VF/pVT will be identified when the cardiac monitor is put in place.

An **asynchronous shock of 4 joules/kg in children and 200 joules in pregnant mothers** should be given immediately and **CPR immediately resumed** without reassessing the rhythm or feeling for a pulse. Immediate resumption of CPR is vital because there is a pause between successful defibrillation and the appearance of a rhythm on the monitor. Cessation of chest compressions will reduce the likelihood of a successful outcome if a further shock is needed. However, no harm accrues from 'unnecessary' compressions.

Paediatric paddles (4.5 cm) should be used for children under 10 kg.

One electrode is placed over the apex in the mid-axillary line, while the other is placed immediately below the clavicle just to the right of the sternum. If the paddles are too large, one should be placed on the upper back, below the left scapula, and the other should be placed on the front, to the left of the sternum.

Automated external defibrillators (AEDs) are now commonplace in well-resourced countries. The standard adult shock is used for children over 8 years of age. For children under 8 years, attenuated paediatric paddles should be used with the AED (if available).

For infants under 1 year of age, a manual defibrillator which can be adjusted to give the correct shock is recommended. However, if an AED is the only defibrillator available, its use should be considered, preferably with paediatric attenuation pads. The choice of defibrillation for infants in decreasing order of preference is as follows:

- 1 manual defibrillator
- 2 AED with dose attenuator
- 3 AED without dose attenuator.

Many AEDs can detect VF/VT in children of all ages, and differentiate between 'shockable' and 'non-shockable' rhythms with a high degree of sensitivity and specificity.

If the shock fails to defibrillate, attention must revert to supporting coronary and cerebral perfusion as in asystole. Although the procedures for stabilising the airway and obtaining circulatory access are now described sequentially, they should be undertaken simultaneously under the direction of a resuscitation team leader.

The airway should be secured, the patient **ventilated** with high-flow oxygen, and **effective chest compressions** continued at a rate of 100–120 per minute, with a compression depth of at least one-third of the antero-posterior diameter of the chest, and a ratio of 15 compressions to 2 ventilations. As soon as is feasible, a skilled and experienced operator should **intubate the child's airway**. This will both control and protect the airway and enable chest compressions to be given continuously, thus improving coronary perfusion. Once the patient has been intubated and compressions are uninterrupted, the ventilation rate should be 10–12 breaths per minute. It is important for the team leader to check that the ventilations remain adequate when chest compressions are continuous. **Obtain circulatory access.** Whenever venous access is not readily obtainable, intra-osseous access should be considered early on in children, as it is rapid and effective. Central venous lines provide more secure long-term access, but they offer no advantages compared with IO or peripheral IV access. In each case any drug is followed by a crystalloid flush (2–5 mL).

Two minutes after the first shock, pause the chest compressions briefly to check the monitor. If VF/VT is still present, give a **second shock of 4 joules/kg** and **immediately resume CPR**, commencing with chest compressions.

**Consider and correct reversible causes (the 4Hs and 4Ts)** while continuing CPR for a further 2 minutes.

Pause briefly to check the monitor.

If the rhythm is still VF/VT, give a **third shock of 4 joules/kg**.

Once chest compressions have resumed, give **adrenaline 10 micrograms/kg in children and 1 mg in pregnant mothers IV** and **amiodarone 5 mg/kg in children and 300 mg in pregnant mothers** intravenously or intra-osseously, flushing after each drug.

After completion of the 2 minutes of CPR, pause briefly to check the monitor, and if the rhythm is still VF/VT give an immediate **fourth shock of 4 joules/kg** and **resume CPR**.

After a further 2 minutes of CPR, pause briefly to check the monitor and if the rhythm is still shockable, give an immediate **fifth shock of 4 joules/kg**.

Once chest compressions have resumed, give a second dose of **adrenaline 10 micrograms/kg** and a second dose of **amiodarone 5 mg/kg** intravenously or intra-osseously in children and **1 mg of adrenaline IV** and **150 mg amiodarone in pregnant mothers**. An amiodarone infusion can be continued if there is refractory VF/pVT of 900 mg over 24 hours in adults and 15 mg/kg over 24 hours in children.

After completion of the 2 minutes of CPR, pause briefly before the next shock to check the monitor. Continue giving shocks every 2 minutes, minimising the pauses in CPR as

much as possible. Give adrenaline after every **alternate** shock (i.e. every 4 minutes) and continue to seek and treat reversible causes.

**Note:** After each 2 minutes of uninterrupted CPR, pause briefly to assess the rhythm on the monitor.

In addition, if at any stage there are signs of life, such as regular respiratory effort, coughing or eye opening, stop CPR and check the monitor.

- If the rhythm is still VF/VT, continue with the sequence as described above.
- If the rhythm is asystole, change to the asystole/PEA sequence.
- If organised electrical activity is seen, check for signs of life and a pulse. If there is ROSC, continue post-resuscitation care. If there is no pulse (or a pulse of < 60 beats/minute) and no other signs of life, continue the asystole/PEA sequence.

In VT or VF that does not respond to the above sequence, and where there is no evidence of previous administration of magnesium for eclampsia, consider giving magnesium sulphate 25–50 mg/kg up to a maximum of 2 grams in children and an **8 mmol IV bolus (4 mL of 50% magnesium sulphate) in pregnant mothers.**

#### Sodium bicarbonate

If VF/VT is due to tricyclic antidepressant overdose or hyperkalaemia, sodium bicarbonate may be helpful. Give 1 mmol/kg (1 mL/kg of an 8.4% solution or 2 mL/kg of a 4.2% solution) in children, and give 50 mmol in pregnant mothers.

#### Amiodarone

Amiodarone is the treatment of choice in shock-resistant ventricular fibrillation and pulseless ventricular tachycardia. The dose of amiodarone for VF/pulseless VT is 5 mg/kg via rapid IV/IO bolus in children, and **300 mg IV in pregnant mothers.**

**Lidocaine** is an alternative to amiodarone if the latter is unavailable. The dose is 1 mg/kg IV or IO in children and **100 mg** as an IV bolus **in pregnant mothers.**

It is DC shock that converts the heart back to a perfusing rhythm, not the drug. The purpose of the anti-arrhythmic drug is to stabilise the converted rhythm, and the purpose of adrenaline is to improve myocardial oxygenation by increasing coronary perfusion pressure. Adrenaline also increases the vigour and intensity of ventricular fibrillation, which increases the success rate of defibrillation.

#### Precordial thump

A precordial thump may be given in monitored patients in whom the onset of VT or VF is witnessed, if there are several clinicians present and if the defibrillator is not immediately to hand. However, it is rarely effective, and early activation of emergency services and obtaining an AED are more appropriate. Start CPR as soon as possible.

#### Drugs used in non-shockable and shockable cardiac arrest

##### Oxygen

**Although 100% oxygen must be used during the resuscitation process,** once there is return of spontaneous circulation (ROSC) this can be detrimental to tissues that

are recovering from hyperoxia. Pulse oximetry should be used to monitor and adjust for oxygen requirement after a successful resuscitation. Saturations should be maintained in the range 94–98%. **Always ensure that oxygen delivery is discontinued during defibrillation shocks, to avoid the risks of explosions and fire.**

#### Adrenaline

Adrenaline is the first-line drug for treatment of cardiac arrest. Its effect is to increase blood flow to the brain and myocardium by constricting alternative arterioles. It renders the myocardium more susceptible to defibrillation.

The initial IV or IO dose is 10 micrograms/kg (0.1 mL/kg of 1 in 10 000 solution) in children and 1 mg (1 mL of 1 in 1000 solution) in pregnant mothers. In children with no existing IV access, the intra-osseous route is recommended as the route of choice, as it is rapid and effective. In each case, adrenaline is followed by a 0.9% saline flush (2–5 mL).

#### Sodium bicarbonate

Good basic life support is more effective than alkalinising agents, which may be considered if spontaneous circulation has not returned after the first or second dose of adrenaline. Sodium bicarbonate is recommended in the treatment of patients with VT/VF due to hyperkalaemia and tricyclic antidepressant overdose (see above).

The dose is 1 mmol/kg in children (1 mL/kg of an 8.4% solution or 2 mL/kg of 4.2% solution), and 50 mmol in pregnant mothers.

- Sodium bicarbonate must not be given in the same intravenous line as calcium, otherwise precipitation will occur.
- Sodium bicarbonate inactivates adrenaline and dopamine, so the line must be flushed with Ringer-lactate or Hartmann's solution if these drugs are subsequently given.
- **Sodium bicarbonate must not be given via the intra-tracheal route.**

#### Glucose

Hypoglycaemia is defined as a glucose concentration of less than 2.5 mmol/litre (45 mg/dL).

All patients, but especially infants and preschool children, can become hypoglycaemic when seriously ill. Blood glucose levels should therefore be checked frequently, and **hypoglycaemia must be corrected.** If it is suspected and blood glucose levels cannot be measured, always give 2–5 mL/kg of 10% glucose in children or 100 mL of 25% glucose in pregnant mothers, preferably IV if not enterally (via a gastric tube). Make 100 mL of 25% glucose by adding 50 mL of 50% glucose to 50 mL of Ringer-lactate or Hartmann's solution. If blood glucose levels can be measured, avoid hyperglycaemia (maintain blood glucose concentration below 12 mmol/litre).

### Cardiac arrest and cardiopulmonary resuscitation in the obstetric patient

#### Background

Cardiac arrest in late pregnancy or during delivery is rare, and maternal survival rates are very low (3–33% in published series). The cause of the arrest is not often reversed, and the physiological changes present in late pregnancy hinder effective CPR.

Cardiac arrest in the mother results in absent uterine

perfusion, and the fetus will also die. Even when CPR is ideal, it is not possible to generate a cardiac output of more than 30%.

### Causes

These include the following:

- massive haemorrhage
- pulmonary embolism
- trauma
- amniotic fluid embolism
- severe infection
- local anaesthetic toxicity.

### Physiological changes of pregnancy that relate to cardiopulmonary resuscitation

- Pregnant mothers more easily develop hypoxaemia.
- The enlarged uterus along with the resultant upward displacement of the abdominal viscera decreases lung compliance.
- The most serious physiological change is aorto-caval compression in the supine position. **It is essential that CPR is performed in the left lateral position in any pregnant woman where the uterus is a significant intra-abdominal mass (usually after 20 weeks' gestation).** During closed-chest cardiac compression the best cardiac output that can be achieved is between one-fourth and one-third of normal. Although many factors contribute to this, poor venous return to the heart is of paramount importance. At term the vena cava is completely occluded in 90% of supine pregnant patients. This results in a decrease in cardiac stroke volume of as much as 70%. **It is helpful to manually displace the uterus to the left in advanced pregnancy** (see Figure 1.13.21).
- Caesarean section performed early in resuscitation greatly improves the effectiveness of maternal resuscitation.

### Perimortem Caesarean section

- Caesarean section should be performed as soon as possible, as described in Section 1.12 on basic life support. This will immediately relieve the vena caval obstruction and increase the likelihood of survival for both infant and mother. CPR must be continued throughout the procedure until spontaneous and effective cardiac activity occurs.
- Assisted ventilation may have to be continued for a longer period of time. Some infants have survived when delivered after 20 minutes of maternal resuscitation.
- Without Caesarean section, less than 10% of mothers who arrest in hospital will survive to discharge. Removal of the infant improves maternal circulation during resuscitation, and cardiac output immediately increases by 20–25%.

**Perform the Caesarean section with a midline vertical incision, or whatever method the operator is most**

**FIGURE 1.13.21** Displacing the gravid uterus to the left.

**familiar with, and remove the baby as fast as possible. Remove lateral tilt when the baby is delivered.**

### When to stop resuscitation

Local guidelines should be in place. Resuscitation efforts are unlikely to be successful, and cessation can be considered, if there is no return of spontaneous circulation at any time after 20 minutes of life support and in the absence of recurring or refractory VF/VT. The exceptions are patients with a history of poisoning or a primary hypothermic insult, in whom prolonged attempts may occasionally be successful. Prolonged external cardiac compressions during which central (femoral or arterial) pulses were felt have successfully resuscitated patients with tricyclic antidepressant overdose.

The presence of the parents at the child's side during resuscitation enables them to gain a realistic understanding of the efforts made to save their child's life. In general, family members should be offered the opportunity to be present during the resuscitation of their child.

**The most important points can be summarised as follows:**

- A staff member (if available) must be designated as the parents' support and interpreter of events at all times.
- The team leader, not the parents, decides when it is appropriate to stop the resuscitation.
- If the presence of the parents is impeding the progress of the resuscitation, they should be sensitively asked to leave.
- The team needs a debriefing session to support staff and reflect on practice.

# 1.14 High-dependency care in pregnancy and childhood

**High-dependency care is a service provided for patients with potentially recoverable pathological processes who can benefit from more detailed observation and treatment than is generally available on the standard hospital ward.**

High-dependency care is usually provided for patients with threatened or established organ failure, which may have arisen as a result of:

- an acute illness
- a complication of pregnancy or delivery
- trauma
- a predictable phase in a planned treatment programme (e.g. after major surgery).

## Introduction

Health needs are best met through an integrated approach involving several agencies, including primary and secondary healthcare, education and social services. **Together such services may help to prevent some of the conditions that lead to patients requiring intensive care.** For example, vaccination programmes will decrease the number of children who develop respiratory failure due to preventable diseases such as pertussis and measles. Education and legislation are important for reducing the number of individuals who are seriously injured in road traffic accidents and in accidents in the home.

High-dependency care is a low-volume, high-demand specialty. Women and girls with complications of pregnancy and children under 2 years of age account for most of those who require high-dependency care. There also may be seasonal variation, with a peak in the winter months associated with respiratory-related illness, or a peak in the rainy season associated with malaria.

**Dedicated intensive care units in large tertiary care centres have been shown to have the best outcomes.** Ideally, every country in the world should have units that provide this service. **However, the majority of patients who require high-dependency or intensive care will present to smaller peripheral hospitals rather than to large tertiary centres.** Therefore it is absolutely essential that staff in smaller district hospitals are able to recognise and appropriately treat sick children and pregnant women in the early stages of their illness (see EESS-EMNCH programme – Essential and Emergency Surgical Skills – *Emergency Maternal, Neonatal and Child Healthcare Manual and Pocket Book*, which can be found on the MCAI website: [www.mcai.org.uk](http://www.mcai.org.uk)).

All medical and nursing staff who undertake high-dependency care should be well trained in emergency care so as to be able to stabilise critically ill or injured patients, and initiate appropriate medical therapy, which may involve intubation and ventilation. A proportion of such patients may then be safely transferred to an intensive care unit if this is still appropriate and a bed is available. Often, with good initial resuscitation and early diagnosis and treatment, the

need for intensive care can be avoided. In a patient who requires intensive care, there should be early consultation with the regional/national intensive-care unit, usually by telephone or radio, so that further management can be jointly decided until a retrieval team, if available, arrives to collect the patient.

Transportation of critically ill patients (see Section 1.19), particularly those receiving assisted ventilation, requires appropriately trained staff and equipment. Transportation is best thought of as ‘a high-dependency care bed on wheels’, and the aim should be that the patient does not deteriorate during transport. Before the patient is moved, proper resuscitation and stabilisation are essential.

Children and pregnant mothers exhibit fundamental differences that influence the training of staff and the type and size of equipment available. These differences extend across anatomy, physiology, pharmacology and behaviour. However, both of these patient groups have less reserve and tend to decompensate early and quickly. They also have a greater capacity to make a full recovery.

Provision of high-dependency care is not just about equipment and facilities. The surrounding environment and contact with their family is crucial to the promotion of a patient’s recovery.

## Levels of high-dependency/intensive care

There are three levels of care that are designed to make the most appropriate use of staff and equipment resources (see Table 1.14.1). In most resource-limited countries, only Level 1 care is likely to be available, and then only in the most well-funded hospitals, such as those in the capital cities or where medical students are trained.

The majority of patients can be managed at Level 1 with close monitoring, good nursing care and appropriate medical therapy. By providing optimal therapy it is often possible to prevent the deterioration of the patient (e.g. through good fluid management, early but appropriate treatment with antibiotics, and the use of oxygen).

Many hospitals will have poor outcomes if patients have to be ventilated in sites where there is a lack of maintained ventilators, and no reliable oxygen source or blood gas analyser. As far as possible in countries with limited resources, intubation and ventilation should be avoided until they are absolutely necessary. Many patients can tolerate high pCO<sub>2</sub> levels with a compensated pH – it is hypoxia that is potentially fatal. It may be appropriate to develop and have available non-invasive modes of ventilatory support, such as nasal mask or cannula **continuous positive airways pressure (CPAP)**, nasal or face mask **intermittent positive pressure ventilation (IPPV)**, **bilevel positive airways pressure (BiPAP)**, or **negative pressure ventilation (CNEP or INPV)**. Similarly, the more invasive a procedure or monitoring process is, the greater the risk of complications.

Finally, it is essential that hospitals which provide high-dependency care have an on-site biomedical engineer to keep all of the equipment serviced and safe.

**TABLE 1.14.1 Levels of high dependency and intensive care**

<b>Level 3 (intensive care)</b>		
Multi-organ failure		
Ideally one or more nurses per patient		
Invasive monitoring		
Examples: ventilation, haemofiltration		
Optimise medical therapy	↓ ↑	
<b>Level 2 (intensive care)</b>		
Single-organ failure		
Ideally one nurse per patient		
Non-invasive or invasive monitoring		
Example: ventilation		
Intubate ↑	↓ ↑	Extubate ↓
Optimise medical therapy		
<b>Level 1 (high-dependency care)</b>		
Requirement for closer observation and monitoring than is available on the standard ward		
Ideally one nurse for every two patients		
Non-invasive monitoring		
Examples: after major surgery, non-intubated child with severe croup, pregnant woman with severe pre-eclampsia or eclampsia		

### Minimum standards for a lead centre providing intensive care

#### Medical staff

- Senior doctors or physician assistants with appropriate training in high-dependency care medicine.
- Training programme for junior medical staff specialising in high-dependency care.
- Provision of 24-hour cover at both senior and junior level.
- Resident junior cover for 24 hours by staff with skills in emergency care and resuscitation, whose only clinical responsibility is to the high-dependency care unit.
- Access on site to other specialist consultants (e.g. obstetrician, paediatrician, ENT surgeon, anaesthetist).

#### Nursing staff

- Nursing staff with training in high-dependency care and resuscitation.
- Ongoing training and support for nursing staff.
- Continuous 24-hour observation of each patient at all times by a nurse qualified in high-dependency care, with observations documented.

#### Support staff

- Availability of a physiotherapist.
- Availability of a pharmacist 24 hours a day.
- Availability of a dietitian.
- Availability of a biomedical engineer 24 hours a day.

#### Equipment and drugs

- Medical staff and nursing staff with training in how to use all equipment.
- Equipment maintained on a regular basis and according to manufacturer's guidelines by a biomedical engineer.
- Controlled drugs, especially morphine, available immediately and for 24 hours a day.

#### Retrieval service

- Available 24 hours a day from the community or other health facilities without high-dependency care (e.g. via an emergency ambulance service; see [www.reproductive-health-journal.com/content/pdf/1742-4755-7-21.pdf](http://www.reproductive-health-journal.com/content/pdf/1742-4755-7-21.pdf)).
- Does not take staff from the high-dependency unit, leaving it uncovered.
- Usually an experienced doctor, midwife or nurse.
- Able to provide phone or radio advice.
- Equipped with portable battery-operated monitors (ECG, heart rate, respiratory rate, oxygen saturation) and suction. Possible to provide hand bag ventilation by face mask or endotracheal tube rather than have a transport ventilator.

#### Clinical effectiveness and management

- Protocols for admissions, discharges, retrievals, resuscitation and stabilisation, and for treating major conditions.
- Data collection and regular audit of deaths and near-miss cases to improve care provided.

#### Facilities for families

- Access for carers of children and partners of pregnant mothers at all times.
- Accommodation and food for families.
- Maternal and Child Health Initiative (MCHI) environment (see MCHI manual).

#### Essential equipment for the high-dependency care of children and pregnant mothers

- 1 Beds that are manually operated to tilt the head up or feet down.
- 2 Wedges for lateral tilt for pregnant mothers.

- 3 Suction systems and suction catheters, both electrical and manual (ideally wall suction).
  - 4 Pulse oximeters and ECG monitors (one for each bed).
  - 5 Resuscitation trolley containing drugs and equipment (particularly oropharyngeal airways, laryngoscopes with spare bulbs, endotracheal tubes and introducers, bag-valve-masks (child and adult), masks with reservoir bags.
  - 6 Mobile screens.
  - 7 Mobile oxygen cylinders and one oxygen concentrator for each bed, with face masks and nasal cannulae (infant, child and adult).
  - 8 Wall sockets (six per bed).
  - 9 One basic infant ventilator and one child/adult ventilator.
  - 10 Nasal or mask CPAP systems (neonatal, child and adult).
  - 11 Two automatic external defibrillators (AEDs).
  - 12 Infusion pumps (if there are sufficient staff).
  - 13 IV drip stands.
  - 14 Basic CVP monitoring system.
  - 15 Blood warmer (ideally).
  - 16 Fridge for pharmacy drugs.
  - 17 Fridge for blood for transfusion.
  - 18 Lockable cupboard for drugs not needing refrigeration.
  - 19 Metal lockable cupboard for controlled drugs.
  - 20 Cupboard for storing IV fluids.
  - 21 End-of-bed chart tables and specially designed high-dependency care charts.
  - 22 One portable ultrasound scanner.
  - 23 One portable fetal heart monitor.
  - 24 Burette giving sets.
  - 25 Portable examination light.
  - 26 Portable fans.
  - 27 Suitable storage boxes (preferably easy to clean and label).
  - 28 Blackboard for documenting priority issues for each patient.
  - 29 Wall-mounted pathways of care.
  - 30 Hand wash facilities × 3/4.
  - 31 Separate sluice and patient and staff toilet and washing facilities.
  - 32 Steriliser.
- For details of procedures that are likely to be used in high-dependency care, see Section 2.13 (on obstetrics) and Section 7 (on children and all-age trauma).

## 1.15 Pain control in pregnancy and childhood

### Introduction

**It is ethically wrong and a failure of professional duties for any patient to suffer uncontrolled pain.**

- Uncontrolled pain has adverse cardiovascular, respiratory, immunological and metabolic consequences, as well as long-term psychological effects.
- Both pharmacological and non-pharmacological approaches are valuable in both acute and chronic pain.
- **Attempts should be made to anticipate and prevent pain rather than trying to relieve it when it is established.** This method usually results in less analgesia being needed. 'As-required' regimens should be avoided. Analgesics should be used in regular and adequate doses.
- There is little place for IM pain relief, particularly as a repeated treatment. Many patients would rather suffer and hide their pain than receive IM analgesia.
- If a **conscious** child has to be restrained for a procedure, this must be done kindly but firmly by a person or persons (ideally a parent or caregiver) and not by contraptions such as straitjackets or the tying down of limbs.
- It is vital to ask for and value the patient's own judgement concerning the adequacy of pain relief provided.
- When beginning a course of treatment for pain it is important to realise that such treatment may continue for a long time. **Pain must be controlled quickly from the onset to ensure confidence in treatment, with an emphasis on preventative measures.**

### Assessment of pain

- Establish the severity of pain that is being experienced.
- Help to select the right amount and type of pain relief.
- Indicate the success of pain management.

### Methods for assessing pain

- Description by the patient (self-reporting), possibly involving the use of a self-report scale (see Figures 1.15.1 and 1.15.2)
- Observation of behavioural changes (e.g. crying, guarding of the injured part, facial grimacing). This method is best for children in collaboration with carers. The Alder Hey Triage Pain Score may be useful in this context (see Appendix on p. 80).
- Physiological changes (e.g. vasoconstriction, tachycardia, tachypnoea). However, these can also be due to serious medical causes.
- Expectation of pain because of the pathophysiology involved (e.g. obstructed labour, placental abruption, fracture, burn or other significant trauma).
- Keeping a diary of long-term pain.

**FIGURE 1.15.1** Visual scale for assessing the severity of pain.

**FIGURE 1.15.2** A commonly used faces pain scale for assessing the severity of pain in children.

**Problems with assessing pain**

- Suffering being hidden by a frightened patient, especially a child.
- Difficulty in differentiating anxiety from pain.
- Family members (and healthcare professionals) may underestimate or overestimate pain.
- Pre-verbal and non-verbal children (and any older patient with learning difficulties or with sensory handicap) may not be able to adequately express their need for pain control.
- Cultural factors (beliefs, perceptions and behaviour).

**Treatment of pain**

Many patients, particularly babies and children, are under-treated for pain because of:

- fear of the harmful side effects of medications
- failure to accept that children feel pain in the same way that adults do
- fear of receiving IM injections
- limited availability of the required spectrum of pain medications.

**Methods for reducing pain without drugs**

**Environmental factors**

Negative aspects of the environment should be minimised or removed. These include an overly ‘clinical’ appearance, and evidence of invasive instrumentation. Needles should be kept out of sight. An attractive, decorated environment with toys, mobiles and pictures may help the child to feel more relaxed.

- Privacy is important.
- Pain caused by fractures can be reduced by splinting to immobilise them.
- Pain from burns can be reduced by applying a light covering.
- Parents should be present with their child during invasive procedures, unless there are very good medical reasons why they should be excluded, or they choose not to be present.

**Supportive and distractive techniques for children**

Age-appropriate distraction strategies include:

- the presence of familiar objects (comforters) (e.g. pillow, soft cuddly toy)
- singing, concentrating on nice things, jokes, games and puzzles
- imaginary journeys
- blowing soap bubbles
- breathing out (but not hyperventilation, which may increase anxiety)

- a mirror that allows the child to see the view through a nearby window
- listening to stories or music.

**Drug treatment for pain using local anaesthetic drugs**

**Infiltration (the most widely used method)**

**Lidocaine 0.5–2%**

- Used for rapid and intense sensory nerve block.
- Onset of action is within 2 minutes; the procedure must not be started until an anaesthetic effect is evident.
- Effective for up to 2 hours.
- Doses:
  - neonates to 12 years: maximum dose given locally 3mg/kg – 0.3mL/kg of 1% solution or 0.6mL/kg of 0.5% solution (7 mg/kg with 1 in 200 000 adrenaline)
  - children over 12 years and pregnant mothers: up to a maximum of 200 mg (500mg if used with adrenaline) not more than 4-hourly.
- Adrenaline is rarely added in children and never for digits.
- Strength: 1% or 0.5%.
- Preparation of lidocaine 0.5% solution. Combine:
  - lidocaine 1%, 1 part
  - Ringer-lactate or Hartmann’s solution or sterile distilled water, 1 part.

**Do not use local anaesthetic containing adrenaline in areas served by an end artery or with a poor blood supply (e.g. finger, toe, penis), as tissue necrosis will occur.**

Advantages of adding adrenaline include the following:

- less blood loss
- longer effect of anaesthetic (usually 1–2 hours)
- lower risk of toxicity because of slower absorption into the general circulation.

The concentration of adrenaline to use is 1:200 000 (5 micrograms/mL). In children, the maximum dose of adrenaline is 5 micrograms/kg.

**Note:** It is critical to measure adrenaline carefully and accurately using a 1-mL or, at the most, 2-mL syringe. (An insulin syringe may be used if a regular 1-mL syringe is not available.) Mixtures must be prepared observing strict infection prevention practices.

**TABLE 1.15.1** Formulas for preparing 0.5% lidocaine solutions containing 1:200 000 adrenaline

Desired amount of local anaesthetic needed (mL)	Ringer-lactate or Hartmann’s solution (mL)	Lidocaine 1% (mL)	Adrenaline 1:1000 (mL)
20	10	10	0.1
40	20	20	0.2
100	50	50	0.5
200	100	100	1.0

**Local infiltration into an abscess is not recommended, because local anaesthetics are ineffective in inflamed tissues.**

### Complications of local anaesthesia

#### Prevention of complications

- If more than 40 mL of 0.5% lidocaine are to be used, add adrenaline as described above. Procedures that may require more than 40 mL of 0.5% lidocaine are Caesarean section and repair of extensive perineal tears.
- Use the lowest effective dose.
- Inject slowly.
- Avoid accidental injection into a vessel. There are three ways of doing this:
  - the **moving needle technique** (preferred for tissue infiltration): the needle is constantly in motion while injecting, which makes it impossible for a substantial amount of solution to enter a vessel
  - the **plunger withdrawal technique** (preferred when

considerable amounts are injected into one site): the syringe plunger is withdrawn before injecting, and if blood appears the needle is repositioned and another attempt is made

- the **syringe withdrawal technique**: the needle is inserted and the anaesthetic is injected as the syringe is being withdrawn.

#### Symptoms and signs of lidocaine allergy and toxicity

**Lidocaine can be absorbed through mucous membranes in a large enough dose to be toxic.**

**Symptoms of allergy:** shock, redness of skin, skin rash/hives, bronchospasm, vomiting, serum sickness (see Sections 2.7.C and 5.1.B on anaphylaxis in mothers and children, respectively).

TABLE 1.15.2 Lidocaine toxicity

Mild toxicity	Severe toxicity	Life-threatening toxicity (very rare)
Numbness of lips and tongue	Sleepiness	Tonic-clonic convulsions
Metallic taste in mouth	Disorientation	Respiratory depression or arrest
Dizziness/lightheadedness	Muscle twitching and shivering	Cardiac depression or arrest
Ringing in ears	Slurred speech	
Difficulty in focusing eyes		

- Direct intra-arterial or IV injection of even a small amount may result in cardiac arrhythmias and convulsions (see above).
- Resuscitative facilities and healthcare professionals with resuscitative skills should be present.
- Lidocaine can be absorbed through mucous membranes in sufficient concentration to be toxic.

Immediately stop injecting and prepare to treat severe and life-threatening side effects.

**If symptoms and signs of mild toxicity are observed** wait a few minutes to see if the symptoms subside. Check vital signs and talk to the patient. Delay the procedure for at least 4 hours if possible.

#### Adrenaline toxicity

This is caused by excessive amounts or inadvertent IV administration, and results in:

- restlessness
- sweating
- hypertension
- cerebral haemorrhage
- rapid heart rate
- cardiac arrest.

#### Bupivacaine 0.25%

- This is used to provide longer-lasting local anaesthesia.
- Onset of action is up to 30 minutes.
- It is effective for up to 8 hours.
- Maximum dosage is 2 mg/kg (in mothers the pre-pregnant weight is used for calculations).

For uses of other preparations of bupivacaine, see Section 1.24.

#### Local anaesthetics given through the surface of the skin or mucous membranes

- 1 **Lidocaine:** apply on gauze to painful mouth ulcers

before feeds (apply with gloves, unless both the family member and the patient are HIV-positive, in which case the family member does not need protection from infection). It acts within 2–5 minutes.

- 2 **TAC (tetracaine–adrenaline–cocaine):** apply to a gauze pad and place over open wounds; it is particularly useful when suturing. Care needs to be taken close to mucous membranes to avoid toxicity from absorption of cocaine. If available, other topical anaesthetic agents such as lidocaine–adrenaline–tetracaine seem to be equally effective and avoid the potential toxicity associated with cocaine.

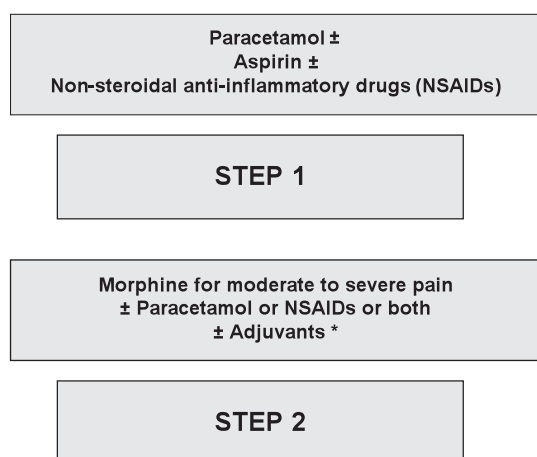

#### Systemic drug treatment for pain

The World Health Organization (WHO) has altered the previous three-step approach to the treatment of pain, removing the use of codeine between Step 1 and Step 2 (see Figure 1.15.3). Although widely available, codeine is unpredictable in its effects, due to its very variable metabolism between individuals, with the potential for both toxicity and inadequate analgesia. It is now recommended that if Step 1 drugs do not control pain, morphine should be used next.

#### Non-opiate analgesics

##### Paracetamol

- This is the most widely used analgesic and anti-pyretic.
- It does not cause respiratory depression.
- It is dangerous in overdose but a very safe and effective drug if used in recommended doses.
- It is given by mouth, rectally or intravenously.
  - The maximum daily dose should not be given for more than 3 days.
  - Caution is needed in patients with liver impairment.
  - There are no anti-inflammatory effects.
  - Paracetamol can be combined with NSAIDs and both have a morphine-sparing effect, lowering the dose, and therefore severity of side effects of morphine.

\*An adjuvant is another drug (e.g. steroid or anxiolytic) or type of treatment (e.g. TENS or radiotherapy) that can prevent and relieve pain.

**FIGURE 1.15.3** WHO two-step analgesic ladder.

### **Non-steroidal anti-inflammatory drugs (NSAIDs) (e.g. ibuprofen, diclofenac)**

- These are anti-inflammatory, anti-pyretic drugs with moderate analgesic properties.
- They are less well tolerated than paracetamol, causing gastric irritation, platelet disorders and bronchospasm.
- They should be avoided in patients with gastric ulceration, platelet abnormalities or significant asthma.
- NSAIDs are especially useful for post-traumatic and bone pain because of their anti-inflammatory effect.
- They are given by the oral or rectal route (e.g. diclofenac).

**Caution: do not give NSAIDs in the third trimester of pregnancy, as they may close the ductus arteriosus and predispose to pulmonary hypertension of the newborn. They may also delay the onset and progress of labour.**

**There is a risk of gastric haemorrhage through whichever route the NSAIDs are given.**

### **Opiate analgesics**

For a discussion of the importance of properly storing, handling and monitoring the use of morphine, see Section 1.6.

### **Morphine**

- Morphine is the most important drug in the world for pain control, and the WHO recommends that it should be universally available.
- **In resource-limited countries it is mostly administered orally, which is useful for chronic or anticipated pain but less effective for acute pain. The latter requires IV administration of morphine.**
- At an appropriate dose, analgesia occurs without impaired consciousness.
- Nausea and vomiting are rare with oral treatment, but when morphine is given intravenously for the first time it may produce this side effect.

### **Intravenous use of morphine**

- In single doses it has minimal haemodynamic effects in a supine patient with normal circulating blood volume.
- In hypovolaemic patients it can contribute to hypotension. Therefore:
  - monitor the patient's cardiovascular status
  - have an IV fluid bolus of Ringer-lactate or Hartmann's solution ready (20 mL/kg for a child and 500 mL to 1 litre for pregnant mothers).
- In excessive dosage it can produce a dose-dependent depression of ventilation and decreased respiratory rate, leading to apnoea.
- Patients who are receiving morphine in hospital (where it is often intravenously administered) need observation and/or monitoring of respiratory rate and sedation.
- Morphine is better controlled by the IV than the IM route. If using the IV route, give a small dose initially and repeat every 3–5 minutes until the patient is comfortable. Individuals vary widely with regard to the dose needed to provide pain relief. **It is rarely appropriate to give morphine intramuscularly, and for patients who are in shock, giving morphine IM is dangerous, as it can be initially poorly absorbed, and then quickly absorbed when perfusion improves, potentially leading to too high a blood level of the drug.**
- Morphine can also be given by subcutaneous infusion in hospital (e.g. as a post-operative analgesic), especially if small battery-operated syringe drivers are available.
- Intravenous morphine can be dangerous in situations of raised intracranial pressure without the means to provide respiratory support.
- During late pregnancy or delivery, morphine can cause respiratory depression in the neonate.

**TABLE 1.15.3** Orally administered drugs for mild or moderate pain

Medicine	Neonate 0–29 days	Infant 30 days to 3 months	3 months to 12 years	Maximum daily dose	In pregnancy
Paracetamol	10 mg/kg every 6–8 hours Maximum 4 doses in 24 hours 5 mg/kg if jaundiced	10 mg/kg every 4–6 hours	15 mg/kg up to 1 g every 4–6 hours Maximum 4 doses/4 g in 24 hours	4 doses in 24 hours	500 mg to 1 g 6-hourly
Ibuprofen	Not recommended	Not recommended	5–10 mg/kg every 6 hours	40 mg/kg/day	Do not use in pregnancy
Diclofenac	Not recommended	Not recommended	<b>Over 6 months,</b> 0.3–1 mg/kg 3 times daily	3 mg/kg/day	Do not use in pregnancy

**Naloxone**

Naloxone is an opiate antagonist that reverses the sedative, respiratory-depressive and analgesic effects of morphine, and so should be given to treat morphine overdose.

**Preparations of non-opioid drugs:**

Doses can be obtained from the *British National Formulary* and the newly published *PCF4 Palliative Care Formulary*, available at [www.palliativedrugs.com/palliative-care-formulary.html](http://www.palliativedrugs.com/palliative-care-formulary.html) (accessed July 2014).

Paracetamol: oral suspension, 120 mg/5 mL, 250 mg/5 mL; tablets, 500 mg.

Ibuprofen: oral suspension, 100 mg/5 mL; tablets, 200 mg, 400 mg.

Diclofenac: tablets, 25 mg, 50 mg; dispersible tablets, 10 mg.

**Notes on ibuprofen and diclofenac**

- Do not use in patients less than 1 year old, or in pregnancy.
- Caution is needed in patients with asthma, liver or renal failure.
- Contraindications include dehydration, shock, bleeding disorders and hypersensitivity to aspirin.
- NSAIDs and paracetamol can be used in combination.

If rectal drugs are available, the doses are similar to oral doses.

**TABLE 1.15.4 Intravenous paracetamol for mild or moderate pain**

Age/weight	Dose	Maximum dose in 24 hours
Preterm over 32 weeks	7.5 mg/kg every 8 hours	25 mg/kg
Term neonate	10 mg/kg every 4–6 hours	30 mg/kg
Pregnant woman or child less than 50 kg body weight	15 mg/kg every 4–6 hours	60 mg/kg
Pregnant woman or child more than 50 kg body weight	1 g every 4–6 hours	4 g

**Intravenous paracetamol**

- Paracetamol IV is formulated as a 10 mg/mL aqueous solution (in ready-to-use 50-mL and 100-mL vials for infusion over 15 minutes).
- It is useful, effective and safe.
- The peak analgesic effect of IV paracetamol occurs within 1 hour, with a duration of approximately 4–6 hours.
- Ensure that the correct dose is given, as serious liver toxicity can occur in overdose.
- Side effects are rare. They include rashes, blood disorders and hypotension on infusion.
- Caution is needed in patients with severe renal impairment, severe malnutrition (and thus low reserves of hepatic glutathione) or dehydration.
- Paracetamol helps to reduce the amount of narcotics required when used in combination with them.

**TABLE 1.15.5 WHO advice: oral and rectal morphine for severe pain in hospital**

Age	Dose	Interval
1 month to 1 year	80–200 micrograms/kg	Every 4 hours
1–2 years	200–400 micrograms/kg	Every 4 hours
2–12 years	200–500 micrograms/kg	Every 4 hours
Over 12 years and in pregnancy	5–10 mg	Every 4 hours

**Note: the upper doses seem quite high – if a child weighs 20 kg, they would be receiving 10 mg – the same as an adult.**

**We suggest that you start with the lower dose and give more frequently, e.g. every hour if needed, until the patient is comfortable, then increase the dose if morphine needs to be given every hour. The Table immediately below (Table 1.15.6) already has lower doses.**

**Almost all patients with chronic pain can be managed with oral morphine when this is given in the doses shown in Tables 1.15.6 and 1.15.7 in combination with non-opioid analgesics**

**These are starting doses and can be increased as necessary on an individual patient basis if pain is not controlled**

**TABLE 1.15.6 British National Formulary (BNF) and BNF for Children (BNFc) recommended doses for oral and rectal morphine**

Age	Initial dose (adjust according to response)	Interval
1–3 months	50–100 micrograms/kg	Every 4 hours
3–6 months	100–150 micrograms/kg	Every 4 hours
6–12 months	200 micrograms/kg	Every 4 hours
1–2 years	200–300 micrograms/kg	Every 4 hours
2–12 years	200–300 micrograms/kg	Every 4 hours
12–18 years	5–10 mg	Every 4 hours
Adults/pregnant mothers	5–10 mg	Every 4 hours

**Preparations of morphine**

- 1 Prepared mixture:
  - 10mg/5mL
  - 30mg/5mL
  - 100mg/5mL.
- 2 Morphine oral solutions can be made by dissolving powder in clean water, and are available in Africa at concentrations of 5 mg/5 mL, 50mg/5 mL and 100mg/5 mL.
- 3 Tablets: 10mg, 20mg and 50mg.
- 4 Suppositories: 15mg and 30mg.
- 5 Slow-release tablets: 10mg, 30mg, 60mg and 100mg.

- 6 Slow-release suspension sachets: 5mg, 20mg, 30mg, 60mg, 100mg and 200mg.

**Note:** See Section 1.16 on palliative care for use of morphine at home.

**Parenteral morphine**

**IV morphine is only needed if oral or rectal preparations are not going to be absorbed (e.g. in shock) or where rapid emergency onset is needed. IV morphine is potentially less safe, especially if staff shortages mean that the correctly calculated dose is not given.**

**TABLE 1.15.7 Intermittent IV (bolus) morphine dosage\***

Age	Dose	Interval	Maximum dose
Neonate	25–50 micrograms/kg	Every 6 hours	
1–6 months	100 micrograms/kg	Every 6 hours	2.5 mg/dose
6 months to 2 years	100 micrograms/kg	Every 4 hours	2.5 mg/dose
2–12 years	100–200 micrograms/kg	Every 4 hours	
Over 12 years and in pregnancy	10 mg	Every 4 hours	

\* We suggest that the total dose recommended is drawn up in 10 mL 0.9% saline and that 2 mL boluses of this solution are given every 3–5 minutes until the patient is comfortable. Also, if pain returns despite regular paracetamol/nonsteroidal analgesia, further dose of oral/IV morphine can be given within 6 hours if the respiratory rate is normal and the patient is not sedated.

Intravenous infusion of morphine requires continuous monitoring including oxygen saturation and respiratory rate and sedation score every 5 minutes for the first 15 minutes after start of the infusion and every 15 minutes subsequently for one hour and at least every 30 minutes after that. It should only be undertaken in a high dependency care situation. In resource limited situations, intermittent IV boluses as in Table 1.15.7 are safer.

*Monitoring during morphine administration:*

**Side effects occur only in overdose and should not be seen at the doses stated here.** They include the following:

- 1 Respiratory depression. **If the respiratory rate is:**
  - < 20 breaths/minute in patients aged less than 6 months
  - < 16 breaths/minute in those aged less than 2 years
  - < 14 breaths/minute in those aged 2–10 years
  - < 12 breaths/minute in those aged 10–18 years and in pregnant mothers

**Alert medical staff and ensure that bag-valve-mask and naloxone are available.**

Monitor SaO<sub>2</sub> as appropriate (it should be higher than 94% in air).

- 2 Constipation. Use prophylactic laxatives.
- 3 Monitor for urinary retention.
- 4 Patients with liver and renal impairment may need lower doses and longer time interval between doses. Caution in patients with head injuries

**Always ventilate with bag-valve-mask first if patient is unresponsive before giving naloxone. This is because arrhythmias and pulmonary oedema can be caused if naloxone is given to a patient with high blood carbon dioxide concentrations.**

**Naloxone doses to reverse opioid induced respiratory depression**

- 1 Neonate to 1 month of age: 5–10 microgram/kg repeated every 2–3 minutes until adequate response
- 2 1 month to 12 years of age: 5–10 microgram/kg, subsequently 100mcg/kg
- 3 12 to 18 years and in pregnancy: – 0.2–2.0 mg/kg. Repeat at intervals of 2–3 minutes to a maximum of 10mg.

If respiratory rate is low, but the patient's oxygen saturation is acceptable (>94%) with facemask oxygen, in order to avoid complete reversal of analgesia draw up 400 microgram naloxone into 20 mL and give 1–2 mLs every 2 minutes until the patient is rousable and the respiratory rate increased to an appropriate rate for age.

**Preparations of naloxone:** Ampoule 20 microgram/mL

Give IV or IM if IV is not possible. Repeat after 2–3 minutes if there is no response; the second dose may need to be much higher (up to 100 micrograms/kg). An IV infusion may be needed if protracted or recurrent depression of respiration occurs because naloxone is short acting compared with most opioids.

**Starting dose for naloxone infusion:** 60% of the dose that maintained adequate respiration for 15 minutes.

Alternatively: Neonate – 5 to 20 microgram/kg/hour, adjusted according to response; 1 month to 18 years and in pregnancy – 5 to 20 microgram/kg/hour.

(For the newborn, to treat respiratory depression due to maternal opioid administration during labour or delivery 200 microgram as a single IM dose is recommended or 60 microgram/kg.)

*Prevention and treatment of nausea and vomiting due to initial high-dose morphine*

- 1 Cyclizine. This covers the widest range of causes of nausea and vomiting with the least side effects. It is not recommended orally in children < 2 years and rectally < 6 years.  
The IV doses are:
  - 1 month to 6 years: 500 microgram to 1 mg/kg 8 hourly
  - 6 to 12 years: 25 mg 8 hourly
  - 12 to 18 years and in pregnancy: 50 mg 8 hourly
- 2 Domperidone – where gastric emptying is a problem, then as in Table 1.15.8 for doses.

**TABLE 1.15.8 Domperidone for prevention and treatment of nausea and vomiting**

Domperidone	
Oral	Rectal
From 1 month up to 35 kg in a child: 250–500 micrograms/kg 3–4 times daily, up to a maximum of 2.4 mg/kg in 24 hours	Not recommended for children weighing < 15 kg
Over 35 kg and in pregnant mothers: 10–20 mg 3–4 times daily, up to a maximum of 80 mg daily	Children weighing 15–35 kg, 30 mg twice daily
Tablets, 10 mg	Children weighing > 35 kg or in pregnant mothers, 60 mg twice daily
Suspension, 5 mg/5 mL	Suppositories, 30 mg

Both of the above can cause extrapyramidal side effects, including acute dystonia, which can be treated with diazepam IV 100 microgram/kg, or, if over 12 years and in pregnancy, 5–10 mg IV.

**Specific clinical situations in which analgesia may be required**

**Invasive procedures**

- These are often painful, undignified, or both. Ideally they should be undertaken in a treatment room so that other patients are not frightened by the procedures, and so that the patient's bed-space remains a safe place that is not associated with such events.
- Such procedures often have to be repeated. Therefore provide optimal treatment on the first occasion in order to reduce the likelihood of dread of future procedures.
- Fear is often the main emotion that needs to be addressed, so explain each step.
- Both pharmacological and non-pharmacological methods should be used.
- For major procedures that require powerful analgesia/sedation, two healthcare workers should be present – one to perform the procedure and the other to administer analgesia and sedation and ensure that the airway is maintained.
- Major procedures include chest drain insertion and repeated lumbar puncture. **Such procedures may be best undertaken under general anaesthesia or ketamine if this can be given safely (which may not be the case in resource-limited countries).**
- For venous cannulation, size-appropriate catheters must

be available. For example, it is not appropriate to use an 18- or 20-gauge cannula in a neonate. Although the use of local anaesthetic creams (e.g. EMLA) prior to cannulation represents best practice, they are expensive. In some circumstances, the urgency of the situation will not allow use of local anaesthetic creams.

- Give analgesics at an appropriate time before the procedure (30 minutes beforehand for IM and 30–60 minutes beforehand for oral medication depending on the drug used) aiming for maximal effect during the procedure.
- Check the level of anaesthesia by pinching the area with forceps. If the patient feels the pinch, wait 2 minutes and then retest.
- Wait a few seconds after performing each step or task for the patient to prepare for the next one.
- Handle tissue gently and avoid undue retraction, pulling or pressure.
- Talk to the patient throughout the procedure.

**Analgesia during labour**

**For severe pain, give morphine bolus 2.5–5 mg and repeat once after 5 minutes if the pain is not controlled. Then wait 2–4 hours before repeating.**

**Nitrous oxide plus oxygen can be effective in reducing pain during labour (see Section 2.3).**

**Barbiturates and sedatives should never be used to relieve anxiety in labour.**

**Severe pain**

- Severe pain is likely to occur in obstetric emergencies, post-operatively, and in patients with major trauma, significant burns, or displaced or comminuted fractures.
- Give IV morphine as described in Table 1.15.6.
- A further dose can be given after 5–10 minutes if sufficient analgesia is not achieved.
- Monitor ABC (heart rate, respiratory rate, chest wall expansions, blood pressure, SaO<sub>2</sub>).
- Have IV Ringer-lactate or Hartmann's solution available (20 mL/kg for children and 500 mL to 1 litre for pregnant mothers as a bolus if hypotension occurs following IV morphine injection: this is unusual).
- Ketamine could be used as an alternative.

**Head injuries**

- An analgesic dose does not necessarily cause sedation.
- If the patient is conscious and in pain, the presence of a potential deteriorating head injury is **not** a contraindication to giving morphine. Give IV up to a maximum dose of 100 micrograms/kg for a child or 5 mg for a pregnant mother.
- If the patient's conscious level does deteriorate, assess ABC. If hypoventilation occurs, ventilate with a bag-valve-mask.
- If necessary, a dose of naloxone will help to distinguish whether reduced conscious level is due to morphine or increasing intracranial pressure, as it will reverse the effects of the morphine, including the analgesic effect.

**Pre-operative management**

This should include patient assessment, including a history of previous painful experiences from the patient and family (the parents of a child). The following questions should be asked.

- What sort of painful things have happened in the past?

- How does the patient usually react to sudden pain? And to chronic pain?
- Does the patient tell you (or others) if he or she is in pain?
- What does the patient do to get relief from pain?
- Which actions appear to be most effective?

### **Pain management during surgery**

- Morphine/NSAIDs can reduce post-operative pain (but do not give NSAIDs to pregnant patients).
- Consider wound infiltration with bupivacaine or lidocaine.
- Use local or regional anaesthetic as part of the overall strategy (see Section 1.24).

Prophylactic anti-emetics for children aged 4 years or older and in pregnancy when morphine is part of the post-operative pain control plan can be very effective (see Table 1.15.10).

### **Post-operative pain management**

- Provide analgesia before the pain becomes established; the amount of pain can often be anticipated depending on procedure.
- Use safe and effective doses of morphine along with other analgesics to reduce the amount of morphine required.
- Avoid intramuscular injections.
- **Assess, give analgesia, and then reassess.**
- Those most at risk of poor pain control are children with limited or no verbal ability.
- If the pain seems to be out of proportion to surgical trauma, consider the possibility of surgical complications and arranged reassessment by surgeons.
- If the patient is asleep, assume that the pain level is acceptable. Don't wake them up to make an assessment, count the respiratory rate and check regularly whether they are still asleep. If they are awake and lying quietly do not assume that they are comfortable without asking them.

### **Special issues with regard to pain in the newborn infant**

- Most studies (some of them controlled) have shown that neonates (both premature and full term) react to pain.
- Infants can easily be forced to put up with suffering.
- Small doses should be measured and given with an oral syringe.
- Adequate general anaesthesia, using morphine when needed, should be given for all surgical procedures on neonates.
- Local anaesthetics must be used when they would be used in an older child undergoing the same procedure.

### **Pain control during procedures in neonates**

- A sugar-dipped dummy, coated with 2 mL of 25–50% sucrose 2 minutes before the procedure, can be helpful.
- Breastfeeding during procedures may be equally helpful.
- In all cases, comfort and containment (swaddling) should be provided by a parent or nurse.

### **Pain management in high-dependency care**

- Where possible, all invasive procedures should be elective. Every effort should be made to avoid unexpected emergency procedures, such as intubation, by adequate monitoring of airway, oxygenation and chest movement.
- **Emergency procedures are frequently extremely painful, dangerous to the patient, and often can**

**be avoided by early recognition of a deteriorating condition (see Section 1.11).**

- Muscle relaxants should be avoided if possible and **never** be used unless the patient is pain free, sedated and being ventilated.
- Provide a day/night cycle (uninterrupted natural sleep can reduce the need for analgesia/sedation).
- Ensure that there is minimal noise and low lighting from 8 pm to 8 am.
- Emergency admissions at night should take place away from sleeping patients.
- Monitors should be set to alarm audibly only when this is essential.
- Consider the use of ear plugs, especially when the patient is paralysed.
- Provide human input through voice, touch, music, cuddling, rocking, holding and pacifying.
- Consider the use of distraction, play therapy, relaxation, behavioural techniques, hypnosis and aromatherapy, particularly for patients who are undergoing long-term intensive/high-dependency care.
- Provide privacy whenever possible.
- Be alert for depression after prolonged intensive care.
- Consider the use of methadone and clonidine for the control of morphine and sedation withdrawal after prolonged treatment.

### **Sedation**

Sedation is not recommended for use in pregnancy after the first trimester, because of the risks of re-gurgitation and aspiration if the airway is not protected.

A health worker skilled in anaesthesia should be asked for advice and help with managing conditions where sedation is being considered.

### **Sedation in children**

- This may be useful when added to analgesics for lengthy or repeated procedures. The aim of sedation is to make the procedure more comfortable while allowing verbal contact with the patient to be maintained.
- Start with a small dose IV, wait for 2–3 minutes, observe the response, and repeat the dose if necessary.
- Sedation relieves anxiety but not pain.
- Sedation may reduce a patient's ability to communicate discomfort, and therefore should **not** be given without concomitant analgesia if there is pain.
- Side effects include hyper-excitability or prolonged sedation, delaying discharge after the procedure.

Sedation and anaesthesia form a spectrum. If you give enough 'sedation' you can induce anaesthesia (i.e. loss of consciousness and the inability to feel pain). This is why it is not recommended in pregnancy, because of the increased risk of aspiration of stomach contents into the lungs, causing life-threatening pneumonia.

The fine distinction lies in the ability of the patient to maintain vital functions without assistance, and to respond to being roused (see Table 1.15.9).

**Any healthcare worker who is administering a sedative, especially a benzodiazepine, must stay with the patient and have available a bag-valve-mask of suitable size and be able to use it to ventilate the patient if they develop abnormally slow breathing.**

TABLE 1.15.9 The differences between sedation and anaesthesia

Vital function	Sedation	General anaesthesia
Response to being roused	Present	Absent
Respiration	Rate and depth may be slightly reduced	Rate and depth are markedly reduced or absent
Swallowing reflex	Present	Absent
Gag reflex	Present	Absent
Cough reflex	May be reduced	Absent
Cardiovascular stability	Mild hypotension may occur	Hypotension should be anticipated

Loss of any of the above reflexes is routine in anaesthetic environments, but should **not** occur when sedation is being provided.

### Minimum information required to prescribe sedation

**Anyone who is giving intravenous sedation could inadvertently produce anaesthesia, and must therefore be able to deal with the possible consequences. This means that they must be able to:**

- support respiration
- manage and maintain the airway
- use suction appropriately
- intubate if necessary.

High-dependency nursing (see Section 1.14) or peri-operative nursing care in the recovery room after surgery is required.

A combination of drugs may give better effects with fewer side effects than continually repeating doses of the same drug (e.g. morphine or ketamine combined with benzodiazepine). Each of the drugs should be given separately and the doses adjusted.

Some patients are difficult to sedate for predictable reasons (e.g. treatment for epilepsy may make the dose required much higher than normal).

Some patients are very resistant to sedation, possibly due to excessive anxiety, so the first dose of sedation may not succeed, and a higher dose may be needed.

Patients who need sedation should have their oral intake restricted as for anaesthesia.

Some children are more vulnerable to the effects of sedation, particularly those with respiratory or upper airway problems, causing complete upper airway obstruction and should not be sedated unless a health worker skilled in anaesthesia/airway management is present.

Sedation in children is difficult and potentially dangerous, and this practice is increasingly being abandoned.

- Children may refuse to take sedatives.
- The effects of sedatives in children are unpredictable.
- The interval between taking the medicine and becoming sedated, and also the time taken to recover, are difficult to predict in children.
- Some children, especially those who are very young, can take large doses of sedatives with no apparent effect.
- Some children become paradoxically over-excited as a result of taking sedatives.
- There is a danger that the dose needed to sedate a child will compromise the reflexes that protect the airway.

**Wherever possible, procedures in children should be done without sedation.** Instead ensure that, if possible, a parent

or other familiar caregiver can stay with the child to reassure and comfort them. Give good analgesia with ketamine, oral morphine and local anaesthesia, and use skilful restraint to keep the child still. Explain carefully to the child, if they are old enough to understand, what you are doing at each stage of the procedure, to reduce their anxiety and encourage their cooperation.

The minimum information required to prescribe sedation includes the following:

- age and weight if the patient is a child
- the procedure for which sedation is required
- the patient's previous sedation history
- any other drugs that are being taken
- **other major illnesses that affect respiratory function and upper airway competence**
- current health status, including coughs, colds and pyrexia
- oral intake status.

TABLE 1.15.10 Patients at risk of airway obstruction/respiratory depression from the effects of sedation

Risk factor	Underlying cause
<i>Impaired upper airway</i> Obstruction	Croup Foreign body Congenital stridor (e.g. Pierre–Robin syndrome, cleft palate) Baby with very blocked nose
Impaired reflexes	Pre-existing neuromuscular problems Swallowing difficulties Known bulbar problems, especially if combined with reflux
<i>Impaired central respiratory drive</i>	Head injury Drug effects (opiates) Raised intracranial pressure Impaired level of consciousness Encephalopathy (hypoxic, metabolic, infective)
<i>Impaired respiratory muscle function</i>	Neuropathy and myopathy Chronic illness and weakness Malnutrition Prematurity Infancy
<i>Impaired lung function</i>	Chest infection Pleural effusions Chronic lung disease
<i>Impaired cardiovascular function</i>	Haemorrhage Sepsis Drugs

**Sedative drugs commonly used for children****Promethazine (Phenergan)**

Give 0.5 mg/kg deep IM or IV or 1–2 mg/kg orally, up to a maximum of 50 mg.

**Chloral hydrate**

Chloral hydrate is more suitable for younger babies (less than 18 months of age or less than 15 kg), but may paradoxically worsen agitation (e.g. in Down's syndrome).

**TABLE 1.15.11 Sedative drugs**

Drug	Route	Onset	Duration	Dose
<i>Promethazine</i> Tablets: 10 mg	Oral	30 minutes to 1 hour	Up to 12 hours	Not recommended for patients under 2 years of age Children: 2–5 years, 15–20 mg 5–10 years, 20–25 mg 10–18 years, 25–50 mg
<i>Promethazine</i> Liquid injection: 25 mg/mL	Slow IV or deep IM injection	30 minutes to 1 hour	Up to 12 hours	1 month to 12 years: 0.5–1 mg/kg (up to a maximum of 25 mg) 12–18 years: 25–50 mg
<i>Chloral hydrate</i> Liquid: 100 mg/mL Suppositories: 100 mg and 500 mg	Oral or rectal	30 minutes to 1 hour	1–2 hours	Neonates to 12 years old: 30–50 mg/kg 12–18 years: 45–60 mg Maximum dose 1 g

**Management of long-term pain and pain during terminal care**

This is discussed in Section 1.16.

**Appendix: Alder Hey Triage Pain Score****Cry/voice**

Score 0: Child is not crying and, although they may be quiet, they are vocalising appropriately with carer or taking notice of surroundings.

Score 1: Child is crying but consolable/distractible or is excessively quiet and responding negatively to carer. On direct questioning the child says it is painful.

Score 2: Child is inconsolable, crying and/or complaining persistently about pain.

**Facial expression**

Score 0: Normal expression and affect.

Score 1: Some transient expressions that suggest pain/distress are witnessed, but less than 50% of the time.

Score 2: Persistent facial expressions suggesting pain/distress more than 50% of the time.

**Posture**

This relates to the child's behaviour towards the affected body area.

Score 0: Normal.

Score 1: Exhibiting increased awareness of the affected area (e.g. by touching, rubbing, pointing, sparing or limping).

Score 2: Affected area is held tense and defended so that touching it is deterred; non-weight-bearing.

**Movement**

This relates to how the child moves their whole body.

Score 0: Normal.

Score 1: Movement is reduced or the child is noted to be restless/uncomfortable.

Score 2: Movement is abnormal, either very still/rigid or writhing in agony/shaking.

**Colour (applicable only to children with paler skins)**

Score 0: Normal.

Score 1: Pale.

Score 2: Very pale 'green', the colour that can sometimes be seen with nausea or fainting – extreme pallor.

# 1.16 Palliative care for children in resource-limited countries

## Introduction

Most children who need palliative care in resource-limited countries will require identification and treatment in the community rather than in hospital. Moreover, in the presence of effective care and support networks, **home has frequently been demonstrated to be the best setting for palliative care for both the child and the family.**

A high proportion of children do not reach hospitals in Africa. This percentage ranges from approximately 57% in Uganda to 85% in Ethiopia. Also, hospitals need to be

aware that most families would wish for their child to die at home, where they can look after them and they can be buried with their ancestors near to the home. The cost of transporting a body is very high, so economic factors also play a part.

**Therefore any treatment that is given in the hospital must be of a kind that can be continued at home,** otherwise the child will never be able to leave the hospital. Healthcare workers in hospital, with the support of Ministries of Health and community leaders, must set up systems to help community health workers to provide care in the community, including the safe management of morphine treatment when it is required.

Allowing the family and child to choose the setting for palliative care is of great importance. However, it is recognised that the necessary resources may be minimal or absent in many locations, and local conditions will determine what options are available.

This section describes the use of affordable medications that have been proven to work in resource poor settings. In resource limited situations, it is vital that government funds are spent carefully on measures which work and are not too expensive thus ensuring that the poorest families can also receive their right to palliative care for their children.

Although palliative care actually means relief of symptoms in all care, the term is usually associated with relieving symptoms when the emphasis is no longer on curative treatment. The decision to stop or withdraw curative treatment will never be easy for parents or healthcare professionals, and may evolve over a period of time. **It is important, however, to state that even when we cannot cure the body, it is never true that nothing more can be done.**

Like all of us, children have personal needs, and careful attention must be given to the physical, social, emotional and spiritual needs of the child and their family. Staff, too, should be receiving support through what can be a distressing time.

## Essential healthcare for the dying child

- Include parents or familiar caregivers.
  - This matters at all times.
  - Their familiar presence will comfort the child.
  - Even apparently unconscious children may still know their parents' or caregivers' voices.
  - Parents invariably want to be able to provide care for their child. This is a natural wish and can aid their own coping strategies.
- Set realistic goals.
  - The art of terminal care is to know when both goal and treatment must change.
  - The goal is to help the child to enjoy and cope with what is left of their life.
  - It should be clearly and well communicated that resuscitation measures are not to be a feature of terminal care.

### BOX 1.16.1 WHO definition of palliative care

Palliative care is an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual.

Palliative care:

- provides relief from pain and other distressing symptoms
- affirms life and regards dying as a normal process
- intends neither to hasten nor to postpone death
- integrates the psychological and spiritual aspects of patient care
- offers a support system to help patients live as actively as possible until death
- offers a support system to help the family cope during the patient's illness and in their own bereavement
- uses a team approach to address the needs of patients and their families, including bereavement counselling, if indicated
- will enhance quality of life, and may also positively influence the course of illness
- is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better understand and manage distressing clinical complications.

### WHO definition of palliative care for children

- Palliative care for children is the active total care of the child's body, mind and spirit, and also involves giving support to the family.
- It begins when illness is diagnosed, and continues regardless of whether or not a child receives treatment directed at the disease.
- Health providers must evaluate and alleviate a child's physical, psychological, and social distress.
- Effective palliative care requires a broad multidisciplinary approach that includes the family and makes use of available community resources; it can be successfully implemented even if resources are limited.
- It can be provided in tertiary care facilities, in community health centres and even in children's homes.

- Our aim is now not to cure, and never to kill, but always to comfort.
- The social needs and goals of a dying child include access to siblings and friends to play with and talk to. They should be made welcome.
- Listen and explain.
  - It should be clear from the child’s deteriorating condition that the goals are changing and death is imminent. This must be gently explained and the parents’ and child’s questions answered. It is wise, especially with children, to clarify the real question that is being asked. Replies must be honest, but the truth should be shared sensitively, a little at a time.
  - Explanations are very important for both parents and children, and appropriate, understandable terms should be used.
  - Forewarning of procedures, with hugs and praise afterwards, will reduce fears and fantasies.
  - Honesty results in greater trust and cooperation than saying something won’t hurt when it will.
  - All of those involved, from a young child to an elderly grandparent, will harbour fears and anxieties. Active listening is a major part of caring for a dying child and their family. Great comfort can be derived from the acknowledgement and expression of anxiety, and this helps to dissipate the feelings of isolation that are frequently experienced.
  - Adolescents will also have particular concerns and worries, and often have spiritual needs as well. Spirituality is a major aspect of life even for younger children in Africa. All members of the team must be aware of this and ready to discuss it with them.
- List and treat the child’s symptoms.
  - In palliative care, symptom intervention and practical care are paramount.
  - Even with limited resources, symptoms can often be helped. Problem lists are a useful key to active needs.
  - The availability of drugs does not guarantee their skilful use, but when medication is used effectively it will make both life and death more bearable. It can be helpful to give the family a treatment chart showing times or relationship to sunrise and sunset (see Figure 1.16.1).

- The child and carer together should make a list of all the symptoms. This can guide palliation even when the cause is incurable.
- Ask the carer to chart extra doses required and any medication-related problems that arise.

The duration and nature of palliative care will be unique to each child and their particular disease. **For those children who cannot be cured (sadly they are the majority in resource-limited settings), highly effective symptom control is paramount to enable a good quality of life for the time that is remaining.**

It is essential to approach the management of any symptom systematically.

For palliative care issues concerning HIV infection, see Section 6.2.D.

### Common symptoms

#### Pain

For pain assessment, see Section 1.15.

#### Principles of pain control

Pain is probably the most common symptom in palliative care, and is frequently seen in both malignant and non-malignant disease. It is a complex sensation related to the physiological insult to the tissues, but is also influenced by psychological, social and cultural factors.

It is helpful to think of severe pain in terms of response to opioids.

- **Opioid-responsive** pain is relieved by opioids.
- **Opioid-semi-responsive** pain is relieved by the concurrent use of an opioid and an adjuvant drug.
- **Opioid-resistant** pain is not relieved by opioids.

Neuropathic or nerve pain is more likely to fall into the semi-responsive or unresponsive groups. Bone pain falls into the semi-responsive group.

#### Analgesic approaches to pain relief

**The optimal approach to pain management in children includes drug therapy, with analgesics usually being the mainstay of treatment. Correct use of analgesic drugs**

Medicine	Reason	Morning		Afternoon		Evening		Night
								Bedtime
		On Waking	10 am	12 noon	2 pm	6 pm	10 pm	
Morphine 5 mg in 5 mL	Pain	2.5 mL	2.5 mL		2.5 mL	2.5 mL		5 mL
Senna	Constipation						2	
Ibuprofen 200 mg	Pain	2		2		2		2

Medication chart for..... Date.....

FIGURE 1.16.1 Example of treatment chart for family use in the community.

will relieve pain in most children, and should be based on the four key concepts recommended by the WHO:

- by the **ladder**
- by the **clock** (or by the sun if there is no clock!)
- by **mouth**. Injections are not given at home because there are too few community health workers. Subcutaneous infusion pumps are not always acceptable, and also need close monitoring, which is often not possible
- by the **child or carer**.

#### By the ladder

Use the 'two-step' approach to analgesia, non-opioids and opioids. The second step in the three-step ladder that was proposed in 1986 by the WHO is now widely being omitted, and a two-step ladder is used instead (see Figure 1.16.2). This is because the middle step, namely codeine, is expensive and causes severe constipation, and if the child has cancer they will need morphine, so can commence with a small dose that can then be titrated to the pain. Pain is classified as mild, moderate or severe, and the analgesic choices are adjusted accordingly. The ladder approach is based on drugs that are widely available in most countries. The sequential use of analgesic drugs is based on the child's level of pain, with a non-opioid analgesic usually being the first step.

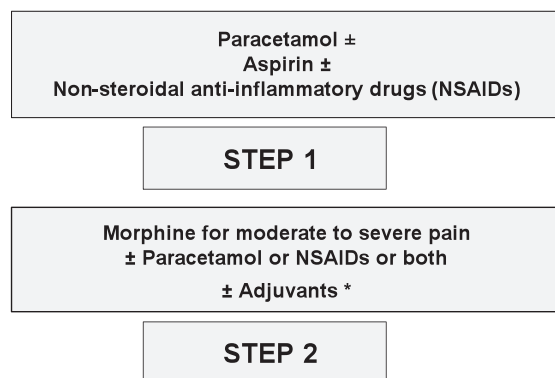

Importantly, however, assessment of a child's pain may indicate the need for immediate use of a strong opioid. Morphine is the safest and most effective opioid, and the only affordable one in resource-limited settings.

**There should be no hesitation in moving on to Step 2 of the analgesic ladder if pain control is inadequate.**

Only one drug from each pharmacological group should be used at the same time but remember that paracetamol plus a non-steroidal drug can be used together if there is no contraindication. Strong opioids can be increased until pain is relieved. Occasionally an alternative strong opioid (rarely affordable in resource-limited countries) may be substituted if side effects from the first opioid tried are intolerable.

The aim is for the child to be:

- pain free on movement
- pain free at rest
- pain free at night.

**FIGURE 1.16.2** WHO two-step analgesic ladder. \*An adjuvant is another drug (e.g. steroid or anxiolytic) or type of treatment (e.g. TENS or radiotherapy) that prevents but can also relieve pain.

#### By the clock (or by sunrise/sunset)

Analgesia should be given regularly (e.g. every 4 hours or according to the half-life).

**There is no place for 'when-requested' prescribing of**

**analgesics in palliative care. The dose must be titrated against that needed to control the pain of the individual patient.**

Paracetamol and ibuprofen should be given at the recommended doses (see Section 1.15), but the dose of morphine needed must be titrated against that needed to control the pain.

The dosing interval should be determined according to the severity of the child's pain and the duration of action of the drug being used. Additional 'rescue' doses for intermittent and breakthrough pain should be prescribed and explained to the family, so that these can be given as soon as breakthrough pain occurs.

The effectiveness of analgesia should be regularly reviewed, so that it can be titrated effectively against pain.

#### By the appropriate route

Children should receive drugs by the simplest, most effective and least painful route. For this reason the oral route is the preferred route.

IM injections should not be used. They are painful, and there is a risk of abscess and/or haematoma formation, particularly in children who may have low platelet counts or other blood-clotting problems. Also, use of the parenteral route means that the patient must be in hospital or a clinic and cannot go home. Children who are afraid of injections may deny that they are in pain and therefore suffer unnecessarily.

When selecting the best route of analgesic administration it is important to consider the nature and severity of the pain, the potency of the drug, the required dosing interval and the compliance of the child.

#### By the child

The doses of any analgesic must be based on the individual child's symptoms and circumstances. There is no single dose that will be appropriate for all children.

Regular reassessment of the child's pain and of the effectiveness of the analgesia is essential, so that the drug doses can be adjusted accordingly to keep the child pain free.

**For some children, particularly those with cancer-induced pain, very large doses of opioids may be required in order to achieve satisfactory pain control.**

Therefore it should be noted that some of the suggested dosage recommendations included in this section differ from those specified elsewhere in the manual. This is appropriate in palliative care, and it reflects the differences in goals and priorities between the acute setting and the palliative setting.

**CASE EXAMPLE:** Haji, aged 3 years, presented with a clinical diagnosis of retinoblastoma. He was in severe pain. The lesion was too friable for a biopsy. Morphine was commenced immediately, based on weight, according to the WHO recommendation for children. This was titrated against the pain, and Haji's pain was controlled on 100 mg 4-hourly and 100 mg at night. The radiologists allowed him to receive radiotherapy without a biopsy. The tumour disappeared. The morphine was reduced until he was pain free and well.

Today Haji is well, aged 9 years, and is attending school.

## Analgesics

### Non-opioid analgesics

Non-opioid analgesics are used to relieve mild pain or, in combination with opioids, to relieve moderate and severe pain. **Paracetamol** is the drug of choice because it has a very high therapeutic ratio for children and can be given orally or rectally. It is available in an elixir, tablet and suppository form, and can be given 4- to 6-hourly. Non-steroidal anti-inflammatory drugs (NSAIDs) such as **ibuprofen** and **diclofenac** are also helpful (for doses, see Section 1.15).

It is now recommended that one should progress straight from paracetamol and NSAIDs to morphine.

### Strong opioid analgesics (morphine)

Morphine is required either alone, or in combination with non-opioid analgesics and/or adjuvant drugs, to provide effective pain relief. Morphine does not have an analgesic 'ceiling affect' (i.e. there is no maximum dose), and children may require extremely large doses to obtain pain relief, but start at the recommended dose for severe pain (as described in Section 1.15).

**The strong opioid of choice internationally is oral morphine.**

The oral route is preferred for morphine, but if the subcutaneous or IV route is required, it can be given by a slow continuous infusion, which will give a steady level of analgesia and is preferred to intermittent subcutaneous or IV administration. Although a continuous infusion is commonly used in well-resourced countries, it is possible to achieve complete pain control with oral or rectal paracetamol or morphine in the palliative care setting. In resource-limited settings, children and their families may be alarmed by infusions.

Children have been found to rapidly eliminate morphine metabolites, and this is most marked in younger children (under 9 years). This group of children may require more frequent dosing and relatively higher doses to achieve pain relief. However, if oral doses are given at regular intervals, the most potent metabolite of morphine, M6G, accumulates and leads to smooth pain control.

**Morphine must be available in all countries.** However, this is not the case at present. In Africa, only 15 out of 56 countries have oral morphine available for use at home, which is where most terminally ill patients want to die. Oral morphine that is made up in the country or within a district of the country is the affordable ideal. The drug is then immediately available, so pain can easily be controlled with it.

More complicated formulae and preparations may be available as immediate- or sustained-release preparations, including immediate-release suppositories. Once-daily preparations are commercially available, but there is little experience of their use in children, and they are too expensive for most resource-limited countries. Ideally, morphine should be free to all in need, and prescribed by a recognised prescriber. Usually only doctors can prescribe. However, in Uganda, nurses can now prescribe after completing a Diploma in Palliative Care and clinical officers after a 9 week special training that emphasises prescribing methods and controls. Clinical officers have been trained for 4 years and can do more than nurses in most countries. In some African countries they are allowed to prescribe class A drugs after qualification.

### Immediate-release morphine (from the list of essential medicines for children published by the WHO in 2010)

- Morphine tablets (Sevredol): 10 mg, 20 mg and 50 mg.
- Morphine sulphate mixture (Oramorph): 10 mg/5 mL.
- Morphine sulphate mixture (Oramorph concentrate): 100 mg/5 mL.

The most affordable preparation is a morphine solution made from morphine powder in a pharmacy without the exorbitant profit taken by the 'middle man' (see Section 1.15).

The oral morphine starting dose is 150–300 microgram/kg every 4 hours.

Immediate-release morphine should be given regularly every 4 hours. It may be useful to increase the night-time dose by 50–100% to eliminate night-time waking. Immediate-release oral morphine is the best choice in children because it is easier to titrate exactly against the pain.

Sustained-release morphine tablets (MST Continus) (5 mg, 10 mg, 15 mg, 30 mg, 60 mg, 100 mg and 200 mg) and morphine granules for suspension (MST Continus) (20 mg, 30 mg, 60 mg, 100 mg and 200 mg), although available, are very expensive and therefore inappropriate for most situations in resource-limited countries. Those planning for a service must keep in mind the needs of the poor and spend the money available for morphine wisely so that there is enough for all in need.

### Breakthrough pain

Immediate-release morphine should be prescribed at a dose equivalent to the 4-hourly doses as soon as pain breaks through (i.e. 16–17% of the total daily dose). The WHO recommends that it should be 5–10% of the total daily dose. This can be given up to hourly for breakthrough pain, and the parents should be advised to keep a record of all extra doses given so that the regular dose of morphine can be titrated accurately, and more supplied as necessary.

### Titration of the morphine dose

Pain relief should be reviewed regularly. The morphine dose should be titrated against the level of pain. If frequent breakthrough analgesia is required, the total dose of morphine taken during the day (regular doses plus 'breakthrough' doses) must be assessed. Usually increments of 20–50% of the previous total daily dose are required. Regular review allows the regular dose of morphine to be adjusted according to the level of breakthrough pain. **Remember to**

**FIGURE 1.16.3** 'As needed' (PRN) versus 'by the clock' versus 'high dose'. Initially, to the left, the PRN dosage regime results in episodes of unrelieved pain. In the middle, too high a dose produces drowsiness. To the right, the by-the-clock dosage regime results in constant relief of pain without drowsiness. (Diagram supplied by Dr Anne Merriman.)

increase the dose of breakthrough morphine accordingly, when the regular dose is increased.

### Alternatives to oral route of administration

Indications for these include:

- persistent vomiting
- non-compliance with oral medication
- dysphagia
- bowel obstruction
- physical deterioration that prevents oral intake
- unsatisfactory response to oral medication.

### Rectal route

This route may be acceptable for some children who are unable to take oral medication. Any oral preparation can be given rectally with similar effects:

- Paracetamol can be given as a suppository.
- Morphine solution (see above) can be easily given rectally and is very effective.
- Morphine suppositories (10 mg, 15 mg, 20 mg or 30 mg) can be given if available.

Although one can use the same dose and interval as for the oral route (i.e. 4-hourly), this is traumatic for the child, and generally a larger dose given in tablet suppository form as half the daily dose 12-hourly is more acceptable.

### Subcutaneous route

Many drugs are well absorbed subcutaneously and can be easily established in those children who do not have established venous access. However, many resource-limited countries will not be able to use syringe drivers, and buccal and rectal administration may be just as effective, especially if human resources for managing the syringe driver/infusion pumps safely are not available, although some parents may be able to manage them.

### Changing from oral morphine to subcutaneous morphine

The potency of morphine administered by injection is approximately twice that of oral morphine. Therefore use **half of the total daily oral morphine dose** as the equivalent 24-hour morphine dose for subcutaneous infusion.

If syringe drivers are not available, parents can be trained to give regular boluses of morphine subcutaneously or IV at home. The total daily dose of either morphine or diamorphine is divided by a practical number that coincides with the number of individual doses to be given (usually 1- to 2-hourly during the day, and 4-hourly at night).

### Intravenous route

- This will usually only be indicated where a child has an established venous access, such as a Hickman line (unlikely to be available in most resource-limited countries), or when death is likely to occur within 7 days, when community health workers may place a peripheral venous cannula.
- Divide the total daily dose of oral morphine by two to obtain the equivalent daily dose of morphine given IV or subcutaneously.

As approximately 80% of children will die at home in resource-limited countries, oral or rectal morphine is likely to be the mainstay of treatment, with IV morphine only available to a small proportion of these patients.

Although diamorphine is the drug of choice for subcutaneous infusion, because it is more soluble, it is not available in most countries of the world. Divide the total daily dose of oral morphine by 3 to obtain the equivalent daily dose of diamorphine given IV or subcutaneously. The starting dose in opioid-naive patients is 12.5–25 micrograms/kg/hour by continuous infusion. For both subcutaneous and IV routes, the diamorphine should be titrated according to breakthrough pain in increments of 20–50%.

### Side effects of opioids

All opioid drugs cause similar side effects. These problems are well known, and should be anticipated and treated whenever children are given opioids, so that pain control is not accompanied by unacceptable side effects. When appropriate, parents and children should be informed about the possible side effects and their management. Children on strong opioids should be assessed regularly.

### Constipation

**This is a common side effect, and laxatives such as bisacodyl (dulcolax) or senna or sodium docusate must always be prescribed with strong opioids** (see below). Advice should be given to increase intake of fluids and fibre (vegetables, fruit and cereals) in the child's diet where appropriate.

### Nausea and vomiting

Routine anti-emetics are not commonly needed, but should be prescribed if required in case of opioid-induced nausea and vomiting. When such symptoms do occur, they normally resolve within 3 to 4 days.

### Drowsiness and confusion

Daytime drowsiness, dizziness and mental clouding can occur at the start of treatment and sometimes following a dose increase. They almost always resolve within a few days. Cognitive and psychomotor disturbances are minimal once the patient is receiving a stable dose of opioid.

### Pruritus

Itching is a not uncommon side effect of opioid treatment in children. Simple skin care alone may be effective. Also consider the following:

- Avoid hot baths
- Avoid using soap. Add Oilatum to the bath water and use aqueous cream as a soap substitute.
- Pat the skin dry rather than rubbing it.
- Avoid overheating and sweating.
- Use cool cotton clothing and bedding.
- Keep the fingernails short to reduce damage caused by scratching.

If itching is persistent, review the medication. If itching is opioid related and the drug cannot be changed, the addition of a systemic antihistamine such as chlorpheniramine may be beneficial.

Pruritus associated with obstructive jaundice will require good skin care plus systemic medication such as stanozolol, ondansetron or levomepromazine, if available.

### Respiratory depression

Respiratory depression is uncommon in the conscious patient with severe pain. If it does occur, management will

be dictated by the child's overall condition and the place of care.

### **Nightmares and hallucinations**

Both can occur. If they are distressing and not resolved by reassurance or resolution of other anxieties, try giving haloperidol at night (50–100 micrograms/kg).

### **Urinary retention**

Urine retention may be a problem, particularly after rapid dose escalation. Most children respond to simple measures such as a warm bath, warm packs or relief of constipation. Catheterisation may be required, but is usually only needed for a short period.

### **Morphine toxicity**

This can occur as a result of:

- too high a dose
- too rapid dose escalation
- pain that is not morphine responsive
- renal impairment
- previous therapeutic intervention to relieve pain (e.g. radiotherapy or nerve block).

Warning signs include:

- drowsiness
- confusion
- pinpoint pupils
- myoclonic jerks
- hallucinations (auditory and visual)
- vomiting
- nightmares.

If toxicity occurs, consider reducing the morphine dose (several doses may need to be missed), then restart at a lower dose or stop morphine altogether.

Toxicity is rare when morphine is titrated against the pain. Constipation is the worst complication, and can be prevented by introducing a laxative when morphine is started, unless the child has diarrhoea already, in which case the constipation would be beneficial for a few days, but the laxative needs to be introduced as soon as it ceases.

**Watch carefully for breakthrough pain.** Address any side effects as discussed above. Escalating doses of opioids and metabolic disorders can exacerbate myoclonic jerks. Oral diazepam can be useful. If the child is unable to swallow, rectal diazepam or subcutaneous midazolam are effective.

Consultation with healthcare professionals who are experienced in palliative care is recommended.

### **Addiction and tolerance**

Fear of addiction is not relevant when using opiates in palliative care, provided that a permanent source of opiates is available, **which must be the case**. In Uganda, in 2012, around 20000 patients had been treated with affordable oral liquid morphine, without any abuse or addiction. Approximately 30% of these cases were children.

### **Prescribing opioids in patients with renal impairment**

The active morphine metabolites are excreted by the kidney and accumulate in renal impairment, causing toxicity. When prescribing any opioid analgesics in children with renal failure, caution must be exercised, as patients with

renal failure are extremely sensitive to opioids. Renal failure is part of the dying process, and the team must be aware of this and reduce doses or increase time intervals as the child approaches death.

Suggested management strategies are as follows:

- Prescribe smaller doses of opioid analgesic.
- If problems with toxicity continue, consider giving smaller doses less frequently (i.e. 6- to 8-hourly).

### **Alternatives to oral morphine for severe pain**

For information on approaches that can be used in well-resourced settings, see the Further reading section on p. 91.

### **Adjuvant therapy**

Few children are truly morphine intolerant, and if the pain is not responding to morphine, always consider the aetiology of the pain and review the use of adjuvant therapy.

### **Neuropathic pain**

Co-analgesics such as an anticonvulsant or tricyclic antidepressants are essential, because this pain is only semi-responsive to opioids. The possibility of neuropathic pain should be considered if the pain has a burning or stabbing/shooting component. According to the WHO, there is no evidence on which to make recommendations for or against antidepressants and anticonvulsants. However, the WHO does agree that there is wide experience of the use of amitriptyline in children, and doctors are familiar with the use of the carbamazepine in children who have seizures. However phenytoin is more available, affordable and therefore of choice in less resourced countries. However some anti-retroviral drugs (ARVs) may interact with phenytoin so there is a need to check this out for children with HIV on ARVs.

### **Nerve compression pain**

This may arise from compression of a nerve root, and morphine plus a trial of oral steroids should be tried. The steroid should relieve pain within 48 hours, probably by reducing oedema around the tumour. If there is no improvement, steroid treatment should be discontinued.

### **Nerve injury pain**

This may arise either from tumour invasion of a nerve or as a side effect of radiotherapy.

### **Anticonvulsants**

These drugs are useful for pain that is shooting or stabbing. Carbamazepine and sodium valproate are commonly used. Clonazepam and gabapentin are more recent additions that are not widely available in resource-limited countries. The cheapest, most effective drug with the fewest side effects is phenytoin.

Start at a low dose and gradually increase the dose to avoid sedation and toxicity. Low doses are usually the most effective, and this therapy should stop if the pain does not respond to low doses.

### **Carbamazepine**

This drug is expensive, has side effects, and needs to be monitored, so is not so useful in the community setting.

- Starting dose: 2.5 mg/kg twice daily, increasing by 2.5–5 mg/kg/day at weekly intervals.

- Maintenance dose: 10–20 mg/kg/day in two to three divided doses, increasing gradually as above.

This corresponds to the *British National Formulary for Children (BNFC)* dose for epilepsy and trigeminal neuralgia.

#### Sodium valproate (often not available)

- Starting dose: 20 mg/kg/day in two divided doses, increasing if required by increments of 5 mg/kg at weekly intervals.
- Maintenance dose: 20–30 mg/kg/24 hours in divided doses.

The *BNFC* doses for epilepsy are:

- Age < 12 years: initially 10–15 mg/kg/day in one to two divided doses, increasing to 25–30 mg/kg/day in two divided doses.
- Age ≥ 12 years: initially 600 mg/day in one to two divided doses, increasing by 150–300 mg every 3 days to 1–2 g/day (maximum of 2.5 g/day) in two divided doses.

#### Phenytoin

- Age < 12 years: (1.5–2.5 mg/kg starting dose to target) and then 2.5–5 mg/kg twice daily (maximum 7.5 mg/kg twice daily or 300 mg once daily).
- Age 12–18 years: 75–150 mg adjusted according to response up to 150–200 mg twice daily (maximum 300 mg twice daily).

The *BNFC* doses for epilepsy are:

- Age < 12 years: 1.5–2.5 mg/kg twice daily, increasing to 2.5–5 mg/kg twice daily (usual maximum 7.5 mg/kg twice daily).
- Age ≥ 12 years: 75–150 mg twice daily, increasing to 150–200 mg twice daily (maximum 300 mg twice daily).

#### Tricyclic antidepressants

- These drugs are useful for pain that is burning in nature.
- Give at night to avoid excessive sedation during the day. They can cause constipation.
- The analgesic effect begins after about 3–7 days of treatment, but may take longer than this.
- Starting dose: amitriptyline 0.5 mg/kg at night increasing, if needed, to 1 mg/kg/day. Increase carefully to avoid excessive drowsiness. Lower doses are the most effective.

The *BNFC* doses for neuropathic pain are:

- Age 2–12 years: 0.2–0.5 mg/kg (maximum 10 mg), increasing gradually to a maximum of 1 mg/kg twice daily.
- Age > 12 years: 10 mg at night, increasing gradually up to 75 mg at night if needed.

For difficult cases, consider referral to or discussion with a pain control team if one is available.

#### Bone pain

##### Non-steroidal anti-inflammatory drugs (NSAIDs)

- NSAIDs have analgesic, anti-pyretic and anti-inflammatory properties. They are often effective in relieving musculoskeletal pain that is associated with bone metastases or soft tissue inflammation.

- Regular dosing is required for their full effect, but the maximum effect is usually seen within 2 weeks.
- It is worth trying another NSAID if there is no response to the first type.
- Damage to the gastrointestinal mucosa is the most frequent side effect. Gastric erosion and bleeding can be severe and difficult to control. If possible, ensure that NSAIDs are taken after food.
- NSAIDs are not usually appropriate for children with thrombocytopenia, because of their potential to cause gastric erosions and so increased tendency to bleed.
- According to the WHO there is no evidence for recommending the use of bisphosphonates in children. In adults, modest improvements in pain have been observed, but also serious side effects such as osteonecrosis of the jaw.

For common dosages of NSAIDs, see Section 1.15.

#### Steroids

Steroids have specific benefits in palliative care because of their ability to produce euphoria, improve appetite and increase weight gain. They also have an anti-inflammatory effect, which may be helpful in patients with nerve compression and raised intracranial pressure.

However, steroids should be used with caution in children, as the side effects of long-term steroid treatment can far outweigh its benefits. They include rapid weight gain, change in appearance, mood swings, behaviour changes and insomnia, which can be distressing for both the child and the parents, and the risk of gastric erosions. Most children experience symptom relief after short intensive courses, and if the prognosis is long, steroids should be withdrawn. If there is no improvement in symptoms within a short period of time (e.g. 5–7 days), steroids should be discontinued. If the initial symptom relief is not maintained, long-term use of these drugs should be avoided.

#### Dexamethasone

Dexamethasone should be taken before 6 pm, and ideally in the morning, in order to minimise insomnia.

**High-dose** dexamethasone is normally used to relieve pain associated with raised intracranial pressure, or spinal cord or nerve compression. Give steroids in the morning to avoid sleepless nights and to copy the normal diurnal rhythm of cortisol.

The initial dose is given in the morning as 25 mg for patients over 35 kg and 20 mg for patients less than 35 kg, followed by a sliding scale of reducing by 4 mg every 3 days until down to 10 mg per day, then continuing to decrease by 1–2 mg per day.

IM or IV in an emergency or until can swallow (usually once only):

- Age 1 month to 12 years: 100–400 micrograms/kg, once daily in the morning.
- Age 12–18 years: 8–24 mg daily.

**Low-dose** dexamethasone is normally used to improve appetite and well-being.

- Age 2–8 years: 0.5–1 mg, once daily in the morning.
- Age > 8 years: 1–2 mg, once daily in the morning.
- Radiotherapy.

This therapy is only available in just over half the countries in Africa.

Radiotherapy can be particularly useful for treating isolated sites of a disease if a tumour is radiosensitive. This may include bony metastases, spinal cord compression, and relief of nerve compression from a solid tumour and isolated cerebral metastases. Radiotherapy can also be used in the management of fungating tumours. Single treatments or short courses are often appropriate and effective in palliative care, if radiotherapy is available.

### Non-pharmacological approaches

Non-drug therapies must be an integral part of the management of children's pain, complementing but not replacing appropriate drug therapy.

A combination of non-pharmacological approaches, used in conjunction with analgesics, may be extremely effective. These approaches include:

- progressive relaxation
- diversional therapy with music, art or traditional games, according to the age of the child
- hypnosis and guided imagery
- massage and reflexology
- heat pads or cold packs
- transcutaneous electrical nerve stimulation (TENS).

## Management of other symptoms

### Nausea and vomiting

These are common symptoms in palliative care. The causes may be multifactorial, and it is important to try to determine the cause(s) in order to implement an effective treatment plan.

#### Common causes

Cancer-related causes include:

- raised intracranial pressure
- the presence of an abdominal mass
- irritation of the upper gastrointestinal tract
- gastric outflow obstruction
- anxiety
- uraemia
- pain
- blood in the stomach.

Treatment-related causes mainly involve the side effects of drugs, especially:

- opioids
- chemotherapy
- NSAIDs
- carbamazepine
- antibiotics.

#### Management

- Identify the cause(s) as described above (e.g. constipation, raised intracranial pressure) and implement appropriate management.
- Consider stopping gastric irritants such as antibiotics, NSAIDs and steroids if possible.
- Prescribe an H<sub>2</sub>-receptor antagonist (ranitidine, 2–4 mg/kg 12-hourly, or cimetidine, 5–10 mg/kg 6-hourly).
- Or the proton pump inhibitor omeprazole (age < 2 years, 700 micrograms/kg once daily increased to 3 mg/kg once daily, maximum dose of 20 mg once daily; body

weight 10–20 kg, 10 mg once daily, increased to 20 mg if needed; body weight over 20 kg, 20 mg daily increased to 40 mg once daily if needed. Give the higher dose for 12 weeks only).

- Prescribe an appropriate anti-emetic according to cause.
- Review the therapy regularly and adjust it as required.
- IV fluids may be needed to counteract dehydration, but nasogastric tube insertion should be avoided where possible.
- If treatment is unsuccessful, consider the following:
  - Was the cause of the vomiting correctly identified and the appropriate anti-emetic prescribed?
  - Has the anti-emetic had time to work at maximum dose?
  - Is the route of administration appropriate for the child?

#### Anti-emetic therapy

Severe nausea and vomiting may require initial management by subcutaneous or IV infusion and then switching to oral medication when control is gained. The choice of anti-emetic depends on the cause of vomiting and the site of the anti-emetic action, so combinations of drugs with different sites of action are sometimes required, but to avoid side effects, avoid combining drugs of the same class. Extra-pyramidal side effects can occur with cyclizine, metoclopramide and domperidone (see Section 1.15).

**Haloperidol** is the anti-emetic of choice for opioid-induced vomiting. It acts on the chemoreceptor trigger zone.

Dosage: 12.5–25 micrograms/kg twice daily by mouth, subcutaneously or IV. Haloperidol can be given orally at night.

**Cyclizine** is used for nausea and vomiting caused by raised intracranial pressure or intestinal obstruction.

Dosage: all ages, by mouth, 1 mg/kg three times daily up to a maximum of 50 mg per dose.

The *BNFC* doses are as follows:

Oral or rectal route:

- Age < 6 years: 500 microgram–1 mg/kg (rectal 12.5 mg) up to three times daily
- Age 6–12 years: 25 mg up to three times daily
- Age > 12 years: 50 mg up to three times daily.

IV or subcutaneous route:

- All ages, 1 mg/kg 8-hourly or

Continuous IV/subcutaneous infusion:

- Age < 2 years: 3 mg/kg over 24 hours
- Age 2–5 years: 50 mg over 24 hours
- Age 6–12 years: 75 mg over 24 hours
- Age > 12 years: 150 mg over 24 hours.

#### Dexamethasone

Dosage: use moderate doses (e.g. 100 micrograms/kg 12-hourly).

#### Metoclopramide

This acts on both the upper gastrointestinal tract and the chemoreceptor trigger zone, and speeds up gastric emptying. The extrapyramidal side effects are more common in children. It is useful for oesophageal reflux, gastric stasis, gastric irritation, gastric outflow and high bowel obstruction.

Its use should be avoided in patients where there is complete bowel obstruction.

Dosage:

Oral route:

- Age 1–12 years: 100 micrograms/kg, two to three times a day
- Age > 12 years: 5–10 mg, two to three times a day.

Subcutaneous/IV route:

- Age 1–12 years: 500 micrograms/kg over 24 hours
- Age > 12 years: 15–30 mg over 24 hours.

**Domperidone** acts on both the upper gastrointestinal tract and the chemoreceptor trigger zone, and speeds up gastric emptying.

Dosage:

Oral route:

- Age 1–12 years: 200–400 micrograms/kg, three to four times a day
- Age > 12 years: 10–20 mg, three to four times a day.

Rectal route:

- Age 1–12 years: 15–30 mg, two to three times a day
- Age > 12 years: 30–60 mg, two to three times a day.

### Constipation

Constipation is common in paediatric palliative care, and the causes may be multi-factorial. The prevention and relief of constipation in the terminally ill child is very important, as if left unresolved it can cause abdominal pain and discomfort, and nausea and vomiting.

Consider the following causes:

- drug induced (e.g. opioids, anticholinergics, antidepressants)
- reduced physical activity
- poor oral intake and general debility
- dehydration
- bowel obstruction
- spinal cord compression.

### Management

- Treat the underlying cause where this is appropriate and possible.
- Constipation should be anticipated when opioid, anticholinergic or antidepressant drugs are being used, and laxatives should be prescribed prophylactically.
- Use laxatives appropriately and at the right doses, and avoid mixing two drugs from the same group (e.g. two stimulants).
- A good first choice is the combination of a stimulant laxative and a softening agent (e.g. senna plus sodium docusate).
- Titrate doses up as required, rather than adding a new laxative.
- If oral therapy fails, consider rectal measures such as suppositories/enemas.

### Bowel obstruction

Bowel obstruction may be mechanical or functional, or both. The aim is to control pain and nausea. In children with advanced disease, surgical management is not usually indicated. The aim of treatment is the palliation of symptoms. Nasogastric tubes and IV fluids are rarely appropriate,

although for persistent vomiting due to obstruction a nasogastric tube may be helpful.

### Management

#### Elimination of pain and colic:

- For constant background pain, administer buccal morphine solution or morphine by continuous IV or subcutaneous infusion, using a portable syringe driver.
- If colic is present, avoid prokinetic anti-emetics (e.g. metoclopramide, domperidone).
- Discontinue bulk-forming, osmotic and stimulant laxatives.
- Relieve associated constipation, continue to use softening agents if possible, and use rectal measures to relieve faecal impaction.
- If colic persists, add hyoscine butylbromide (Buscopan), 10–20 mg orally 8-hourly or give IV as a single dose over at least 1 minute (age 2–5 years, 5 mg IV; 6–10 years, 10 mg IV; 11–15 years, 15 mg IV; 15–18 years, 20 mg IV). Repeat 8-hourly as required.

#### Elimination of nausea and reduction of vomiting

- The choice of anti-emetic depends on whether colic is present.
- If colic is present, cyclizine is the first-line drug. Add haloperidol if nausea persists.
- If colic is absent and flatus is present, a trial of subcutaneous or IV metoclopramide is indicated. If this is ineffective, instigate management as described above.
- Dexamethasone may be of benefit in second-line management.

### Dyspnoea

Shortness of breath associated with pulmonary complications in advanced paediatric cancer can be very distressing for both the child and the parents, and requires effective management. The underlying pathophysiology needs to be considered when deciding on the management.

Common causes of dyspnoea include:

- metastases
- effusions
- pulmonary fibrosis
- anaemia
- infection
- superior vena cava (SVC) obstruction
- anxiety/fear
- increased secretions
- cardiac failure
- chest wall pain or constriction
- pulmonary embolus
- gross ascites.

### Management

- Identify the cause.
- Give a clear explanation to the parents and the child.
- Treat the specific cause(s) or modify the pathological process (e.g. high-dose steroids and radiotherapy for superior vena caval obstruction).
- Non-drug measures are also important and include:
  - a calm approach
  - breathing exercises
  - an appropriate position
  - providing cool air (e.g. with a fan)
  - play therapy.

## Drug treatment

**Morphine** has a complex effect on respiration, which is not fully understood. It can reduce the respiratory rate to a more comfortable level. This drug should be prescribed regularly in children with continuous breathlessness at standard analgesic starting doses. If the child is already on morphine, increase the dose by 30–50%.

The anxiolytic and sedative effects of **benzodiazepines** also cause relaxation of the respiratory muscles. This may be helpful if the child or teenager is very anxious, and these drugs should be administered as a single dose and then at night or twice daily. The long half-life of benzodiazepines (around 36 hours) means that they should be avoided if possible.

**Diazepam** (oral route):

Dosage:

- Age 4 weeks to 1 year: 200 micrograms/kg, two to three times daily
- Age 1–12 years: 2 mg, two to three times daily
- Age > 12 years: 5–10 mg, two to three times daily.

**Lorazepam** is not always available, but is well absorbed sublingually (so is useful for panic attacks), short acting, with a rapid onset of relief and a shorter half-life.

Dosage:

- Age 1–12 years: 50–100 micrograms/kg (maximum of 4 mg per dose) (*BNFC*).
- Age > 12 years: 1–4 mg per dose. The dose may be repeated after 12 hours.

**Corticosteroids** may be useful, particularly in patients with superior vena caval obstruction and multiple lung metastases. Moderate doses of dexamethasone should be used and the benefit should be apparent within 5 days. The dose should then be reduced to the lowest effective dose.

**Oxygen** will be of benefit for hypoxic patients, but is rarely available for home use. It may also be helpful if a child is very anxious.

Nebulised saline or **salbutamol** may provide subjective relief, especially if wheezing is present.

## Cough

Consider the following causes:

- respiratory infection
- airways disease
- malignant obstruction
- drug induced
- oesophageal reflux
- aspiration of saliva.

Wherever possible, the cause of the cough should be treated. Symptomatic management should follow the guidelines for the management of dyspnoea.

Drug management may include the following:

- simple linctus
- codeine linctus (this will cause constipation, so add a stool softener)
- opioids (as above)
- nebulised saline
- oral antibiotics (these are indicated if symptomatic chest infection with a productive cough is affecting quality of life).

## Anxiety

Anxiety is not uncommon in palliative care. Talk to the child and give enough time to both the child and the parents or carers to discover the cause, and give reassurance. Try to identify the cause of the child's anxiety (e.g. whether it is related to symptoms or fears about what is happening). Simple explanations, reassurance and a calm environment are important. Physical therapies such as relaxation and massage may be helpful, or anxiolytics such as diazepam or lorazepam as required or regularly may be of benefit if other measures fail.

Anxiety and discomfort go together, so reassess the child's pain.

## Bleeding

### Massive external bleeding

**Death from massive external bleeding is uncommon in children, but the risk of this is frightening and distressing for both the child and the parents, and prevention of such bleeding should be the aim of management, although this may not always be possible.**

Causes of external bleeding include the following:

- a low platelet count
- clotting deficiencies
- primary or secondary liver disease
- disease progression
- initial treatment (e.g. radiotherapy, chemotherapy).

### Management

If there is a risk of massive haemorrhage, it is extremely valuable to have IV or subcutaneous morphine and an appropriate sedative (e.g. rectal diazepam, buccal midazolam) readily available at home.

### Persistent surface bleeding

This is not uncommon in children with leukaemia, and can be alarming to both the child and their family, but can be managed in the home environment.

### Management

- Topical treatment soaking gauze in adrenaline 1 in 1000 solution and applying it directly to the bleeding point.
- Other haemostatic dressings can be used for persistent surface bleeding (e.g. in fungating tumours). These include crushed metronidazole sprinkled on to the area, or an alginate dressing such as **Kaltostat** if this is available.
- **Tranexamic acid** can be useful if it is available, and can be used topically undiluted, applied directly to bleeding gums or nostrils, or used as a mouthwash. It can also be given systemically or parenterally as prophylaxis.
- The use of a dark-coloured handkerchief or towel at home to mop up the blood may help to reduce anxiety.

### Spinal cord compression

Consider spinal cord compression if the following signs and symptoms are present:

- localised pain in the spine, radiating around the chest
- sudden onset of weakness (e.g. of the legs)
- sensory disturbance
- sphincter dysfunction.

**This is usually a clinical diagnosis, and action needs to be taken immediately.**

Investigations such as computerised tomography (CT) and magnetic resonance imaging (MRI) are not usually available.

### Management

- Patients with paraparesis have a better prognosis than those who are totally paraplegic.
- Loss of sphincter function is a poor prognostic sign.
- Rapid onset of complete paraplegia has a poor prognosis.
- The main therapeutic options are:
  - corticosteroids that can shrink the tumour and relieve spinal cord compression
  - radiotherapy.
- Steroids should be given in high doses initially and then reduced according to the response. These drugs often bring about an early improvement and relief of pain by reducing the peri-tumour inflammation. Give steroids in the morning to avoid insomnia and to copy the normal diurnal rhythm of cortisol.
- High-dose **dexamethasone**: The initial dose is given in the morning as 25 mg for patients over 35 kg and 20 mg for patients less than 35 kg, followed by a sliding scale of reducing by 4 mg every 3 days until down to 10 mg per day, then continuing to decrease by 1–2 mg per day. The initial dose can be given IV if urgency required but oral doses should then follow. However, if symptoms recur revert to a higher maintenance dose.
- Referral for concurrent radiotherapy should be considered if the prognosis is not very poor. This therapy is not available in around 30% of African countries, and unless the parents have enough financial resources to take their child to another country, palliative support is the best option.
- Surgery, such as laminectomy, is only rarely indicated.
- Consider using a pressure-relieving mattress, and give pressure area care.
- Pay attention to bowel function.
- Start physiotherapy to prevent contractures.
- Perform catheterisation.
- Avoid danthron-containing laxatives if the child is catheterised or incontinent, because of the risk of danthron burns.

### Psychological support

Children experience significant psychological suffering as a result of loss of their ability to walk or run, as well as their inability to play and go to school. They therefore need understanding and sympathetic advice from their healthcare provider and carer at this time.

### Convulsions

Convulsions may be a potential or existing problem for children with brain tumours or other neurological and metabolic disorders.

For emergency management of seizures in palliative and terminal care, **diazepam** given rectally is the drug of choice.

Dosage:

- Age < 1 year: 2.5 mg (half of a 5 mg rectal tube/rectal solution)
- Age 1–4 years: one 5 mg rectal tube/rectal solution
- Age 5–12 years: 5 mg or 10 mg rectal tube/rectal solution
- Age > 12 years: 10 mg rectal tube/rectal solution.

For continuing severe seizures, consider giving midazolam by the buccal route, subcutaneously or by IV infusion if the

child is in hospital (see Section 5.16.E). Care is required with midazolam as it may give permanent anaesthesia so that communication becomes impossible.

### Muscle spasm

Muscle spasm can be severe in children with neurological and neurodegenerative disorders. It may occur alone or be triggered by pain elsewhere (e.g. due to constipation).

#### Useful drugs for muscle spasm

**Diazepam** orally (initial doses are shown):

- Age 1 month to 1 year: 250 microgram/kg twice daily
- Age 1–5 years: 2.5 mg twice daily
- Age 5–12 years: 5 mg twice daily
- Age > 12 years: 10 mg twice daily up to a maximum dose of 40 mg/day (*BNFC*).

#### Baclofen orally

- Age 1–10 years: initial dose 300 microgram/kg/day in four divided doses, increasing to usual dose of 0.75–2 mg/kg/day in divided doses
- Age > 10 years: 5 mg three times daily, increasing to 20 mg three times daily (up to a maximum dose of 100 mg/day).

### Incontinence

Incontinence can be the source of much discomfort and anxiety for both children and their families, as well as presenting difficulties in keeping the child clean and protecting their skin.

Children with some degenerative conditions may have had faecal or urinary incontinence for a long time, whereas for others this may become a feature during the end stage of their disease (e.g. due to local tumour, neurological/spinal cord damage to bladder control, laxative imbalance).

For children with long-standing difficulties, intermittent catheterisation or the use of an indwelling catheter may be a well-established, successful and accepted method (see Section 4.2.D).

Some useful suggestions include the following:

- Review laxatives where appropriate.
- Consider giving intranasal **desmopressin**, 20–40 micrograms at bedtime, if nights are disturbed by urinary incontinence. Alternatively, desmopressin tablets, 200–400 micrograms, or sublingual tablets, 120–240 micrograms, can be used (*BNFC* doses for enuresis). Care is needed as desmopressin can cause water retention and hyponatraemia, so start with lower doses.
- Keep a urinal or bedpan close to the bedside.
- Use cotton pads or towels (with plastic underneath) on top of the bed sheet. This will avoid the need to change all the sheets, and thus minimise disturbance to the child.
- Keep the area well ventilated (or keep a window open if appropriate).
- Try to ensure that the skin is kept clean, and use dimethicone, zinc and castor oil or other barrier creams if these are available.
- Help the child to wash regularly.
- Try to preserve and maintain the child's dignity at all times. Give reassurance and support to both the child and the parents.

## Fungating wounds

Fungating wounds are rare in paediatric palliative care, but in resource-limited settings they are not infrequently encountered. They may occur with soft tissue sarcomas, often of the head and neck, which can be very distressing for the child and their family.

Useful tips for management (where available) include the following:

- Soak any dressings with saline or Ringer-lactate or Hartmann's solution to ease removal, as these tumours may be friable and prone to bleeding.
- If possible, have available topical adrenaline 1 in 1000, or an alginate dressing (e.g. Kaltostat, or tranexamic acid), to apply topically to the tumour if it bleeds profusely (e.g. during a dressing change).

These tumours can cause offensive smells due to anaerobic microorganisms, which can be distressing to the child and their family. Sprinkle crushed metronidazole tablets on the fungating area. Oral metronidazole does not penetrate the fungating area, as the blood supply to it is poor. Metronidazole is cheap and readily available in all resource-limited countries, and it is very effective. Charcoal dressings, if available, may help to absorb the odour. The use of honey for dressings is also of benefit in controlling bacteria and odour. Simple measures such as the use of aromatherapy oils around the home may be helpful, too.

## The final days and hours of life

### Terminal restlessness and agitation

These symptoms are not uncommon in the final stages of life. Useful drugs include buccal midazolam, and oral or rectal diazepam.

**Midazolam** is the sedative of choice, as it can be given via the buccal mucosa.

Dosage:

The initial regime is 30–100 micrograms/kg given as required. Titrate upwards as required (the upper dose may be limited by volume).

**Rectal diazepam** may also be useful.

Dosage:

5–10 mg rectal tube as required. The dose may be repeated if child remains very agitated and restless.

### Increased secretions

- Increased secretions (the 'death rattle') can be more distressing for the parents and carers than for the child. It is important to explain this to those caring for the child.
- Good mouth care is essential.
- Anti-secretory agents are useful, but can cause drowsiness and anti-cholinergic side effects.
- Start drug treatment early in order to avoid build-up of excessive secretions.

### Hyoscine hydrobromide (scopolamine)

- This drug is anticholinergic.
- It reduces pharyngeal secretions.
- It should be used prophylactically at the first sign of excess secretions.
- It mixes with other commonly used drugs.
- Potential routes for administration: oral, as a sublingual tablet, IV or subcutaneous.

Dosage:

Oral/sublingual route:

- Age 1–12 years: 10 micrograms/kg/dose, four times a day
- Age > 12 years: 300 micrograms/dose, four times a day.

Subcutaneous or IV infusion:

- All ages: 10–50 micrograms/kg/24 hours.

### Loss of the oral route for food and medication

As a child's condition deteriorates it may become difficult to use the oral route for medication. Buccal and rectal routes are the best options in this situation, and work well. As discussed earlier, other routes that can be used at this point are the rectal, subcutaneous and (where already established) IV routes. Children who have been treated for cancer in well-resourced hospitals may have central IV access, which can be used effectively in palliative care, but usually only in hospital.

Drugs that can be given via the subcutaneous or IV route include analgesics, anti-emetics, sedatives, anxiolytics and anticholinergic drugs. These can be combined together in an infusion, provided that they are compatible with each other.

If they are available, it is possible to use small portable infusion pumps (e.g. Graseby MS 26, WalkMed) to deliver combinations of medication over 24 hours. However, these devices are unlikely to be available for home use in these resource-limited countries, and home palliative care teams would not generally be able to provide this form of treatment. Sometimes individual carers may be able to manage this form of treatment.

### Additional notes

- Avoid administering high concentrations of drugs in combination, especially when using cyclizine.
- Avoid mixing dexamethasone with other drugs if possible.
- Never give chlorpromazine, prochlorperazine or diazepam subcutaneously.
- More than two drugs can be combined in portable syringe drivers, although there is little supporting evidence in the form of clinical data. Always consult your local pharmacist before using any unusual combinations.

### Psychological support for the child, parents and siblings

Care that is child and family centred is an essential principle of palliative care. The availability of an experienced key worker to coordinate the child's care with community healthcare professionals is essential, with good communication both between professionals and between professionals and the family being of paramount importance.

Initially, parents may need a lot of support when deciding whether to withdraw curative treatment and where to care for their child. Whether the care setting is in hospital or at home, the parents will have many questions, fears and anxieties at this time, and if possible the opportunity to discuss their worries, changes in the child's condition and symptom management should be available 24 hours a day. Commonly asked questions include 'How long will it be?' and 'How will my child die?' These questions are not easy to answer, and will also depend on the nature of

the child's illness. For example, a child with leukaemia may have a very short period of palliative care, whereas a child with a brain tumour or neurodegenerative disease may live for several months. It is probably best to give an indication of time span, but to emphasise that every child is different, and to guide the parents as the disease progresses. 'Days or weeks', 'weeks or months' or even 'hours rather than days' give adequate warning without being too precise.

Parents may worry about their child being in pain, but also have anxieties about the use of strong medication such as morphine. A clear explanation of the use of analgesics is essential in this situation.

Many parents will want advice on talking to the dying child and their siblings. How to prepare the child's brothers and sisters will depend very much on their age and level of understanding, and on parental beliefs. For older children and teenagers it is probably best to be honest, to prepare them gradually for what is happening and allow them to ask questions and participate in their sibling's care if appropriate. With younger children, the language used must be very simple and clear. For example, it is important to avoid using the phrase 'going to sleep' as the analogy for death. It is probably more appropriate to prepare younger children for a sibling's death when the end is obviously very close. Cultural preferences also need to be taken into account.

Talking to the child who is dying is a very personal matter for parents, and will also be influenced by the child's age and understanding of the illness. For example, a teenager with cystic fibrosis may have anticipated death in adolescence or young adulthood, and a teenager who has had multiple relapses of cancer for many years may now realise that the treatment is no longer working. Where possible and appropriate, it is important that children and teenagers are given the opportunity to express their wishes and anxieties. When children are not allowed to express themselves they can become very anxious and agitated, or even withdrawn. Healthcare professionals can only try to encourage the parents to have an open and honest approach to their child's questions and wishes at this time.

### Preparation for death

Parents commonly have many questions about the time and nature of death, and what happens afterwards. It can be very helpful to try to prepare them for what may happen at the time of death if they wish to have this information. Changes in breathing are commonly distressing, and simple explanations of, for example, Cheyne–Stokes respiration or the 'death rattle' can avoid unnecessary distress. A single expiratory breath after death if the child is moved is not uncommon, and it should be explained to the parents that this does not mean that their child is still alive. Explanations of the changes in colour and very cold feel of the skin are important for parents and siblings. If they are not warned in advance, parents may become distressed that their child was incontinent at the time of death. In the case of some diseases (e.g. leukaemia), the parents will need to be warned that their child may bleed from the nose or mouth at the time of or after death, and given simple practical measures for managing this situation.

Some families will require professional support around the time of the child's death, and it is essential that this is available.

After their child has died, the parents must be reassured that they need not rush to do anything, but may spend some

time with their child. However, it is also important that any specific cultural or religious requirements are acknowledged and attended to. The parents should be encouraged, if they wish to do so, to hold, wash and dress their child. Some parents may want to take photographs, locks of hair, or hand and foot prints, or organise favourite toys, photographs, letters or other items for the child 'to take with them'. The participation of siblings in these activities can be very helpful.

In countries where it is usually necessary for a child's death to be confirmed by a medical practitioner it is very rare for a post-mortem to be required. The death certificate then gives the authority for the death to be registered (according to each country's prevailing law) and the funeral arrangements to be made.

The specific cultural and religious beliefs of the family and the country in which they live will play an important role in the child's funeral. However, the parents may need advice about the choice between burial or cremation, or about the funeral service itself.

### Support after death

Support for parents, siblings and the extended family around the time of the child's death and in the weeks and months afterwards will be very much influenced by the family's culture and family network, and by the support provided during the child's terminal care. Bereavement contact from the professionals involved with the family should be offered wherever possible.

Clinicians need to be aware of the cultural support and customs that affect bereavement, and refrain from imposing their own personal needs and values on others.

Ongoing bereavement support should be based on the family's specific needs and requests, and the availability of appropriate bereavement support for both parents and siblings. Bereavement literature and parent support groups may be helpful where available.

Recognition of the child's birthday and the anniversary of their death provide an opportunity for healthcare professionals and friends to show the family that their child has not been forgotten.

### Acknowledgement

We are extremely grateful to Dr Janet Goodall for her help with writing this section.

## 1.17 Hospital issues regarding immunisation

### Introduction

Immunisation is one of the most effective disease prevention strategies in children. In this process, an antigen is introduced into the body, where it stimulates immunity against the specific antigen by priming the specific memory cells. Subsequent natural infection produces an effective and vigorous response by the body, and the patient is thus protected from the disease and its effects and complications.

In 1974, the World Health Organization (WHO) initiated the Expanded Programme on Immunisation (EPI). This aims to develop widespread national commitment to achieve high vaccination coverage in mostly low-income countries. The choice of the original six EPI vaccines was based on the importance of the disease and the availability of safe, efficacious and low-cost vaccines.

The WHO recommended vaccination schedule is widely used in almost all countries, with newer vaccines being added as some programmes evolved (see Table 1.17.1).

**TABLE 1.17.1** Current EPI vaccination schedule recommended by the WHO, May 2014

Age	Vaccine
Birth	BCG*, OPV#0, HBV#1
6 weeks	DTP#1, HiB#1, OPV#1, HBV# 2 PCV#1 RV#1
10 weeks	DTP#2, HiB#2, OPV#2, HBV#3 IPV#1 PCV#2 RV#2
14 weeks	DTP#3, HiB#3, OPV#3, IPV#2 PCV#3
9 months	MCV/RCV #1 Yellow fever (in countries where it poses a risk)
12–15 months	MCV/RCV#2
9 years girls	HPV#1 plus HPV# 2 after at least 6/12

BCG, bacillus Calmette-Guérin; OPV, oral poliovirus vaccine; IPV, inactivated polio vaccine HBV, hepatitis B vaccine; DTP, diphtheria, tetanus and pertussis; HiB, Haemophilus influenzae type B; Pneumococcus PCV; Rotavirus RV; Measles/Rubella MCV/RCV; Human papilloma virus HPV

\*BCG must not be given if HIV infection is present or clinically suspected

See these links for further information:

[www.who.int/immunization/policy/immunization\\_tables/en/](http://www.who.int/immunization/policy/immunization_tables/en/)  
[www.who.int/immunization/policy/immunization\\_routine\\_table2.pdf?ua=1](http://www.who.int/immunization/policy/immunization_routine_table2.pdf?ua=1)

Vaccine schedules are a continuously changing phenomenon. It is recommended that regional variations on programmes are followed.

### Polio

Live oral poliovirus vaccine (OPV) and inactivated poliovirus vaccine (IPV) are the two effective vaccines that are available, but there are important differences between them.

- WHO no longer recommends an OPV only vaccination schedule, at least 1 dose of IPV should be added to the schedule.
- In polio-endemic countries and in countries at high risk for importation and subsequent spread, WHO recommends an OPV birth dose (a zero dose) followed by a primary series of 3 OPV and at least 1 IPV doses.
- The WHO target to eradicate poliomyelitis within the next 10 years is dependent on high infant immunisation coverage and national immunisation days (NIDs), which aim to eradicate the circulation of wild virus. NIDs are designed to complement routine immunisation by targeting the most vulnerable individuals in as short a time period as possible. OPV is given over a 2-day period, 1 month apart, and the NIDs are repeated annually for at least 3 years.

### Pertussis

Fever and mild local reactions are common. Consider a two-dose schedule for those areas where services can be provided only twice a year.

### Measles

Accelerated implementation of strategies to reduce the burden of measles is required. Targeting children under 5 years of age in major cities is a priority. Strategies to reduce the impact of infant measles include:

- increasing coverage to the 9–23 months age group
- a two-dose schedule at 6 months and 15 months is most appropriate for epidemic situations, and a two-dose

schedule at 9 months and 15 months is currently recommended routinely.

### **Tetanus**

**All healthcare workers at antenatal clinics should guarantee that no women attending will have a child who dies of neonatal tetanus, by giving immunisation and advice about umbilical cord care.** Vaccination of young adolescent girls is recommended in areas with poor antenatal coverage. Mothers who were not seen antenatally should be vaccinated when they bring their infants to clinic.

### **BCG**

This offers good protection against disseminated tuberculosis and also affords some protection from leprosy. Where the risk of tuberculosis is high, BCG is recommended at birth or as soon as possible thereafter.

It is recommended for children living in countries with a high-disease burden for HIV and for high-risk children living in countries with low-disease burden.

Children who are HIV positive or have unknown HIV status with symptoms consistent with HIV should not be vaccinated.

### **New vaccines and EPI**

Hepatitis B and yellow fever vaccines have been recommended since 1992. The HiB vaccine is also a priority, and is given as combination now in EPI programmes with the DPT and HBV as three doses. Newly introduced vaccines are the pneumococcal conjugate vaccine (PCV) and the rotavirus vaccines. Unfortunately there is no vaccine yet available against HIV or hepatitis C.

Other vaccines to consider based upon local epidemiology and resource limitations would be:

- MMR (Measles, Mumps and Rubella) vaccine instead of MCV/RCV as at present recommended
- Typhoid vaccine
- Varicella vaccine
- Meningococcal (Conjugate) vaccine.

### **Contraindications to immunisation**

#### **All vaccines**

- Anaphylactic reaction.
- Moderate to severe acute illnesses with or without fever.
- Evolving neurological disease.

### **Specific vaccines**

- Encephalopathy (DPT/DaPT).
- Immunodeficiency (OPV, BCG, MMR).
- Anaphylactic reaction to egg and neomycin (MMR, VZV).
- Pregnancy (MMR, OPV, IPV).
- Precautions for DPT:
  - fever > 105 °F
  - collapse or shock-like state
  - seizures
  - persistent inconsolable crying.

### **Conditions that are not contraindications to immunisation**

- Minor illnesses, such as upper respiratory infections or diarrhoea, with fever < 38.5 °C.
- Allergy, asthma or other atopic manifestations (e.g. hay fever, 'snuffles').
- Prematurity, small-for-date infants.
- Malnutrition.
- Child being breastfed.
- Family history of convulsions.
- Convalescent phase of illness.
- Penicillin or other allergies.
- Treatment with antibiotics, low-dose corticosteroids or locally acting (e.g. topical or inhaled) steroids.
- Dermatoses, eczema or localised skin infection.
- Chronic diseases of the heart, lung, kidney or liver.
- Stable neurological conditions (e.g. cerebral palsy, Down's syndrome).
- History of jaundice after birth.

### **HIV infection and vaccination**

Individuals with known or suspected asymptomatic HIV infection should receive all EPI vaccines (including against rotavirus) as early in life as possible according to nationally recommended schedules. Because of the risk of early and severe measles, infants should receive a standard dose at 6 months, with a second dose as soon after age 9 months as possible.

Children who are HIV positive or have unknown HIV status with symptoms consistent with HIV should not be vaccinated with BCG.

Also see Sections 2.8.C and 6.2.D HIV Infection.

**TABLE 1.17.2 WHO/UNICEF recommendations for the immunisation of HIV-infected children and women of childbearing age**

Vaccine	HIV positive without symptoms	HIV positive with symptoms	Optimal timing of immunisation
BCG	No	No	
DPT	Yes	Yes	6, 10 and 14 weeks
OPV	Yes	Yes	0, 6, 10 and 14 weeks
Measles	Yes	Yes	6 and 9 months
Hepatitis B	Yes	Yes	As for uninfected children
Rotavirus	Yes	Yes	6, 10 weeks
Yellow fever	Yes	(No pending further studies)	–
Tetanus toxoid	Yes	Yes	5 doses

Additional vaccines that should be seriously considered in HIV-infected children include the following:

- Varicella vaccine:

- recommended in asymptomatic/mildly symptomatic children
- two doses should be given with a 3-month interval

- strongly recommended for HIV-negative siblings and other children in the household
- contraindicated in moderately and severely immunocompromised children.
- Other vaccines:
  - influenza virus vaccine annually, specific strain only
  - hepatitis A
  - parenteral typhoid vaccine (oral administration is contraindicated).

**TABLE 1.17.3 Recommended vaccine storage time and temperature**

Vaccines	Shelf life	Transport state-district	State/district	Transport to PHC	PHC
DTT/TT and typhoid	1–1.5 years (4–8°C)	+4 to +8°C	3 months (4–8°C)	4–8°C	1 month (4–8°C)
BCG	8 months (4–8°C)	+4 to +8°C	3 months (4–8°C)	4–8°C	1 month (4–8°C)
Measles and OPV	2 years at –20°C	–20°C to +8°C	3 months (–20°C)	–20°C to + 8°C	1 month (4–8°C)

**Logistic actions** to avoid unnecessary risk, vaccine wastage and missed opportunities are essential.

### **Immunisation instruments recommended by EPI**

Disposable single-use plastic syringes are safe and economical, but it is important to correctly destroy and dispose of the syringes and sharps after use. Used needles and syringes should be placed in a hard container, sealed, autoclaved, and ideally incinerated for disposal.

- Opened vials of OPV, DPT and hepatitis B vaccines may be used in subsequent immunisation sessions until a new shipment arrives (provided the expiry date has not passed, vaccines are kept in the cold chain and the vials have not been used outside the health centre).
- Opened vials of measles, yellow fever and BCG vaccines must be discarded at the end of each immunisation session.
- Vaccine vial monitors (VVMs) will enable field staff to reject vials of vaccine that are heat damaged.
- Screen and immunise at every contact. The rate of non-immunisation of eligible children at clinics may be as high as 30%.
- Reduce wastage by choosing the correct vial size.
- Ensure appropriate use of the vaccine cold box. Cold boxes only work if they are kept cold with the lid tightly shut. Ice packs are placed in the bottom and around the sides of the box and on the top of the vaccines. Newspaper should be placed between the vaccines and the icepacks to protect DPT and tetanus vaccines from the ice. A thermometer should be placed with the vaccines to record the temperature of the vaccines when they are removed from the cold box. The diluent that is used to reconstitute measles and BCG vaccine must also be kept cold.
- Effective supervision requires focus on the essentials.
- Evaluate and monitor the programme.

### **Care of refrigerators**

A constant supply of electricity, gas or kerosene is required. The electric plug can be taped to its socket to ensure that it is not inadvertently removed. For gas and kerosene fridges, a reserve full bottle of gas or can of fuel should always be present. A regulator valve should be used with the gas bottle. Kerosene tanks should be filled daily using a funnel and filter to remove dirt. The refrigerator should be positioned in a completely upright position with a draught blowing on the temperature exchanger to keep it cool. A

fan can be used for this if there is no wind and the ambient temperature is high.

### **Summary**

- Vaccines are the best form of prevention, especially for children under 5 years of age.
- They are safe, effective, generally economical, and easily available.
- Immunisation of a child should start at birth and continue until they are old enough to attend college.
- Standards must be maintained with regard to procurement, delivery, storage and administration of all vaccines.
- In the event of missed doses, in most cases the vaccination schedule can be completed from the time when the dose was missed.
- Mild fever and upper respiratory tract infections are not contraindications to giving vaccination.
- Do take every opportunity to recommend vaccination for children.

### **Immunisation issues in pregnancy**

#### **Vaccination against tetanus**

The most important vaccination that should be given to all pregnant women and girls is to prevent tetanus in women and in the newborn infant. After two doses, protective antibodies are present in more than 80% of recipients. The vaccine is safe in pregnancy, and two doses of vaccination last for at least 3 years.

If the woman or girl has a tetanus-susceptible wound, including following an unsafe abortion, protect against future tetanus risks by immunising her immediately if she is not already protected. In addition, provide prophylaxis with tetanus immunoglobulin if the wound is large and possibly infected with soil or instruments contaminated with animal excreta.

In the antenatal setting, check the immunisation status of the pregnant woman (either by a history or from the record card), regardless of whether she intends to continue the pregnancy.

If the woman has not previously been vaccinated, or her immunisation status is unknown, give two doses of TT/Td 1 month apart as soon as possible before delivery, TT1 and TT2 (one dose is not enough to give protection to the mother or newborn baby). Two doses protect for 1 to 3 years. If there is time in the remainder of the pregnancy, give another dose, TT3, 6 months after the second initial dose; otherwise give the third dose, TT3, in the next pregnancy. Three doses protect for at least 5 years. A fourth

dose can be given at least 1 year after TT3, and protects for at least 10 years.

If the woman can prove her previous vaccination history, and provided she has had between 1 and 4 doses in the past, give one additional dose before delivery.

Before giving the vaccine, shake the vial and make sure that the material in the base of the vial is completely mixed with the liquid. If it is suspected that the vaccine has been frozen and thawed, this mixing may not occur and the vial should not be used.

If neonatal tetanus occurs, give the mother one dose of TT as soon as possible, and repeat the dose 4 weeks later and then again 6 months after the second dose.

Record the doses given on a central hospital/clinic register. However, it is of paramount importance to record them on a card or maternal health record kept by the mother.

### Immunisation against hepatitis B virus (HBV)

All pregnant women and girls should ideally be offered screening for HBV.

They may have become infected at their birth (vertical transmission) or by sexual contact or through infected blood transfusion or use of dirty needles. Hepatitis B can be passed from a mother to her baby during or shortly after delivery. Having a Caesarean section does not prevent the virus from being transferred to the baby. If a ventouse delivery is undertaken a soft cap is preferred to the metal cup. Breastfeeding is safe.

During pregnancy, all women should have a blood test for a marker of hepatitis B virus, which is called hepatitis B surface antigen (HBsAg). Normally the HBsAg should be negative.

If a pregnant woman's HBsAg test or hepatitis B e-antigen (HBeAg) test are positive, the infant must be given hepatitis B immunoglobulin (HBIG) as soon as possible after birth to reduce the transmission rate from 70–90% to 5–10%.

Similarly, if a woman develops HBV infection during pregnancy, HBIG prophylaxis (400 IU given intramuscularly), which is safe, should be administered urgently within 24 hours of infection if possible. Acute HBV infection may be asymptomatic or present with signs of acute hepatitis. If available, antiviral therapy can be given to pregnant women who have high viral loads.

HBIG provides immediate protection for the woman or infant, but the effect only lasts a few months. Women or their babies should then be given a course of HBV vaccination (the initial dose being given at the time of HBIG, and then two further doses at 1 and 6 months after the initial dose).

The newborn infant, in addition to receiving the HBIG described above, should receive the hepatitis B vaccine at birth, again at 1–2 months, and finally at 6 months of age.

It is important to complete all three doses for long-term protection. The infant should have a blood test for hepatitis B infection and for hepatitis B antibody at 9–18 months of age. If the antibody test is negative, a fourth dose of the vaccine should be given at that time.

Women who are HBsAg-positive must not donate breast milk.

### Vaccinations that should not be given during pregnancy

#### Live vaccines

- BCG (live attenuated strain).
- Oral typhoid vaccine.
- Measles–mumps–rubella (MMR).
- Rotavirus.
- Varicella.
- Yellow fever (unless travelling to areas in which yellow fever is endemic).

#### Inactivated vaccines

- Oral cholera.
- 7-Valent pneumococcal conjugate.

WHO recommendations for Immunisation of Health Care Workers:

*Hepatitis B.* Immunisation is suggested for groups at risk of acquiring infection who have not been vaccinated previously (for example HCWs who may be exposed to blood and blood products at work).

*Polio.* All HCWs should have completed a full course of primary vaccination against polio.

*Diphtheria.* Particular attention should be given to revaccination of HCWs with diphtheria boosters every 10 years. Special attention should be paid to immunising HCWs who may have occupational exposure to *C. diphtheria*.

*Measles.* All HCWs should be immune to measles and proof/documentation of immunity or immunization should be required as a condition of enrolment into training and employment.

*Rubella.* If rubella vaccine has been introduced into the national programme, all HCWs should be immune to rubella and proof/documentation of immunity or immunisation should be required as a condition of enrolment into training and employment.

*Meningococcal disease.* One booster dose 3–5 years after the primary dose may be given to persons considered to be at continued risk of exposure, including HCWs.

# 1.18 Recognition by hospital workers of the abuse and exploitation of pregnant women and children

For health workers in hospitals, the two most important issues are:

- 1 that abusive injuries are recognised and diagnosed
- 2 that future abuse is where possible prevented by the involvement of agencies such as social services, the police and legal teams working together.

**Child abuse and family violence against pregnant women represent a worldwide problem.**

## Categories of ill treatment and abuse

A new way of looking at this subject divides the ill treatment or abuse into three categories based on the intention of the perpetrators.

### Ill treatment resulting from human weakness

This occurs at some time in every family, often without realisation.

It is best addressed through education, religious or other community initiatives.

### Ill treatment resulting from stress

This can involve violence, which is sometimes very severe. Perpetrators are often unhappy, are suffering from an undiagnosed or untreated mental illness, dependent on drugs or alcohol, unsupported, and were often inadequately parented in their own childhood. After violent acts, the perpetrator usually becomes distressed. They do love and care for their victim.

This problem needs professional support that is appropriately led by local social services staff, not punitive legislation.

### Abuse that is undertaken for gain

This often involves the most serious and prolonged forms of violence, resulting in great suffering. The perpetrator usually has a psychopathic personality disorder and is immune or insensitive to the suffering of others. Indeed, they may even enjoy inflicting emotional or physical pain. Mental illness is not responsible for this form of abuse. Although the perpetrators are aware that what they are doing is wrong, they are gaining from doing it. They will do all that they can to avoid being detected, by employing elaborate and plausible lies, characteristically weaving objects of truth into a latticework of deceit. The perpetrators are usually dangerous and frighten local social workers, health visitors, doctors and teachers, who need to be involved in a protected manner. The perpetrators may work in groups such as the criminal gangs involved in human trafficking.

The kinds of abuse undertaken in this third category include:

- trafficking of women and children as slaves or for prostitution
- sadistic injuries (e.g. deliberate burns from cigarettes, scalding, holding the person against hot objects, etc.)
- multiple fractures, often inflicted at different times, reflecting the severity of violence

- excessive ritual punishments (e.g. regular and savage beatings, usually with implements)
- deliberate starvation, as distinct from neglect as in the second category
- the fabrication or inducement of illness
- sexual abuse.

**The most difficult issue is to distinguish this form of abuse from perpetrator stress-related ill treatment (the second category above).**

The possibility of ill treatment or abuse must be considered in the differential diagnosis of all children or pregnant women or girls who have suffered an injury and present to hospital.

**All professionals who are working with children and pregnant women or girls need to be aware of the clinical manifestations of abuse and do everything that they can to protect their patients from further harm.**

Some cultural practices are abusive. For example, female genital cutting (see Section 2.10) not only causes great suffering at the time, but can interfere with future childbirth and sexual relationships.

Abuse and ill treatment occurs across all social classes.

## Features of family members known to be associated with ill treatment or abuse

Observe the relationship between the family and the patient.

- Is it loving and caring?
- Were any family members themselves abused as children?
- Are the parent(s) of a child young and/or unsupported?
- Are the parent(s) of a child single or substitutive?
- Does the parent of a child have learning difficulties?
- Do the parents of a child have a poor or unstable relationship?
- Is there existing domestic violence, drug or alcohol abuse in the family?
- Does the parent of a child have a mental illness (e.g. postnatal depression)?

### Critical threshold for concern

Arriving at the critical threshold may be immediate and straightforward (e.g. the finding of bruising on a small infant, or a direct disclosure of abuse from a child or pregnant girl). In some circumstances the situation is less clear (e.g. if there are a number of non-specific signs or indicators, or in cases of neglect). At some point a balanced assessment is required between the provision of family support for a patient who is judged to be 'in need', and taking action directly to protect them.

The 'critical threshold' is that point beyond which behaviour(s) towards a patient can be considered to be ill treatment or abuse, and beyond which it becomes necessary to take action. That is the time to raise concerns with the parents, carers and/or family and the time to refer to the statutory agencies (either social services or the police, depending on the local legislative system).

# 1.19 Transport of ill patients

The transport of patients who are ill should follow the same principles whether the distance is long or short, and whether the journey is within or between healthcare facilities.

All transfers pose a potential risk, and should only be undertaken if safe treatment cannot be given within the facility where the patient is at present.

Preparation and planning allow mitigation of risks to both the patient and healthcare staff.

Staff who are trained in transport provide better-quality transfers.

Stabilisation prior to transport is preferable, as better-quality transport is of benefit to patient outcomes. However, time-critical pathologies may change the balance of risk and benefit between time spent on stabilisation and the need for rapid transfer for definitive treatment.

Never assume that resources and equipment will be available in transport vehicles. Prepare beforehand to be self-sufficient.

Use the principles of ABCD to guide management of the patient for transport.

Use a checklist (see Table 1.19).

Pregnancy-related emergencies involve two patients – the mother and the baby.

Many obstetric emergencies require urgent, rapid and safe transport from home to the nearest facility where there is comprehensive emergency obstetric care (EmOC). This is particularly relevant for emergencies such as massive obstetric haemorrhage, eclampsia, obstructed labour, shoulder dystocia and complicated breech delivery.

Ideally, every pregnant woman or girl should have a local transport plan ready in advance for an unexpected

**FIGURE 1.19.1** Safe transport rules.

emergency. This could consist of a village taxi, a relative's car, or some other form of transport, the fuel for which needs to be secured in advance.

Ideally, there should also be an emergency transport system based in the nearest health facility with comprehensive EmOC and having a midwife on call 24 hours a day who can go out with an ambulance containing suitable emergency equipment and drugs to the home of a mother with a life-threatening emergency, stabilise her and transport her back to the health facility.

The following paper describes a system of this type: [www.reproductive-health-journal.com/content/pdf/1742-4755-7-21.pdf](http://www.reproductive-health-journal.com/content/pdf/1742-4755-7-21.pdf).

Motor cycle and side-car ambulances (e.g. [www.eranger.com](http://www.eranger.com)) can be extremely effective for transporting pregnant women and girls along difficult roads in rural areas to a hospital or clinic.

**TABLE 1.19** Transport checklist

<i>Airway/Breathing</i>		Yes/No
Is the airway safe?	Is there anything that can be done to improve the airway?	Yes/No
Is oxygen required?	Pulse oximeter (battery operated with additional power from the ambulance cigarette lighter) can help to guide the need for oxygen	Yes/No
Is oxygen available?	Oxygen cylinders full and working – enough for the return expected journey	Yes/No
Is ventilatory support required?	Bag-valve-mask of the correct size available and working	Yes/No
Suction	Manual system and catheters available	Yes/No
<i>Circulation</i>		Yes/No
IV access	Working and secured	Yes/No
Volume	Ringer-lactate or Hartmann's solution bags and delivery kits	Yes/No
<i>D Neurology</i>		Yes/No
Temperature	Sufficient blankets available	Yes/No
Blood sugar level	Glucose for IV or gastric tube administration available	Yes/No
<i>Other</i>		Yes/No
Birth needs	Delivery kit, bag-valve-mask for neonate, towels, oxytocin, misoprostol, magnesium sulphate and condom catheter	
Documentation	All relevant documentation with the patient	Yes/No
Family members	Family members know what the plan is	Yes/No
Healthcare communication	Receiving site is aware of the patient and their expected time of arrival	Yes/No

## 1.20 Ethics in healthcare

### Introduction

Ethics is the study of morality. Morality is defined as the values used in human behaviour and decision making.

### Medical ethics

Medical ethics is the branch of ethics that deals with moral issues in medical practice.

Anyone who is involved in patient care uses ethics, whether or not they have had formal teaching in medical ethics (most people have not).

Usually law and ethics are closely related, but there are some differences:

- Laws differ between countries, whereas ethics are applicable to all countries.
- Ethical obligations take priority over legal duties.
- When law conflicts with medical ethics, healthcare workers should advocate for changing the law.

There are four basic principles of ethics in healthcare which apply to most moral issues that arise in healthcare:

- 1 **Autonomy:** this means self-determination. If a patient is fully informed and competent (i.e. is able to understand the implications of having treatment or no treatment), they have the right to refuse or accept treatment. Such decisions must be respected, even if they are not thought by health workers to be in the patient's best interests.
- 2 **Beneficence:** this means doing good and promoting well-being. This has to be considered for the individual patient, and may conflict with autonomy.
- 3 **Non-maleficence:** this means doing no harm. In healthcare, it is recognised that there is a risk of harm whenever investigations or treatment are carried out to benefit the patient. Maleficence refers to harm inflicted with no intended benefit to the patient.
- 4 **Justice:** this means equality before the law or fairness. It refers to the fair allocation of scarce resources to patients, and the justification for money spent in the health service. This may mean equal access to healthcare, maximum benefit of resources available, or allowing people choice in their healthcare. This decision may not be able to be taken by an individual. In a society where justice prevails, the aim is for all citizens to have equal access to healthcare.

### Medical ethics in different countries

Different cultures and societies have different expectations about the relative values of the individual ethical principles. Some societies expect a beneficent or non-maleficent approach, whereas others expect an overriding respect for autonomy. It is essential that, as well as working within professional ethics, health workers respect the law in the countries where they practise, provided that the law does not harm the patient.

**If a law or laws do harm patients or fail to protect them**

**from harm, the healthcare workers should advocate for appropriate change in those law(s).**

Some cultures put less weight on individualism, and involve the family and/or community in decision making.

Gender may also affect decision making. In some societies, decision making is the man's responsibility and the woman has no autonomy.

In some countries, health workers will not be forced to do anything unethical, whereas in others, there may be pressure from the police or the army to participate in torture or reveal the names of patients and their injuries and so break confidentiality.

In 2001 in South Africa, the Treatment Action Campaign (TAC) launched legal action to demand more widespread access to nevirapine to reduce mother-to-child transmission of HIV/AIDS. The High Court issued an order to the government to make nevirapine available to pregnant women with HIV.

In the USA, the emphasis is on the individual's autonomy, whereas in Africa the community may be more important, so the principles of beneficence and distributive justice may predominate.

### Codes of ethics

The nursing and medical professions have their own international codes of ethics, adopted by the International Council of Nurses (ICN) and the World Medical Association (WMA), respectively.

There are more similarities than differences in medical ethics worldwide, and the World Medical Association has the role of setting standards in medical ethics that are applicable worldwide. The association was set up in 1947 to prevent a repetition of the unethical conduct of physicians in Nazi Germany and elsewhere. The WMA has developed an *International Code of Medical Ethics*, which was last revised in 2006.

The International Council of Nurses developed a code of ethics for the nursing profession in 1953, which was last revised in 2005.

### WMA International Code of Medical Ethics

- This was adopted by the 3rd General Assembly of the World Medical Association, London, England, in October 1949.
- It was amended by the 22nd World Medical Assembly, Sydney, Australia, in August 1968.
- It was next amended by the 35th World Medical Assembly, Venice, Italy, in October 1983.
- It was most recently amended by the 57th World Medical Association General Assembly, Pilanesberg, South Africa, in October 2006.

**Duties of physicians in general**

A physician shall:

- always exercise their independent professional judgement and maintain the highest standards of professional conduct
- respect a competent patient's right to accept or refuse treatment
- not allow their judgement to be influenced by personal profit or unfair discrimination
- be dedicated to providing competent medical service in full professional and moral independence, with compassion and respect for human dignity
- deal honestly with patients and colleagues, and report to the appropriate authorities those physicians who practice unethically or incompetently or who engage in fraud or deception
- not receive any financial benefits or other incentives solely for referring patients or prescribing specific products
- respect the rights and preferences of patients, colleagues, and other health professionals
- recognise their important role in educating the public, but use due caution in divulging discoveries or new techniques or treatment through non-professional channels
- certify only that which they have personally verified
- strive to use healthcare resources in the best way to benefit patients and their community
- seek appropriate care and attention if they suffer from mental or physical illness
- respect the local and national codes of ethics.

**Duties of physicians to patients**

A physician shall:

- always bear in mind the obligation to respect human life
- act in the patient's best interest when providing medical care
- owe his or her patients complete loyalty and all the scientific resources available to him or her. Whenever an examination or treatment is beyond the physician's capacity, he or she should consult with or refer to another physician who has the necessary ability
- ensure that he/she remains competent to provide medical care in his/her field by continual professional development
- submit him/herself to assessment of health, probity, knowledge and competence by peers when appropriate
- respect a patient's right to confidentiality. It is ethical to disclose confidential information when the patient consents to it or when there is a real and imminent threat of harm to the patient or to others and this threat can be only removed by a breach of confidentiality
- give emergency care as a humanitarian duty unless they are assured that others are willing and able to give such care
- in situations when they are acting for a third party, ensure that the patient has full knowledge of that situation
- not enter into a sexual relationship with their current patient, or into any other abusive or exploitative relationship.

**Duties of physicians to colleagues**

A physician shall:

- behave towards colleagues as he or she would have them behave towards him or her

- not undermine the patient–physician relationship of colleagues in order to attract patients
- when medically necessary, communicate with colleagues who are involved in the care of the same patient. This communication should respect patient confidentiality and be confined to necessary information.

**The ICN Code of Ethics for Nurses**

This code has four principal elements that outline the standards of ethical conduct.

**Elements of the code****1 Nurses and people**

- The nurse's primary professional responsibility is to people requiring nursing care. In providing care, the nurse promotes an environment in which the human rights, values, customs, spiritual beliefs of the individual, family and community are respected.
- The nurse ensures that the individual receives sufficient information on which to base consent for care and related treatment.
- The nurse holds in confidence personal information, and uses judgement in sharing this information.
- The nurse shares with society the responsibility for initiating and supporting action to meet the health and social needs of the public, in particular those of vulnerable populations.
- The nurse also shares responsibility to sustain and protect the natural environment from depletion, pollution, degradation and destruction.

**2 Nurses and practice**

- The nurse carries personal responsibility and accountability for nursing practice, and for maintaining competence by continual learning.
- The nurse maintains a standard of personal health such that the ability to provide care is not compromised.
- The nurse at all times maintains standards of personal conduct which reflect well on the profession and enhance public confidence.
- The nurse, in providing care, ensures that use of technology and scientific advances is compatible with the safety, dignity and rights of people.

**3 Nurses and the profession**

- The nurse assumes the major role in determining and implementing acceptable standards of clinical nursing practice, management, research and education.
- The nurse is active in developing a core of research-based professional knowledge.
- The nurse, acting through the professional organisation, participates in creating and maintaining safe, equitable social and economic working conditions in nursing.

**4 Nurses and co-workers**

- The nurse sustains a cooperative relationship with co-workers in nursing and other fields.
- The nurse takes appropriate action to safeguard individuals, families and communities when their health is endangered by a co-worker or any other person.

Ethics in different situations, namely consent, confidentiality, end-of-life decisions and research, will be discussed below.

## The ethics of consent

Informed consent is the process of a 'competent' patient receiving information needed to make a choice. It has five elements:

- 1 **Disclosure of information:** The patient has the right to the information necessary to make his or her decisions and to be informed of the consequences of his or her decisions.
- 2 **Comprehension:** The patient should understand the purpose of any test or treatment, the implications of the results, and the implications of not having the test or treatment.
- 3 **Voluntariness** (freedom from control by others): The patient has the right to self-determination, which includes making free decisions regarding him- or herself.
- 4 **Competence:** A mentally competent adult patient has the right to give or withhold consent to any diagnostic procedure or therapy.
- 5 **Choice:** Children may be able to consent to some procedures, but not to other more complex procedures.

Article 12 of the United Nations Convention on the Rights of the Child (1989) states:

'A child who is capable of forming his/her view has the right to express those views freely on all matters affecting the child, the views of the child being given due weight in accordance with the age and maturity of the child.'

## The child's competence and parental involvement: respect for autonomy

Where a child is not competent to give or withhold consent to treatment, a person with parental responsibility must act as an advocate for the child to authorise investigations or treatment which are in the child's best interests. Parents have the right to be involved in the decision-making process, and this right is protected by law in most countries.

It is the doctor's responsibility to assess a child's capacity to decide whether he or she can consent to, or refuse, a proposed investigation or treatment before providing it. A competent child must be able to understand the nature, purpose and possible consequences of the proposed investigation or treatment, as well as the consequence of non-treatment. Competence is presumed at different ages in different countries. Children's competence is related to experience as well as to age, and young children can often clearly demonstrate that they have the competence to make decisions about treatment. Such competence has a legal standing in some countries (such as the so-called 'Gillick' competence in English law).

## Providing the information: an essential component of consent

In some societies, disease and pain are interpreted in terms of sin and retribution. This may make it difficult for health workers to explain diagnostic and management options in medical terms.

Information should include details of the possible diagnoses and prognosis, possible management options, the purpose of a proposed investigation or treatment, and the likely benefits and probabilities of success, and discussion about any serious or frequently occurring risks. Wherever

possible the information should be given in a way that is clearly understood and remembered.

All this information may be overwhelming for patients and their families. The principles of beneficence and non-maleficence might suggest that a more paternalistic and less forthright doctor might be behaving more ethically. However, it is important that personal views about how much to disclose are not imposed on the patient when explaining an illness or treatment to them.

When providing information, it is essential that professionals do their utmost to find out about the patient's (and family's) needs and priorities. This is often the most difficult part of the communication process, and involves responding honestly to any questions the patient or family raise and, as far as possible, answering these as fully as possible. It is for the competent patient, not the doctor, to determine what is in the patient's own best interests.

Finally, information for decision making should not be withheld from the patient and their family, unless it is judged that disclosure would cause the patient or family serious harm (the principle of non-maleficence). It may also be inappropriate to discuss treatments that are not available.

## Emergency situations

If the patient is unconscious or otherwise unable to consent to, or decline, treatment and there is no one legally able to consent for them (this varies between countries, and may be the patient's child, brother, sister, etc.), urgent investigation and treatment may be carried out. This is sometimes called presumed consent, where the healthcare worker does what they think is in the best interests of the patient.

The UK General Medical Council (1998) advice on consent for emergencies includes the following:

'In an emergency, where consent cannot be obtained, you may provide medical treatment to anyone, provided the treatment is limited to what is immediately necessary to save life or avoid significant deterioration in the patient's health.'

## Summary of consent

- Practise within the limits of the law of the country (unless this is harmful to the patient).
- Assess the level of competence of the patient before deciding how much and how to tell them.
- The patient and their family can tell you how much information they need to make a decision.
- All decisions must be free from coercion.

## Confidentiality

This is not an ethical principle, but it involves a respect for autonomy, beneficence towards the patient, and a desire to act with non-maleficence.

Confidentiality respects an individual's autonomy and their right to control information relating to their own health. In keeping information confidential, the doctor is acting beneficently.

Most countries have laws to enable the breaking of confidentiality in some circumstances – for example, to protect the safety of a third person, or:

- 1 to prevent a serious crime, as information may need to be disclosed to the police
- 2 to report suspected child abuse
- 3 to report someone who is HIV positive who is unwilling

to inform their sexual partner(s) about this and does not consent to the healthcare worker telling the partner(s). The healthcare worker should inform the patient of his or her intention to inform the partner(s).

**Information should only be disclosed without the patient's consent by health workers to individuals who need to know, and the recipient(s) of such information should keep it confidential.**

### **Patient rights (family rights in the case of young children)**

These are as follows:

- 1 to participate in developing a plan of treatment
- 2 to receive an explanation of how components of treatment will be provided
- 3 only to have confidentiality broken under certain conditions (e.g. knowledge or suspicion of child abuse, intent of the patient to harm him- or herself or others, or the presence of a communicable disease that may harm others)
- 4 to receive clinically appropriate care and treatment
- 5 to be treated in a manner that is free from abuse, discrimination and/or exploitation
- 6 to be treated by staff who are sensitive to the family's cultural background
- 7 to be given privacy.

### **End-of-life issues**

These include the following:

- attempts to prolong the life of a dying patient
- euthanasia and medically assisted suicide
- care of terminally ill patients.

### **Attempts to prolong the life of a dying patient**

Where there is no benefit to the patient these attempts are unethical. Futile treatments are those that are assessed as bound to fail and which are prolonging the dying phase. Withholding or withdrawing treatment is not the same as participating in assisted suicide or assisted euthanasia. This does not include palliative treatment, which must always be offered (see Section 1.16).

The patient may decide to discontinue treatment for a life-threatening illness while able to understand the information needed to make an informed choice, and prefer to die with dignity, being treated palliatively. Alternatively, they may wish to continue treatment even if they understand that it can provide little benefit. They must always be offered palliative treatment, whatever their choice.

Euthanasia and assisted suicide are illegal in most countries and prohibited in most medical codes of ethics, and the WMA states that assisted suicide is unethical.

### **Euthanasia**

Euthanasia (also known as 'assisted dying') means intentionally performing an act that is intended to end another person's life and:

- the patient has voluntarily asked for their life to be ended and is competent, informed and has an incurable illness

- the agent knows about the patient's condition and their desire to die, and commits the act with the intention of ending life
- the act is undertaken with compassion and without personal gain.

### **Assisted suicide**

This is knowingly and intentionally providing a person with the knowledge or means to commit suicide, including counselling about lethal doses of drugs, prescribing or supplying the drugs.

This does not mean that healthcare workers should abandon dying patients, but rather they should provide compassionate end-of-life care, including relief of pain and suffering (see Section 1.16).

This includes patients who have refused potentially life-saving treatment while competent to do so. For example, if a patient refuses potentially life-saving surgery for a ruptured ectopic pregnancy, they should still receive nursing and medical care and symptomatic relief of suffering.

### **Withholding or withdrawing medical care**

If the patient is a child, the healthcare team and the parents must enter a partnership of care whose function is to serve the best interests of the child.

- 1 Although there is no significant ethical difference between withdrawing and withholding treatment, there are significant practical differences.
- 2 Optimal ethical decision making concerning patients requires open and timely communication between members of the healthcare team, the patient and the family.
- 3 Parents must decide on behalf of a child who is unable to express preferences, unless they are clearly acting against the child's best interests. Cultural practices and religious beliefs may have an impact on this.
- 4 The wishes (antecedent, if known) of a child who has sufficient understanding and experience should be given substantial consideration.
- 5 Resolution of disagreement should be by discussion, consultation and consensus.
- 6 The duty of care is not an absolute duty to preserve life by all means.
- 7 A shift from life-sustaining treatment to palliation represents a change in aims and objectives, and does not constitute a withdrawal of care.
- 8 Health workers should never withdraw treatments that alleviate pain or promote comfort.
- 9 There is a difference between treatment of the dying patient and euthanasia. When a dying patient is receiving palliative care, the underlying cause of death is the disease process. Treatments that may incidentally hasten death are justified, if their primary aim is to relieve suffering.

### **Hospital ethics committees**

Despite the growth of medical ethics and the publication of many professional codes of practice in recent years, it is still difficult for individuals to obtain guidance in resolving specific ethical dilemmas they face. Some hospitals have set up a hospital ethics committee or clinical ethics forum to discuss these dilemmas.

The jurisdiction of the ethics committee includes clinical

situations involving all patients, including infants and children under 18 years of age.

### **Function of hospital ethics committees**

- 1 **Education:** The committee should provide members of the hospital/medical staff with access to the language, concepts, principles and knowledge of ethics.
- 2 **Policy review and development:** the committee can assist the hospital and healthcare staff in the development of policies and guidelines regarding recurrent ethical issues and questions which arise in the care of individual patients.
- 3 **Case review:** the committee should be a forum for analysis of ethical questions that arise in the care of individual patients.

### **Appointment and membership**

The committee is multidisciplinary, and should include doctors, nurses, midwives, social worker, pastoral care, hospital director and chief of medical staff. A 30% membership from the general community has been suggested to ensure breadth of perspective and clarity of output.

### **Research ethics**

Each year £35–40 billion is spent on healthcare research worldwide, but only 10% of this is aimed at the health problems of 90% of the world's population.

Under-resourced countries need research to help to prevent and treat diseases such as tuberculosis and malaria, but lack funds and trained personnel, and therefore need expertise and financial support from public and private sectors in wealthy countries. This can lead to exploitation of the people in the country where research is needed and undertaken.

The principles that should be followed by anyone who is designing or conducting healthcare research in under-resourced countries are as follows:

- to alleviate suffering
- to show respect for people
- to be sensitive to cultural differences
- not to exploit those who are vulnerable
- the scientific and social importance of the research should outweigh the risks and burdens to the study subjects
- all research should have social as well as scientific value
- the populations involved in the research should benefit from the results
- staff working in the public sector where there are insufficient staff to provide proper care for patients (e.g. in most of sub-Saharan Africa) should not be taken from their work in order to undertake research.

It is important that there are national guidelines in every country which set priorities for healthcare research, and if external sponsors propose research outside these priorities, it must be justified to the appropriate research ethics committees.

There should be three levels of review for each research proposal:

- 1 relevance to healthcare priorities in the country
- 2 scientific validity
- 3 ethical acceptability.

There are a number of national and international guidelines and regulations with regard to research (e.g. WMA, Council for International Organizations of Medical Science in collaboration with WHO, European Council and European Parliament), but these are often inappropriate for under-resourced countries.

### **Consent to research**

For this to be valid, it should be given freely after full disclosure of all relevant information in a manner understandable by the research subject. Consent for the research may be withdrawn by the subject at any time without there being any adverse effects on the subject. However, in some communities it is usual for male members of the family or a community to make decisions on behalf of women and children.

### **Level of care**

The level of care provided to the control group (i.e. the group that is not having the active potential treatment) is controversial. Some argue that, if the research is externally sponsored, the people in the control group should receive the same standard of care as would be received in the sponsor's country. Others argue that this prevents some research from being conducted. For example, if two treatments are being compared in the under-resourced country, it is more appropriate for the new treatment to be compared with the one currently available in that country, not one that is inaccessible there.

### **Post-research considerations**

If an intervention is effective, should it be made available to the research participants and the community? The country concerned may not be able to afford this, particularly if it is a new and expensive drug, but a decision should be made with the national government via its research ethics committee about what will happen after the trial period is over.

### **Healthcare worker relationships**

As well as having an ethical duty towards patients, healthcare workers have an ethical duty towards other healthcare workers, to the healthcare system and to society.

#### **The health worker–patient relationship**

- 1 The healthcare worker's primary role is to be an advocate for each patient's care and well-being. They should always place the interests of their patients first. The healthcare worker also has a duty to accept responsibility for his or her clinical decisions.
- 2 The healthcare worker must treat each patient with honesty, compassion, dignity and respect. They should not exclude or discriminate against any patient because of ethnic origin, race, sex, creed, age, socio-economic status, diagnosis, physical or mental disability, or sexual orientation.
- 3 The healthcare worker's commitment to patients includes health education and continuity of care by good communication with subsequent health workers.

#### **The healthcare worker–healthcare worker relationship**

Traditionally, healthcare workers have been part of a hierarchical system, both within and between professions.

Doctors have been at the top of the caregiving hierarchy, above nurses and other healthcare workers. This situation is gradually changing, with other healthcare professionals increasingly questioning the reasoning behind a doctor's decision.

- 1 Healthcare workers have a responsibility to maintain moral integrity, intellectual honesty and clinical competence. They should be aware of the limitations of their expertise and seek consultation or assistance in clinical situations in which they are not expert.
- 2 Healthcare workers should work as a team, supporting each other and working together for the benefit of the patient.
- 3 Healthcare workers have an obligation to educate and share information with colleagues, including trainee healthcare workers. They should be committed to life-long learning and continuously improve their knowledge and clinical skills relevant to their practice.
- 4 There is an ethical obligation to report impairment or misconduct of colleagues in order to prevent potential harm to patients.

### **The relationship between the healthcare worker and the system of care**

- 1 The healthcare worker's duty of patient advocacy should not be altered by the system of healthcare delivery in which they practise.
- 2 If there are conflicts of interest, the patient's interests should take priority over those of others.
- 3 Healthcare professionals should campaign against unethical practices.
- 4 Healthcare professionals should not be influenced by commercial enterprises (e.g. companies that manufacture drugs, diagnostic tools or equipment). The duty of the physician is to evaluate objectively what is best for the patient. Gifts designed to influence clinical practice are not acceptable.
- 5 Healthcare professionals should advocate to their departments of health for improved medical facilities and treatments for patients where acceptable basic facilities and treatments are lacking (e.g. oxygen, effective pain relief, blood transfusion services, access to vital skills such as surgery, basic life-saving drugs).

In many countries, there are huge divisions between the rich minority and the poor, exploited and disadvantaged majority. Healthcare professionals should be aware of this and acknowledge how their actions support such divisions, and aim to provide high standards of care independent of a patient's or family's ability to pay.

### **The relationship of the healthcare worker to society**

Healthcare workers have a responsibility to society as well as to patients, and sometimes society's best interests may take precedence over those of the patient (e.g. mandatory reporting of patients with a designated disease, those who are unfit to drive and those suspected of child abuse).

In other circumstances there may be requests from the police or the military to take part in practices that violate human rights (e.g. torture). Healthcare workers should report unjustified interference in the care of their patients, especially if fundamental human rights are being denied. If the authorities are unhelpful, contact with a national medical or nursing association, the WMA or World Nursing Federation, or a human rights organisation may be needed.

The increasing mobility of society means that healthcare workers have a responsibility for global health, including preventing the spread of infectious diseases between societies and countries.

Another effect of globalisation is the mobility of healthcare professionals, and their migration from low-income to high-income countries. The shortage of healthcare workers is one of the biggest health problems facing low-income countries today.

The governments of low-income countries invest in the education and training of healthcare professionals, and therefore lose these resources and the contribution of these workers when graduates migrate. The factors considered by the migrant may be economic, social and/or family related. Often in low-income countries there are low wages, poor working conditions, lack of leadership and very few incentives, as well as limited opportunities for their children. High-income governments encourage migration when there is a need, often with no compensation for the government where the migrant was trained.

This presents an ethical dilemma whereby if emigration was prevented it would restrict the autonomy of the individual, but on the other hand the health of a society suffers if there is mass migration of healthcare professionals.

## 1.21 Traditional medicine and its relevance to hospital care

### BOX 1.21.1 Minimum standards

- Consider traditional medicine as a possible cause of any child presenting with symptoms suggesting poisoning.
- ABCD structured approach.
- Hypoglycaemia and electrolyte disturbance management.
- Antibiotics.
- Wound management.
- Tetanus immunisation promotion.

### Introduction

Traditional medicine encompasses diverse health practices, remedies, approaches, knowledge and beliefs incorporating plant, animal and mineral products, spiritual therapies, charms, manual techniques, exercises, and in fact any kind of salutary method applied singly or in combination to diagnose, treat and prevent illnesses or maintain well-being, which has been handed down by the tradition of a community or ethnic group. In contrast with conventional medicine, which focuses on experiment and disease-causing pathogens, traditional medicine postulates that the human being is both a somatic and spiritual entity, and that disease can be due to supernatural causes arising from the anger of ancestral or evil spirits, the result of witchcraft, or the entry of an object into the body. It is therefore not only the symptoms of the disease that are taken into account, but also psychological and sociological factors. Thus the holistic nature and culture-based approach to traditional healthcare is an important aspect of the practice, and sets it apart from conventional western approaches. Traditional medicine is culturally treasured by various communities around the world. It thus plays an almost inestimable role in healthcare delivery to the people.

In many parts of sub-Saharan Africa, it is estimated that about 80% of the population use traditional health services. Most rural and urban dwellers often supplement treatment by orthodox medical practitioners with treatment by traditional healers. In Ghana, Mali, Nigeria and Zambia, it has been found that the first-line treatment for 60% of children with high fever from malaria is the use of herbal medicines at home. Traditional medicine is extensively used in Latin America and Asia. In China, 40% of all healthcare is delivered by traditional health practitioners. In 2007, there were an estimated 190 000 traditional health practitioners in South Africa. They treat an array of health-related problems as well as culture-bound syndromes or ailments considered to be non-responsive to western medicine. In 2002, the World Health Organization (WHO) estimated that traditional medicine provided 80–90% of healthcare in Africa.

For example, among Nigerians, there are powerful cultural and religious beliefs and practices relating to health. Approximately 85% of the population use traditional medicine and consult its practitioners for healthcare. The majority

(70%) of Nigeria's population is rural and relies almost exclusively on traditional medicine for its healthcare needs.

The popularity of traditional medicine has been attributed to poverty, limited or no access to good-quality orthodox medicine, illiteracy and ignorance. Other factors include affordability, availability, efficacy, costly or inefficient orthodox medical facilities, unfriendliness of hospital staff, poor communication (e.g. patients not being told the nature and cause of their illness), inadequate technical services leading to poor-quality care, treatment that is divorced from the patient's culture, family and community, and the treatment only addressing biological aspects of the illness rather than also addressing spiritual aspects.

The traditional healer, as defined by the WHO (1976), is a person who is recognised by the community in which they live as being competent to provide healthcare by using vegetable, animal and mineral substances and certain other methods based on the social, cultural and religious background, as well as the knowledge, attributes and beliefs that are prevalent in the community, regarding physical, mental and social well-being and the causation of disease and disability. They rely exclusively on practical experience and observations handed down from one generation to the next, whether verbally or in writing. For most countries of the world, a traditional healer may be able to perform many functions, thus being more versatile as a healer.

The elements of traditional medicine include, among others, herbal medicine, massage, homeopathy, mud baths, music therapy, wax baths, reflexology, dance therapy, hydrotherapy, mind and spirit therapies, self-exercise therapies, radiation and vibration, osteopathy, chiropractic medicine, aromatherapy, preventive medicine, radiant heat therapy, therapeutic fasting and dieting, spinal manipulation and psychotherapy.

### Traditional healers

There are various categories of traditional healers. Some of them may have areas of special interest.

#### Herbalists

A herbalist is a person who specialises in the economic or medicinal uses of plants. The whole plant may be used or parts of the plant, including the whole root, root bark, whole stem, stem bark, leaves, flowers, fruits and seeds, which may be administered to the patient in the following forms:

- 1 a powder that can be swallowed or taken with pap/traditional porridge (cold or hot) or any drink
- 2 a powder that is rubbed into cuts made on any part of the body with a sharp knife
- 3 a preparation that is soaked for some time in water or local gin, and decanted as required before drinking; the materials could also be boiled in water, cooled and strained
- 4 a preparation that is pounded with native soap and used

- for bathing; such 'medicated soaps' are commonly used to treat skin diseases
- 5 pastes or ointments, in a medium of palm oil or shea butter
  - 6 soup which is consumed by the patient
  - 7 herbal preparations may also be administered as an enema.

The plants are gathered from the environment, and are therefore part of every cultural tradition and have helped the development and growth of herbalism. Some of the plants that are facing extinction due to drought, bush burning, rapid growth of communities, farming or other factors are specially cultivated by some herbalists to maintain a steady source of supply.

#### **Traditional birth attendants (TBAs)**

A traditional birth attendant assists the mother at childbirth, and initially acquired her skills delivering babies by herself or by working with other birth attendants. TBAs are predominantly female. For example, around 60–85% of childbirth in Nigeria is overseen by TBAs, especially in the rural communities. They therefore occupy a prominent position in the healthcare system. Their skills are wide ranging, including diagnosis of pregnancy, antenatal care, conduct of labour and postnatal care. They are quite acceptable to those living in rural communities because their practice is linked to socio-cultural practices. For this reason, some governments have started to train TBAs in an attempt to reduce maternal and child morbidity and mortality.

#### **Traditional bone setters**

Traditional bone setters are knowledgeable in the art and skill of setting broken bones in the traditional way, using their skill to ensure that the bones unite and heal properly. They are involved in setting various types of fractures using wooden splints made from bamboo plants, and they use dry fibre from banana stems as bandaging. Wounds resulting from such fractures are usually cleaned and bleeding stopped by the application of plant extracts. Some practitioners fracture similar bones in a bird and treat it alongside the fractured limb of the patient. This is used to determine the time that it will take for the patient's fracture to heal, and the correct time for removing the wrapped splints and clay cast. Importantly, some bone setters collaborate with orthodox medical practitioners who treat the open wounds, offer radiological services and give advice on cases that require referral. This may help to reduce the number of complications occurring in their practices.

#### **Traditional surgeons**

These practitioners undertake minor surgery. The procedures that they perform include the cutting of tribal marks, male circumcision and female genital mutilation (see Section 2.10), ear piercing, and incision and drainage of abscesses, to name just a few. Complications such as haemorrhage, tetanus and sepsis have been reported in their practices.

#### **Traditional psychiatrists**

The traditional psychiatrist specialises mainly in the treatment of patients with mental disorders. Psychotics who are violent are usually restrained by chaining them with iron or by clamping them down with wooden shackles.

Those who are diagnosed as demon possessed are usually caned or beaten into submission and then given herbal hypnotics or highly sedative herbal potions to calm them. Such herbal preparations include extracts of the African *Rauwolfia* species. Treatment and rehabilitation of people with mental disorders usually take place over a long period of time. Incantations and various forms of occultism are often employed.

#### **Practitioners of therapeutic occultism**

These are traditional practitioners who use supernatural or mysterious forces, incantations, or prescribed rituals associated with the community's religious worship, and they adopt various inexplicable methods to treat a range of diseases. They are usually respected within the community because of their ability to deal with unseen and supernatural forces. They are regarded as witches and wizards.

#### **Traditional medicine ingredient dealers**

These dealers are involved in the buying and selling of plants, animals (including insects) and minerals used to make herbal preparations. Some of them also cultivate certain medicinal plants. Although they are not traditional healers, they have knowledge of products that cure different disease conditions, and can therefore prescribe and administer these. Due to this fact, some of them are referred to as traditional healers.

#### **Relevance of traditional medicine**

Many communities have developed various traditional systems using locally available resources for the alleviation of their health problems. This has resulted in the appearance of a number of different categories of healers, and a variety of healing methods, strategies and medicines or remedies.

Most people who live in rural communities do not have access to orthodox medicine. For example, in Nigeria it is estimated that about 75% of the population still prefer to solve their health problems by consulting traditional healers. Furthermore, many rural communities have great faith in traditional medicine, particularly its inexplicable aspects, as they believe that it represents the wisdom of their forefathers which also incorporates their socio-cultural and religious background, which orthodox medicine seems to neglect.

There is some justification for the use of herbs by the various traditional healers. A range of herbs have been used in the treatment of various disease conditions, including the African *Rauwolfia* species (used to treat cardiovascular diseases such as hypertension), rose periwinkle (used to treat diabetes), the Chinese herb *Artemisia annua* (used to treat malaria) and lemon grass (used to treat diseases of the respiratory system). Although herbal medicines may have beneficial active ingredients, the dosage cannot be controlled as there is no assay system for defining potency, and this increases the risk to patients who receive such treatment.

In environments where illness is believed to have a magical/spiritual origin, people become involved in intense prayers and sacrifices to compensate for their frailty and powerlessness. Western explanations of illness are rarely taken seriously. Local people may embrace traditional medicine to the exclusion of all other approaches, or combine it with orthodox medicine. Adverse drug interactions may result from such combinations of approach. Medical

practitioners working in places where traditional medicine is practised must be patient and respectful in their encounter with patients who are using traditional approaches. With health education and therapy that bring real health benefits, local people will become persuaded to accept effective evidence-based treatment.

Although the disadvantages of traditional medicine are numerous, it does also have a few advantages. The traditional healers and their drugs are available in these communities and their drugs are relatively easy to obtain compared with those of orthodox medicine. The healing system cares for the body, mind and soul of the patient in the context of the family, community, God or gods. The relationship between the practitioner and the patient can be close, encouraging and intense, with active participation of the family and neighbours. The practitioners are well known, trusted and respected in the community, and their methods fit very well with the culture and customs of the people. The drugs are cheap and readily available, and the healers accept payments either as a whole, in part or in kind, which also makes their treatments much more accessible for the people.

### **Complications of traditional medicine**

Contrary to popular opinion that traditional medicine, especially herbal medicine, is natural or safe, it can be hazardous to health if these preparations are taken in recommended or larger amounts, injected or combined with prescription drugs. Some Asian herbal products have been found to contain potentially dangerous concentrations of harmful substances such as arsenic, mercury and lead, many of which cause liver failure, haemorrhage or heart failure.

Where confidence in conventional medical care is low, there is a tendency to resort to more risky traditional remedies which may be more toxic. Conversely, when confidence in conventional medical care improves, there is an increasing movement towards the use of less toxic remedies, even though the use of some traditional remedies may continue to satisfy cultural and social needs.

In many low-income countries, patients are subjected to traditional treatment as first aid therapy in emergency conditions at home. Caregivers may apply interventions that are ineffective, harmful, and have no pathophysiological basis.

The application of traditional medical care that is ineffective may also lead to delayed presentation of potentially curable conditions to conventional care, resulting in unnecessary deaths and morbidity.

Some cultural practices are harmful to the health and survival of the newborn infant, and it is often young 'first-time' mothers who are most likely to follow these practices. Giving newborn infants cold baths, discarding colostrum, and providing food other than breast milk soon after birth is common practice. The application of butter, ash or other substances, such as cow dung, to the umbilical stump increase the risk of life-threatening infection.

### **Examples of problems resulting from traditional medicine practices**

#### ***Experience of the use of traditional medicine in Nigeria***

In Nigeria, as in most other developing countries, children are subjected to unorthodox treatment as first aid therapy in emergency conditions at home. Caregivers may apply

interventions that are ineffective, harmful, and have no pathophysiological basis. The use of traditional medicine is largely ethnocentric.

#### **Crude oil**

In the Niger Delta region of Nigeria, crude oil is available in large amounts. It is highly regarded locally as a remedy for a variety of ailments, including febrile convulsions, gastrointestinal disorders, burns, 'foot rot' and leg ulcers, and poisoning. It is also used in witchcraft. The oil is applied to the skin, mixed with alcohol or water as a drink, and instilled into body orifices such as the nostrils, ears, anus, vagina and urethra. The use of crude oil as traditional medicine in Nigeria has been reported to have an analgesic effect comparable to that of aspirin. Complications associated with its use have been reported in children with febrile convulsions.

Complications caused by crude oil have been reported to affect a number of organs, including the skin, lungs, liver and kidneys. Skin exposure may result in the formation of vesicles, blisters and even extensive epidermolysis. Ingestion of crude oil may result in nausea, vomiting and diarrhoea, and the aspiration of crude oil during vomiting results in chemical pneumonitis. Central nervous system symptoms range from vertigo and headache caused by ingestion of small doses, to lethargy, convulsions, coma and death with larger doses. Renal failure has been described as another toxic effect.

#### **Cow's urine concoction**

'Cow's urine' concoction (CUC) is a traditional medicine used in the management of convulsive disorders in childhood among the Yoruba-speaking people of south-western Nigeria. It is prepared from leaves of tobacco, garlic and basil, lemon juice, rock salt and onion bulbs, which are soaked in cow urine, which acts as the vehicle in which the active principles of these constituents dissolve. Over 50 chemical compounds have been identified in CUC, the major ones being benzoic acid, phenylacetic acid, p-cresol, thymol and nicotine. These components are toxic, and have harmful effects on the different systems of the body. The main effects are severe respiratory depression, effects on the cardiovascular system and the central nervous system, and hypoglycaemia. These toxic effects acting singly or in combination are believed to be the cause(s) of death from CUC.

#### **Cow dung**

It is estimated that 30–40% of infections resulting in deaths from neonatal sepsis are transmitted at the time of childbirth and have early onset of symptoms (developing during the first 72 hours after birth). Worldwide, 60 million births occur outside healthcare facilities, and even within such facilities, hygienic practices may be suboptimal.

The unhealed umbilical cord is an important portal for local and invasive infections during the neonatal period. It is rapidly colonised by bacteria from the maternal genital tract and then from the environment. Infection can emanate from the bamboo stick that is used to cut the umbilicus, and from the cow dung (believed to have desiccating properties) that is used to dress the umbilical stump. Localised umbilical infection (omphalitis) emanating from these sources can spread to the abdominal wall, the peritoneum, or through the umbilical or portal vessels leading to systemic sepsis, which if untreated has a high fatality rate. Neonatal

tetanus is a very important complication resulting from these practices, which are common among the Yorubas of south-western Nigeria and the Maasai people of Kenya. Cow dung is also used to anoint the heads of the sick among the Maasai people.

### Traditional eye medications

In one study, complications occurred in 55% of the individuals studied, and included corneal opacities, staphyloma and corneal ulcers. Other complications were panophthalmitis, endophthalmitis, uveitis, cataract and bullous keratopathy. Eleven individuals in one study underwent enucleation of the affected eye.

Traditional healers tend to prefer to use substances that cause irritation and pain, as these are perceived by both healers and patients to be more potent. Such substances may be acidic or alkaline, resulting in ocular burns. No particular attention is paid to concentration and sterility, as most of these concoctions (mixture of various substances, which may be plant or animal extracts) are prepared without regard for hygiene, including the use of contaminated water, local gin, saliva and even urine.

Most of these ocular conditions could have been adequately treated using standard medicines, which were sometimes available.

### Experience of the use of traditional medicine in pregnancy in South Africa

A recently published review showed that a large percentage of pregnant women still use herbal remedies during pregnancy and childbirth, and in one study the use of at least 56 botanical species was documented.

Such herbal treatments are known collectively as *Isihlambezo*, which is taken as an antenatal tonic during the last trimester of pregnancy in the belief that it promotes a favourable pregnancy and a quick and uncomplicated labour. It is also used to treat common pregnancy-related ailments such as oedema, indigestion, constipation, infection and high blood pressure. It is even believed by some that such traditional medicines may be able to turn a breech baby.

Many different plants are ingredients of *Isihlambezo*, and the recipes for this tonic vary depending on factors such as the traditional healer consulted, the general state of health of the woman, the geographical area and the tribal community. The ingredients are boiled or infused in water and the 'tea' is then taken by the spoonful or cupful. The concentration of the mixture may be increased at the end of pregnancy in order to speed up labour.

*Isihlambezo* mixtures can be purchased from and dispensed by traditional healers and herbalists or 'muti' shops, and individual ingredients can be obtained from open herbal medicine markets throughout the country. In the rural areas, the ingredients for *Isihlambezo* are often harvested from the local countryside by senior women in the tribal community or by traditional birth attendants.

*Imbelekisane* and *Inembe* are more specific remedies used as uterotonic drugs in cases of prolonged and difficult labour. However, interviews conducted with traditional healers in KwaZulu-Natal revealed that *Imbelekisane* and *Inembe* are regarded by them as dangerous medicines.

Teratogenicity can be largely ruled out, as these remedies are usually only used in the last trimester. However, the potential for maternal and fetal toxicity remains. Sixteen

of the species used in these remedies are known to be poisonous, and one of these, *Callilepis laureola* (*Impila*), is extremely poisonous and has been responsible for many fatalities resulting from hepato-renal failure. Other toxic effects that have been linked to the use of these medicines in pregnancy include low neonatal birth weights, fetal meconium staining of amniotic fluid, and fatal uterine rupture.

All of the plants investigated in the above-mentioned study were able to directly stimulate uterine contraction to varying degrees. *Clivia*, *Agapanthus* and *Rhoicissus* significantly augmented the initial response of the uterus to oxytocin, and were able to produce initial phasic contractions followed by tonic contractions at higher doses. Herbal remedies containing these plants must therefore be considered to have the potential to cause uterine hyperstimulation and its associated adverse effects, including uterine rupture.

### Experience of traditional medicine in the Eastern Cape area of South Africa

In another publication, traditional remedies were found to be regularly used in the home management of children in the Eastern Cape, and probably in the great majority of cases these remedies do little harm beyond delaying presentation to the healthcare system. However, serious effects were occasionally identified. Most often the traditional remedy was given to treat a symptom of an underlying disease, rather than being the cause of the condition or symptoms.

- **iYeza lo moya:** commonly given to infants by mouth, with few problems reported. However, a traditional enema may also be given, which may have more toxic effects.
- **Senecio extracts:** infusions of this weed with yellow flowers have been reported to cause veno-occlusive disease in a small number of children.
- **Impila:** extracts from this root may cause fatal hepato-renal failure, often presenting with hypoglycaemia.
- **River onion:** this is used both orally and rectally, and causes hepato-renal failure in a significant number of children.
- **Jeyes fluid:** this is sometimes added to rectal and oral remedies, and causes local and systemic effects.

### Surgical complications of traditional medicine in East Africa

A series of case histories in 2007 included a 6-year-old girl sustaining a spiral fracture of the humerus during a road traffic accident. The parents refused hospital treatment and took her to a traditional bone setter. Two weeks later she was brought back to the hospital with a gangrenous upper limb, which was the result of placing a tourniquet around the axilla. Debridement was undertaken but the child lost the whole of the skin of the forearm and most of the hand.

A second case involved an 18-month-old boy who underwent circumcision by a traditional practitioner. On subsequent admission to hospital he was found to have partial amputation of the glans penis.

### Traditional medicine used in pregnancy in Malaysia

In one study, 108 mothers (51% of those studied) used at least one type of herbal medicine during pregnancy. The type most commonly used (by 64%) was coconut oil

ingested only during the third trimester. The most common indication (90% of cases) was to facilitate labour.

The older generation, parents and in-laws were those who most strongly encouraged the use of herbal medicines. The main reasons for using these medicines were to facilitate labour, to promote the baby’s physical health and intelligence, to prevent a retained placenta or to promote abortion.

- Airway
- Breathing
- Circulation
- Disability.

Regular assessment and treatment of these essential systems will ensure that management keeps abreast with progress and with the prevention of deterioration.

**However, when treating patients who have been given traditional medicines, first look for a medical cause of the symptoms and signs before assuming that the illness is due to the traditional remedy.**

### Management of suspected adverse effects of traditional medicine

These include a rapid assessment of:

**TABLE 1.21.1 Serious complications caused by traditional medicines, and their management**

System affected	Symptoms and signs	Treatment
Cardiovascular	Increased cholinergic actions such as lacrimation, salivation, rhinorrhoea, diarrhoea, vomiting and miosis, severe bradycardia or heart block	IV atropine may help
	Anticholinergic actions such as hyperthermia, tachycardia or tachyarrhythmias, mydriasis, constipation or acute urinary retention	Anticholinesterase drugs may help
Neurological	Weakness, epileptic fits, coma and intracranial bleeding	Check blood clotting Anticonvulsants
Pulmonary	Anaphylaxis, bronchoconstriction Severe interstitial pneumonitis, non-cardiac pulmonary oedema, acute eosinophilic pneumonia	Specific treatment for anaphylaxis and bronchoconstriction (see Section 5.1.B) Corticosteroids
Liver toxicity	Nausea, anorexia, vomiting, jaundice with elevated liver transaminases	Supportive (see Section 5.7.A)
Nephrotoxicity	Acute renal failure and tubular dysfunction	Supportive (see Section 5.6.C)
Heavy metal contamination with lead, arsenic, thallium or uranium	Gastrointestinal disorders, hepatitis, polyarthritis, encephalopathy (including ataxia and severe psychiatric disturbances)	(see Section 7.4)

- Clean any areas that are visibly affected with a topical application of sterile water, and apply a non-adhesive dressing if necessary.
- If available, laboratory investigations can be helpful for identifying organ systems that may be affected by a toxic traditional medicine. Take blood for a biochemical profile (urea and electrolytes, liver function tests, amylase and glucose) and a full blood count with indices. If there is any significant abnormality, refer the patient to the relevant specialist team.
- Symptoms and signs such as convulsions should be treated with diazepam injection, hypoglycaemia should be corrected with glucose infusion, and fluid and electrolyte disturbances should be corrected with appropriate oral administration or intravenous infusion.
- Appropriate antibiotics should be administered to patients with infective conditions.

### Conclusion

Traditional medicine continues to represent a very large component of community healthcare, especially in resource-limited regions. Efforts to make traditional medicine safer are urgently required, and might include official regulation to monitor the activities of traditional practitioners, standardise their practices and undertake toxicity studies on their products, in collaboration with scientists and recognised institutions. However, this will also require the traditional healers to be willing to work with such control of their practice, which could be a problem if the healers see this as an attempt to limit their practice, or to steal their secrets and remedies.

# 1.22 Emergency equipment and drugs for obstetric and paediatric care

## Introduction

Wherever healthcare is offered, people who consider that they need emergency care will arrive unexpectedly. All healthcare facilities should be prepared to receive and treat such patients as quickly, effectively and compassionately as possible.

**Preparation, training and practice** are the keys to success in emergency care.

**Preparation** involves considering and having available the necessary equipment and drugs for all of the possible pathologies requiring emergency care that are likely to present to the facility.

**Training** involves ensuring that healthcare workers in the emergency area have been trained to assess life-threatening and urgent care needs and to respond to these in a recognised and structured way so that no essential steps are omitted.

**Practice** involves the emergency team rehearsing their response to emergencies together so that they become competent when presented with real situations.

Hospitals should have a dedicated 'Emergency Room' where patients of all ages and with all conditions can present. However, patients will often attend the ward where they have previously been seen, and of course emergencies can arise within any ward, especially if that ward is understaffed.

Therefore it is vital that every ward, as well as the emergency room, is prepared with the drugs and equipment necessary to respond successfully to any emergency in that area.

This section describes the drugs and equipment necessary to treat emergencies in women and girls during pregnancy, labour and the postpartum period, as well as in infants and children.

The emergency room should be staffed at all times. The number of staff will depend on the size of the facility and the expected number of patients. In a large city hospital where hundreds of patients attend every day, there may be 10 to 20 nurses and 6 to 8 doctors on duty at any one time. However, in a small peripheral clinic, with only one or two inpatient wards and three or four labour-room beds, there may not be enough staff for one of them to spend all of his or her time awaiting an emergency. In that case, a simple and reliable means of calling for assistance must be put in place for emergency cases arriving at the facility. Again, **preparation** is key, and the immediate availability of the necessary emergency equipment and drugs, together with a **trained and practised** healthcare worker, is paramount.

Training in the structured approach to recognition and treatment of life-threatening illness and injury should be available to all healthcare workers who may be called upon to treat emergency patients. There are a number of training programmes available, including the World Health Organization's Integrated Management of Neonatal and Childhood Illnesses (IMNCI), the Emergency Triage Assessment and Treatment (ETAT) course, the Emergency Maternal and Neonatal Health (ESS-EMNH) and Emergency

Child and Trauma Health (ESS-ECTH) courses of Maternal Childhealth Advocacy International ([mcai.org.uk](http://mcai.org.uk)), and the Advanced Life Support Group (ALSG) courses ([alsg.org](http://alsg.org)).

Wherever there are unexpected emergencies, decisions have to be made about which patient is the most urgent one. Emergency healthcare is not offered on a 'first come, first served' basis. Those with the greatest need are treated first. This sorting system is called **triage** (for a detailed explanation, see Section 1.10).

Throughout this textbook, details of diagnoses and treatments, including practical procedures, for improving the care of patients with emergency healthcare needs can be found. In this section we now list the emergency equipment and drugs that are essential for providing this care.

## Resuscitation equipment for the emergency room

### Airway and breathing

- Suction apparatus:
  - wall, electrical or manual suction
  - Yankauer (adult and paediatric) and soft suction catheters
  - a manual suction device, for use by midwives.
- Face masks – adult, child, infant non re-breathing with reservoir bags (for delivering 100% oxygen).
- Self-inflating resuscitation bag with 500-mL (for infants and young children) and 1600-mL (for older children and adults) reservoir bags and face masks in a range of sizes (masks that are too large may be used inverted).
- Nasal cannulae for prolonged lower level oxygen delivery.
- Airway devices:
  - oropharyngeal airways in a range of sizes (000, 00, 0, 1, 2 and 3)
  - endotracheal tubes in a range of sizes (2.5–7.5 mm), and connectors.\*
- Laryngeal masks (e.g. I-Gel Size 1, 1.5, 2, 2.5, 3 and 4).
- Laryngoscopes:\*
  - adult curved and paediatric straight-bladed
  - spare bulbs and batteries.
- Magill's forceps.\*
- Cannulae for cricothyroidotomy.\*

### Circulatory access and bleeding control

- Peripheral vascular cannulae in a range of sizes (18–25G).
- Intraosseous needles (16–18G) or EZ-IO drill with adult and paediatric needles.
- Sterile catheters 4, 5, 6.5, 8 Fr gauge 40 90 cm long (for suction, feeding, etc.) for umbilical access (for newborn), umbilical vessel dilator, and artery forceps.
- Central venous catheters.\*
- Syringes, including a 50-mL syringe for fluid boluses, plus a three-way tap.
- Intravenous giving sets and graduated burettes.
- Condom catheter (see Section 2.5.D.iv).
- Cut-down instruments, scalpel and forceps.

\*These items are to be used only if facilities exist for intubation and assisted ventilation (e.g. on a high-dependency or intensive-care unit).

### Trauma

- Hard cervical collars (adult short and regular, paediatric) and sandbags/foam blocks.
- Peripheral vascular cannulae, (18–25G) three-way taps and syringes.
- Scalpels, sutures, needle holders and scissors.
- Splints.
- Chest drains in a range of sizes (12, 18, 20, 22, 28, 32 Ch).
- Dissecting forceps.
- Underwater drainage system, or flap valves.
- Nasogastric tubes in a range of sizes (4, 5, 6.5, 8, 10 Fr).

### Drugs, fluids, etc.

- Oxygen supply.
- Ringer-lactate or Hartmann's solution or 0.9% saline, vials and bags or bottles.
- Colloid (e.g. 4.5% albumin, gelatine, hetastarch).
- Adrenaline, 100 micrograms/mL (1 in 10000) and 1 mg/mL (1 in 1000).
- Amiodarone, 30 mg/mL.
- Glucose, 10%, 25% and 50%.
- Water for injection.
- Normal saline for injection.
- Mannitol, 20% and/or saline, 2.7% (or 3%).
- Diazepam, rectal solution.
- Lorazepam, diazepam or midazolam (can be used as buccal or IV treatment).
- Phenytoin.
- Phenobarbitone.
- Atropine.
- Sodium bicarbonate.
- Calcium chloride.
- Magnesium sulphate.

- Broad-spectrum antibiotic (e.g. cefotaxime, ceftriaxone, gentamicin).
- Penicillins: penicillin G, amoxicillin, flucloxacillin.
- Metronidazole.
- Hydralazine.
- Misoprostol.
- Quinine.
- Morphine/diamorphine.
- Naloxone.
- Insulin.
- Local anaesthetic (e.g. lignocaine) and general (e.g. ketamine) anaesthetic agents.\*
- Paralysing agents.\*
- Skin cleansing solution (e.g. chlorhexidine, alcohol, iodine).
- Vaginal antiseptic lotion (Hibitane).
- Steroids (prednisolone, hydrocortisone).
- Salbutamol nebulas, inhaler and IV solution.
- Aminophylline.
- Furosemide.

### Monitoring and other equipment

- Pulse oximeters.
- ECG monitors including one with with defibrillator with paediatric pads or an automatic external defibrillator (AED).
- Sphygmomanometer or blood pressure oscillometer.
- Thermometers (including low-reading thermometer).
- Nebuliser.
- Large-volume spacers.
- Blood/urine glucose testing kits.
- Urine protein testing sticks.
- Urinary catheters (silicon, rubber or soft feeding tubes) of various sizes (12–30 Fr).

\*These items are to be used only if facilities and skills exist for intubation and assisted ventilation.

## 1.23 Grief and loss in societies affected by conflict and disaster

### Introduction

Why do we grieve? Wouldn't life be much simpler if we did not experience all those painful emotions that occur when someone we love dies? Perhaps so – no weeping and wailing, no stoical silence, no anger and irritation, no smiling and carrying on as usual, no sudden flood of pain and memories to overwhelm and paralyse us, no rush of tears when we hear a familiar tune. That sounds much easier. The trouble is that grief is actually the price tag on another emotional experience, without which human life would be quite unbearable. We grieve because we love. Love is the essential emotion that keeps us connected and attached to family and friends and allows us to survive as rather puny animals in a hostile world. If we did not love we

could not suffer loss, but neither could we survive in selfish isolation.

This section provides a brief introduction to understanding grief and loss in families living in societies affected by disaster and conflict, and offers some guidance on how to support these families. It will address the following questions:

- What is the impact of loss on individuals and groups in conflict and disaster settings?
- What is grief and how is it related to attachment?
- Is grief an illness?
- How does grief affect our health?
- When is grief abnormal?
- What is mourning and why does it matter?

- What happens when large numbers of people die at one time?
- How do we distinguish between the effects of traumatic events and the effects of loss?
- What is cultural bereavement?
- What are the effects of grief in childhood?
- What can we do to help grieving families and children?

In a society affected by conflict or disaster, most children will be seen in the company of their surviving adult relatives, whose own mental state will have a profound effect on the child. The family doctor must therefore be responsive to, and able to assess and support, the whole family. For this reason, this section looks at grief in both adults and children, and it outlines a general approach to supporting families and children. However, it does not give detailed management advice on the wide variety of specific symptomatic problems that can occur in grief (e.g. bedwetting, sleep disturbance), as there are a number of excellent manuals available on this topic.<sup>1</sup>

### What is the impact of loss on individuals and groups in conflict and disaster settings?

The central experience for almost all of those living in communities affected by conflict or disaster is loss. Even if no one in your family dies, something will be lost. You may be injured or lose your health. Your home or your school may be destroyed, or the neighbourhood may be swept away. Your friends or work colleagues may be killed or flee. If you flee yourself you will lose everything that made up your world and kept you rooted and connected. As well as these external losses, you may lose aspects that are central to your internal sense of self, such as feelings of being safe and in control, and your sense of identity as, for example, a mother, father, schoolchild, farmer or shopkeeper. Some of the possible losses that can be experienced are listed in Table 1.23.1. Their effect can be overwhelming. Understanding how people react to such losses, how to distinguish between normal and abnormal grief, and how to assist in appropriate mourning will be some of the key tasks for healthcare workers in these contexts. It is also essential to understand other psychological reactions, such as post-traumatic stress disorder (PTSD), and set them in context.

**TABLE 1.23.1** Some of the losses that can be experienced by those exposed to conflict, disaster, or life as a refugee

Internal losses	External losses
Control	Family members
Autonomy	Friends
Security	Home
Identity	Community/country
Self-respect	Work/school
Belief in the future	Money and other material possessions
Sense of belonging	Physical health
Trust	Religion
The past	Language
Meaning of life	Familiar life

### What is grief and how is it related to attachment?

The ability to form strong relationships with others is necessary for our survival as human beings. We call this ability **attachment**. The sense of loss that we feel when a loved one is absent leads us to search them out. Attachment is the glue that keeps families and groups connected together. Human beings could not have survived in previous eras if they had not lived in groups that enabled them to feed and shelter themselves. Loss is the sense of sadness, fear and insecurity that we feel when a loved person is absent. It can also be felt in relation to objects and places.

In the 1950s, the World Health Organization (WHO) commissioned John Bowlby to observe what happened to small children when they were separated from their mothers. In Britain in those days, if a child went to hospital for an operation, the parent was not allowed to remain with them. John Bowlby sat watching the infant to see how they reacted, how they adapted to the separation, and how they behaved when the parent returned. He defined a cycle of behaviours that can be observed in any infant who is separated from their mother and then reunited with her.

First there would be a period of loud and angry protest. The child would hope that their cries would bring their mother running back. When this did not happen, a period of despair and withdrawal followed in which the child would cry, not wish to engage with others, and refuse to eat or play. Later the child might appear to 'adapt'. They would start to eat again, play with other children, make friends with the nurses and appear detached and indifferent to the loss of their mother. Indeed if the parent reappeared at this stage, the child's first response might be to ignore her, and then if they did engage with her, to be naughty and angry. Only after some time would the original relationship reform and re-engagement occur. Bowlby noted that this attachment/separation behaviour is most visible in children between 6 months and 3 years of age. However, these behaviours can reappear in any individual throughout the life cycle when they are faced with separation from someone they love.

Attachment behaviour is any form of behaviour that results in a person attaining or maintaining proximity to some clearly identified individual who is conceived as better able to cope with the world. It is most obvious whenever a person is frightened, fatigued or sick, and is assuaged by comforting and caregiving. At other times, the behaviour is less in evidence. Nevertheless, for a person to know that an attachment figure is available and responsive gives him a strong and pervasive feeling of security and so encourages him to value and continue the relationship. Whilst attachment behaviour is at its most obvious early in childhood, it can be observed throughout the life cycle, especially in emergencies. Since it is seen in virtually all human beings (though in varying patterns), it is regarded as an integral part of human nature and one we share (to a varying extent) with members of other species. The biological function attributed to it is protection. To remain within easy access of a familiar individual known to be ready and willing to come to our aid in an emergency is clearly a good insurance policy – whatever our age.

Bowlby, 1988<sup>2</sup>

Many writers have noted the similarity between a child's behaviour after separation from a parent and our reactions to the loss of a loved person who has died. Death reactivates attachment behaviour. Faced with the permanent loss that death represents, we may find ourselves angrily protesting, searching and yearning, trying our best to maintain and hang on to the connection. Or we may experience periods of indifference and denial as a way of avoiding the pain. Many people alternate between periods of acute grieving and yearning and periods of avoidance or detachment. In the past, some authors have argued that these feelings occur in stages. Elisabeth Kubler-Ross constructed a model of bereavement in which the individual was said to progress through the following periods, often cyclically:<sup>2</sup>

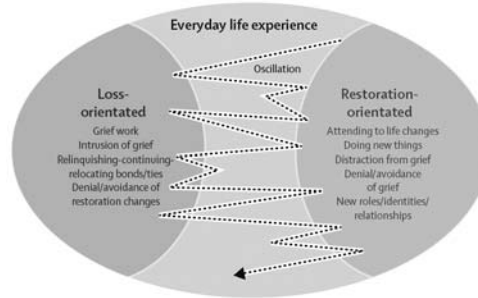

- 1 denial
- 2 anger
- 3 bargaining
- 4 depression
- 5 acceptance.

It was suggested that people could become stuck at different stages, and that 'grief work' was necessary to progress through all the stages to recovery. There is now a growing understanding of the enormous variability in our responses to bereavement. How people grieve and how they cope will depend on individual factors such as their temperament and personality. What were their experiences as a child? Were they loved and securely attached to those who cared for them or were they abused or insecure? This will affect the way that they form relationships with other people, and the way that they experience loss, as will their age, gender, and experience of previous losses. The way that people grieve will also depend on the nature of the loss and how it occurred. Was it sudden or expected? Was it violent, unjust, or part of a massive loss, or did it occur after a prolonged illness? What did the loss mean to the person? Were they thrust into isolation and poverty, or were they possibly liberated from an abusive relationship? In all cases, social factors such as cultural and religious beliefs and community and family dynamics will play a role in determining how grief is experienced and expressed. The current social situation will also influence this. Is the family in danger or in flight? What material resources do they have? Do they face legal difficulties because of the loss? Is social support available or are they isolated? The case examples below and the vignettes in the Appendix all illustrate these variations.

Table 1.23.2 lists the wide variety of emotional, cognitive, behavioural and physiological changes that can occur in response to bereavement. An individual may experience some, all or none of these. The reactions may occur in many different patterns and combinations depending on the factors described above. Some individuals experience few reactions, others more. Some people find that their reactions change over time or occur in varying combinations.

People may feel anger and sadness at the same time. An anniversary or a particular place may trigger a memory, which reactivates the feelings of grief again, perhaps years after the event, possibly interrupting a long period of acceptance. Some have described grief as a 'relapsing illness'. Stroebe and her colleagues have created a model to show how many people may fluctuate between a 'loss orientation' of yearning and sadness and a 'restoration orientation' of

more avoidant states of denial and getting on with things (see Figure 1.23.1).

**FIGURE 1.23.1** The dual process model of coping with bereavement. Thanks to Stroebe M, Schut H. *Death Studies* 1999; **23**: 197–224.

Which feelings and behaviours occur, which state dominates and what is regarded as normal for both children and adults will depend very much on how grief is expressed in that culture, by that family and in that individual, as well as on the religious values, temperament and personality of the individual. For example, in Bosnia it is regarded as appropriate for Serbian women to attend the funeral and to display their emotions visibly, keening and weeping. In Bosnia, Muslim culture values a more stoical approach and sees the open display of emotions as inappropriate. In some cultures, for example in parts of South-East Asia, vivid dreams may be regarded as appropriate messages from the dead. In western culture, dreams may be seen as an upsetting form of sleep disturbance. In Kosovar families with whom I have worked, there was often one individual (usually an older adolescent girl), who might cry a great deal, hyperventilate and faint, while the rest of the family remained stoical. The fainting girl might cause concern, but also seemed to play a role in vividly expressing grief for the rest of the family, whose concern for her also acted as a form of distraction from the loss (see Appendix, Vignette 2).

Near the end of his life, Sigmund Freud was consulted by a woman who had become depressed following the death of her husband. After listening to her, Freud quietly stated, 'Madam, you do not have a neurosis, you have a misfortune.'

### Is grief an illness?

Acute grief may be painful and feel like an illness, but it should be understood, in all its variety, as a normal reaction to loss. Some combinations of reactions do appear to mimic certain acute mental illnesses. For example, loss of appetite combined with sleep disturbance, sadness, ruminations and various somatic complaints appears similar to clinical depression. However, that diagnosis should not be made if someone has suffered an acute loss. Some individuals may adopt the behaviours of the deceased, dress in their clothes, act strangely or hear their voice, see them and talk to them. Again this should not be regarded as psychotic behaviour, but rather as a possible manifestation of acute grief. Or there may be flashbacks, vivid intrusive thoughts and dreams of the deceased, and the individual may be anxious and aroused, similar to those with PTSD. None of these reactions are necessarily pathological.

TABLE 1.23.2 Reactions to bereavement<sup>8</sup>

Affective	Cognitive	Behavioural	Physiological-somatic
Depression, despair, dejection, distress	Preoccupation with thoughts of the deceased, intrusive ruminations	Agitation, tenseness, restlessness	Loss of appetite
Anxiety, fear, dread	Vivid memories	Fatigue, apathy	Sleep disturbances
Guilt, self-blame, self-accusation	Sense of the presence of the deceased	Overactivity	Energy loss, exhaustion
Anger, hostility, irritability	Lowered self-esteem, self-reproach	Searching	Somatic complaints
Anhedonia (loss of pleasure)	Helplessness, hopelessness, pessimism about the future	Weeping, sobbing, crying	Physical complaints similar to those of the deceased
Loneliness	Suicidal ideation	Social withdrawal	<i>Endocrine and immunological changes</i>
Yearning, longing, pining	Sense of unreality	Normal behaviour and continuation of normal activities	Susceptibility to illness, disease, mortality
Shock, numbness	Memory and concentration difficulties	<i>In children</i>	
No reaction	Suppression, avoidance, disbelief	Acting out	
	Fantasies	Regressive behaviour	
		School difficulties	
		Rapid maturing	

### How does grief affect our health?

That is not to say that bereavement does not have physical and mental health consequences.<sup>4</sup> Bereaved people experience more physical complaints, have more health consultations, use more medication and experience more hospitalisations than those who are not bereaved. Paradoxically, those who are grieving intensely actually have fewer health consultations than the normal population, and high-intensity grief is a predictor of more severe physical disorders 1 year later. Perhaps this is because early warning signs are missed. Regarding the impact of bereavement on mental health, the majority of people recover but there is a greater vulnerability to depression, anxiety and PTSD. Bereavement is associated with increased mortality from many causes. People who have suffered a recent bereavement are more likely to die of alcohol-related disorders, coronary artery disease, unnatural deaths and suicide. It is thought that this additional risk may be due to a number of factors, including loneliness, changes in social circumstances, a reduction in material resources, and lack of care. The mortality risk is higher in the earliest months and in specific groups, namely mothers who have lost a child and widowers. Therefore there is some basis for the saying that you can die of a 'broken heart'.

### When is grief abnormal?

The decision as to what is abnormal and inappropriate grief will depend on an understanding of the individual, the family, the culture and the wider context. You cannot decide what is abnormal without this cultural and personal knowledge. The community and family may be able to tell when they feel that the grief is too intense, too long or unusual in its manifestations. The new diagnostic formulations,<sup>5</sup> *DSM-V* and *ICD-11*, that psychiatrists are using to categorise mental disorders are considering formulations for prolonged or complicated grief. For example, the suggested definition of prolonged grief disorder in *ICD-11* is as follows:

'Prolonged grief disorder is a disturbance in which, following the death of a person close to the bereaved, there is persistent and pervasive yearning or longing

for the deceased, or a persistent preoccupation with the deceased that extends beyond 6 months after the loss and that is sufficiently severe to cause significant impairment in the person's functioning. The response can also be characterised by difficulty accepting the death, feeling one has lost a part of one's self, anger about the loss, guilt, or difficulty in engaging with social or other activities. The persistent grief response goes far beyond expected social or cultural norms, and depends on cultural and contextual factors.'

### What is mourning and why does it matter?

Mourning refers to the culturally appropriate processes that help people to pass through grief. All societies and cultures mourn, but they do so in different ways. Mourning processes usually include acknowledgement and acceptance of the death, saying farewell, time periods for grieving, processes for continuing to focus attention on the dead, and processes for moving beyond the loss and forming new attachments. It might be helpful to take a moment to jot down on a sheet of paper the ways in which you mourn the dead in your own culture. Try to answer the following questions:

- How do other people know that someone has died or that you are bereaved?
- What happens at a funeral?
- What are the burial customs?
- What happens to the body?
- Who visits the bereaved?
- What are the different roles, if any, for men and women?
- What do younger and older children do?
- Are there different ceremonies at different time periods after the death to mark different stages of mourning?
- What ways do you use to remember the dead?
- What is the role of the dead person in continuing family life?

Different societies have different time periods set aside for mourning, and different ideas about what is appropriate

behaviour for different family members. They may also have different views on the appropriate role of children in these rituals. Sometimes families may be in conflict over what is appropriate to communicate to children and what is the appropriate way to mourn. This is particularly the case in societies that are in a state of upheaval (see Appendix, Vignette 1).

### What happens in situations of massive loss?

Conflict, disaster and displacement disrupt the possibility of appropriate mourning. There may be uncertainty about missing relatives. The body may have been lost, abandoned, treated inappropriately, or buried in a mass grave. During flight it is impossible to carry out the normal mourning rituals. Other processes also occur in large-scale upheavals. For example, in Aceh, Indonesia, after the 2004 Tsunami, people found themselves living in a landscape that had been swept completely clean by the Wave, where every familiar marker had disappeared along with their communities, families and livelihoods. There were no bodies and no places to go to remember the dead. In Haiti, after the earthquake, people camped out among crushed houses that entombed their families. Massive losses that affect whole communities may remove entire social networks of support. Moreover, even in functioning communities, they have the effect of depriving each individual of the normal support that they would have received if their loss had been a singular occurrence. Because everyone is affected, few are in the position to play the role of visitor and comforter. There is no one to come round, help the bereaved widow with the childcare and household tasks, arrange the funeral and cook a meal, because everyone who survived is in the same situation. Everyone struggles alone. And the bereaved may become more reticent than usual about their own feelings, not wishing to burden similarly affected neighbours. At the same time, the pain of the loss is amplified by the knowledge that the bereaved person's loss is one of many in a community. The outside world is focused on the scale of the event: '300 000 dead', 'half a million killed'. Lost within these figures, the individual bereavement becomes insignificant, just one of many thousands, adding to the pain of the survivor.

#### CASE EXAMPLE: Giving significance to loss

In early 2005 I was working on the East Coast of Sri Lanka after the tsunami. On one occasion, when I was walking along a completely deserted, devastated street, a man came running up to me. I was holding my camera and assumed I might have offended him by taking pictures. 'No, no,' he said, 'please take a picture of *this house*.' I looked at the gutted empty building and did as he requested, then turned back. He was near to tears. 'My mother died here,' he said. So we sat on the ground and he talked for some time about his mother. I suddenly realised that for this man I was more than just a sympathetic ear, I was the outside world witnessing and memorialising his individual loss. Not just 10 000 dead, but his mother. I was making her significant.

### Traumatic experiences, grief and mourning

Traumatic experiences can interfere with mourning. Avoidance that may be protective in helping the bereaved to cope with the memories of a traumatic event may make it difficult for them to mourn their loss because the memories

of the lost person are always accompanied by painful memories of the circumstances of the loss, so 'remembering' is too painful. In such circumstances, the traumatic symptoms may need treatment before the bereaved person is able to mourn. Table 1.23.3 lists the differences in emotional, cognitive and behavioural reactions that may occur.

### Cultural bereavement

The Australian anthropologist and child psychiatrist Maurice Eisenbruch has pulled some of these experiences together in the term 'cultural bereavement' to describe the massive losses experienced by refugees and all those displaced by war:

'Cultural bereavement is the experience of the uprooted person – or group – resulting from loss of social structures, cultural values and self-identity: the person – or group – continues to live in the past, is visited by supernatural forces from the past while asleep or awake, suffers feelings of guilt over abandoning culture or homeland, feels pain if memories of the past begin to fade, but finds constant images of the past (including traumatic images) intruding into daily life, yearns to complete obligations to the dead and feels stricken by anxieties, morbid thoughts and anger that mar the ability to get on with daily life. It is not in itself a disease but an understandable response to catastrophic loss of social structure and culture.'<sup>7</sup>

In his work with Cambodian adolescents, Eisenbruch found that those refugee children who had been encouraged to assimilate rapidly into a new culture suffered more cultural bereavement than those who were encouraged to participate in traditional ceremonies and cultural practices. He believes that the concept allows for a more integrated and culturally sensitive approach to the experience of loss than attempting to classify any disabling symptoms only in terms of pathological categories according to western diagnostic criteria such as PTSD or traumatic bereavement. Disabling symptoms may be best addressed by a combination of restoring appropriate cultural practices and, if necessary, symptomatic relief.

### Grief in childhood

The following are some frequently asked questions about children who have suffered a bereavement:

- Do children grieve?
- Are they too young to understand?
- Should we protect them from unpleasantness and distress?
- Will loss in childhood cause later mental illness?

### Children's understanding of and reactions to death

Children's reactions to death are as variable as those of adults, and any or all of the reactions listed in Table 1.23.2 may occur. The most important point to note is that their understanding of death changes according to their development and life experiences. The following notes are based on western experience, and should be taken as a guide only. Working with victims of conflict and disaster in many low-resource settings has taught me that in many societies, particularly rural ones, children understand death at

TABLE 1.23.3 Distinguishing between the effects of traumatic events and loss<sup>6</sup>

Reactions to loss	Reactions to traumatic event
Separation anxiety	Anxiety about threat presented by traumatic event
Sadness more than anxiety	Anxiety more than sadness
Yearning and preoccupation with loss	Fearful, anxious and preoccupied with traumatic event
Sense of security intact	Personal sense of safety challenged
Primary relationships disrupted	Primary relationships intact
Intrusive memories are images and thoughts of the deceased	Intrusive memories of traumatic event plus re-experiencing accompanying emotions
Memories are positive and comforting	Uncontrollable intrusions are negative and distressing
Dream of the dead person is comforting	Nightmares of event are terrifying
Seeking out reminders of the loved one	Hypervigilant, scanning environment for threat
Avoidance of reminders of the absence of the loved one (denial)	Avoidance of reminders of threat
Anger at loss	Irritable, diffuse, unfocused anger and rage
Guilt about not doing enough	Guilt about surviving
Mourning as a tribute to the dead person	
Sleep EEG is normal	Increased REM sleep intensity
Coping involves reconstructing life without the loved one	Coping involves re-establishing a sense of safety
<i>Recovery</i> : Resolves attachment issues	<i>Recovery</i> : Habituates to fearful responses

an earlier age. In other respects the categorisation below holds true.

#### **Children under 5 years**

There is little understanding that death is final. For example, a 4-year-old child in England, having helped to formally bury his dead pet rabbit in the garden, asked if he could now dig it up so that he could have the rabbit back again. Magical thinking results in misconceptions about cause and effect. An egocentric view of the world can lead to feelings of responsibility (e.g. 'Mummy won't come back because I was naughty'). Reactions are similar to those following any separation – the longer the absence, the greater the distress. The death may be followed by detachment, so that the surviving family may think the child does not care about the loss. Regressive behaviour, soiling, bed wetting, clingy behaviour, sleeplessness and minor illnesses can all occur.

#### **Children over 5 years**

Children begin to understand that death is irreversible, that certain physical changes occur, and that there is permanent separation. They may still not regard it as something that can affect them. They may continue to have some magical, concrete and egocentric thinking. At this age, children more commonly use concepts of good and bad, they are curious about cause and effect, and are able to articulate concern for others.

There is a desire to stay connected to the dead parent. Many children dream about and talk with the dead parent frequently, feel that the dead parent is watching them, and keep physical objects associated with them. One study found that 43% of children in a large community sample thought about their dead parent on a daily basis 1 year after the death.<sup>9</sup> The reactions were variable. Boys were already learning to suppress their feelings, 91% of the children in the same study cried on the first day, and 50% had transient emotional and behavioural problems. Concentration and school work are also affected, and repetitive play is very common.

#### **Children from 10 years to adolescence**

There is a growing understanding of abstract concepts – for example, that death is universal and inevitable and can affect the child or adolescent personally. There is a growing concern with justice and injustice, and an awareness of inconsistencies. The conflict between the desire for autonomy and the need for closeness can be resolved by 'indifference and detachment', or by identification and nostalgia. In a group for adolescent refugee boys who had been 'ethnically cleansed' from Northern Bosnia (all of them had lost their homes, and some had also lost their family), all of the boys spoke passionately and with great longing about their home towns, describing them as the 'most beautiful place to live'.<sup>9</sup> Revenge fantasies are not unusual. There are fewer somatic and behavioural problems, and a depressed mood is common. Poor concentration and lack of interest occur at school. The oldest child in the family who has lost a same-sex parent is at greatest risk.

#### **CASE EXAMPLE: The surviving brother**

G is a 13-year-old boy. During a long and brutal war his older brother was killed on the front line. G had always been very close to his brother. Three years later he continued to think about him on a daily basis. He visited the grave frequently and watched the video of the funeral once a week. He did not like to sleep alone, and he felt sad much of the time, although he was doing well at school. He talked about his brother a great deal. He wanted to be as much like his brother as possible, whom he believed was one of the bravest and most incorruptible people. He was angry about the peace agreement. He felt that it was unjust and made a mockery of the aims for which his brother fought.

As in adults, the reactions of children to bereavement are enormously variable. Age, personality, culture and family values, and especially the way the parents or surviving caregivers react, will all affect the expression of grief.

Children within one family exposed to the same losses may all handle grief in different ways (see 'Case example: When to tell the story', p. 118). And the experience of grief may wax and wane. When discussing grief feelings with children, I sometimes use the image of a wave. (This is obviously inappropriate with children who have either never seen the sea or who have experienced the Tsunami.) I ask them to imagine that they are standing at the edge of the sea and that a big wave comes along and knocks them over. They feel terrible, but manage to struggle to their feet. Then there is a period of calm water before the next wave. This time they are more prepared, so that when the next wave comes it does not knock them over. What will happen over time is that, although the waves never go away completely, the periods of calm sea will grow longer, the waves will get smaller and the child will grow stronger (see Figure 1.23.2).

**FIGURE 1.23.2** Waves of grief. The time intervals between waves get longer, and the waves get smaller.

**Long-term effects**

Many people worry that if children experience the loss of someone significant early in life this will have long-term effects on their mental health. Research evidence suggests that children who suffer an early bereavement do have a higher incidence of psychiatric disorder in later childhood, and that adults who lost a parent in childhood are more vulnerable to psychiatric disorder than the general population, and are particularly vulnerable to depression and anxiety precipitated by further losses.

Research has shown that the following life events are most likely to be associated with later mental illness:

- those that require people to undertake a major revision of assumptions about the world
- those that are lasting in their implications
- those that take place over a short period of time without preparation.

A traumatic death can have all of these features. However, there are significant factors that can modify the impact of a bereavement. The child's long-term mental health also depends on the following:

- the response of the surviving parent or relatives
- the availability of other support
- subsequent life circumstances
- the degree of continuity in the child's life
- how the loss is viewed by others
- what resources are available.

This list provides an immediate guide to what needs to be done to enhance a child's resilience and coping in the face of loss. The 'Case example: Different girls' from Pakistan illustrates how important these aspects are and what a great difference the behaviour of the surviving relatives can make.

**CASE EXAMPLE: Different girls**

After the Pakistan Earthquake in December 2005, I worked with children who had lost their parents. Contrast the experiences of two young teenage girls from the same rural Islamic society, affected by the same terrible event, but living in somewhat different settings with quite different responses from those caring for them. Shamsa was 14 and living with her aunt and uncle and her six younger brothers and sisters in one tent in a displaced persons camp near the town of Balakot. Her village had been completely destroyed and her mother and father had been killed. Shamsa acted as mother to her siblings and helped her aunt to care for her cousins. The aunt and uncle had told the children 'Your mother is in the village and will come soon.' Shamsa and her smaller sisters looked ill-kempt and neglected. They cried constantly, which suggested that the comforting lie was not working. They knew that their house had been turned to rubble, so where was their mother now? When I asked Shamsa what she thought, she told me in a whisper that her mother was dead. The aunt and uncle gave me permission to explain to all the children what had actually happened. Their calm reaction suggested that I was confirming something they already knew. Shamsa also told me she would like to get out of the tent. As she was the oldest girl, she carried the burden of household tasks and childcare, and her aunt was very reluctant to let her go to the camp school or any of the other activities arranged for children. However, she let the younger ones go and the improvement in their mood was very apparent. Shamsa continued to weep and grieve. Finally, when the aunt herself became involved in a livelihood programme with other camp women, she gave Shamsa permission to go to school. This had the immediate effect of alleviating some of Shamsa's sadness. In contrast, 12-year-old Sadia still lived in her village higher up in the mountains above the town. She too had lost her mother when their house was destroyed. She moved in with her grandmother but stayed in her village. When I met her she was laughing and playing with the other village children. She had just had her hands hennaed in beautiful flower patterns. She had been told that her mother was dead and said she still felt very sad. But she liked living with her grandmother and she did not cry all the time. When playing with the other village children she was able to be happy, and she had many relatives and friends who cared about her.

NOTE: names changed for reasons of confidentiality

**How do we assist grieving families?**

**TABLE 1.23.4** Key actions to support grieving families

● Attend to their basic needs
● Access resources
● Assist mourning in a culturally appropriate manner
● Answer questions and provide information
● Accompany them
● Be available
● Focus attention on their individual loss: give it significance
● Altruism opportunities
● Avoidance as required
● Advice as needed

Not all grieving families require a health worker's intervention. But in situations of conflict, disaster and displacement the natural sources of social support are absent for the reasons listed above. In this case, the healthcare worker is the supportive community if unaffected him- or herself. Some key activities are listed in Table 1.23.4. Your role may be to accompany and support the bereaved as any neighbour might do in normal times. Obviously if a family lacks basic resources or is not safe, helping to address these basic needs is a priority. Help may be needed to trace missing bodies or identify them. Outsiders may have a significant role to play simply by encouraging and taking part in the normal processes of mourning. This may involve assisting an individual to organise a funeral, or it may involve helping a community. Vignette 3 provides an illustration of how one non-governmental organisation (NGO) assisted mourning in a disaster-affected community. If any individual has such severe symptoms of distress that they cannot function or carry out necessary tasks, providing symptomatic relief will help.

Regarding discussion of the loss, you should follow the lead of the bereaved. This usually means being available and able to listen without forcing them to talk. There is no evidence that 'grief work' (i.e. the experiencing, confronting and working through of negative emotions) is helpful, and there is some evidence that it may have long-term negative consequences. Contrary to some popular western stereotypes, positive emotions in the early period after loss are indicative of good outcomes, not pathology. Individuals who choose the more avoidant orientation (see Figure 1.23.1) are not in harmful denial, and this does not have to be challenged.<sup>10</sup>

On the other hand, it is not necessary to 'break down' continuing attachment to the deceased. Good memories assist mourning and give pleasure and comfort. This connection may be maintained throughout a bereaved person's life without pathological effect. Depending on the culture, it may involve regular visits to the grave, talking actively or praying to the dead, frequent dreams or visions. Indeed, ritualised celebrations of connection with the dead in some societies actually strengthen living family bonds as they bring families together.<sup>11,12</sup> A continuing connection should only cause concern if continuing yearning, searching and longing cause misery and dysfunction, dominate life in the long term and prevent the bereaved from forming any new attachments.

If the loss has occurred as a result of some form of political injustice or abuse, unresolved issues of reparation and justice may prolong grief and make mourning difficult. Helping the victims to access justice may be another part of your role (see 'Case example: When to tell the story' on p. 118).

### How do we help grieving children?

**Many families present to healthcare workers because they have concerns about the long-term impact of events on the child, and want advice on how to talk about such abnormal events with their children. The healthcare worker's role should be to facilitate the process of normal grieving, and to help to sustain and support the protective aspects mentioned in this section. While treating pathology where it is evident, you should take care to avoid pathologising where it is not.**

**A particularly important role may be to facilitate clear communication between family members. As some of the case studies and vignettes in this section illustrate, many families are concerned that telling the child what happened will cause unnecessary distress, and that as the child is 'too young to understand', it is better to lie or avoid the subject when it comes up. Children are very protective of surviving parents, and are quick to sense when a question is causing distress. They may avoid asking for information because the questions make their parent cry. False information leads to confusion and a lack of trust. The following case example illustrates this.**

#### **CASE EXAMPLE: Telling the truth**

The father of this family was a member of a 'Liberation Army', and was killed in the fighting. His 32-year-old wife had two surviving children aged 8 and 9 years, and continued to live with her husband's relatives. She told the children that their father was working in another country. The children would frequently ask her why he did not phone and if he would bring them presents. They were confused because other children in the village told them their father was dead. When they questioned their mother she would start to cry, so they became nervous about asking her. The mother and her brother-in-law asked for advice about what to do, and accepted my suggestion that they should sit with the children and explain in simple terms what had happened, answering all the children's questions as they came up, and sharing the experience of grief. The mother told me that the relief of not having to lie to the children had slightly eased her own distress and made it easier to respond to them. Moreover, rather than being bewildered by their father's silent absence, the children now talked about him in the village with pride.

The following is a list of pointers specifically for supporting grieving children:

- 1 **Provide consistent, enduring, appropriate care.**
  - Reunite children with their families or extended families as soon as possible.
  - In the absence of family, create enduring family-type networks with a low ratio of caretaker to children.
  - Consistent caregiving by one or two caregivers, not a number of different volunteers (however well intentioned), is essential to prevent attachment problems, particularly in younger children.
- 2 **The more continuity that there is with the child's previous life the better.** Children may wish to avoid traumatic reminders, especially at the outset, but removing them completely from a familiar environment will cause more pain and problems in the long term.
- 3 **Support the carers by attending to their basic needs and their own mental states.** Help them to access the appropriate agencies to solve the practical problems that they will encounter. Attention to basic needs is essential. Engaging in the process of rebuilding their lives helps families to come to terms with their losses (see Appendix, Vignette 1).
- 4 **Facilitate normal grieving and mourning** with memorials for absent bodies, and appropriate religious ceremonies.

- 5 **Don't hide the truth.**
  - Children need clear, honest, consistent explanations appropriate to their level of development.
  - They need to accept the reality of the loss, not be protected from it.
  - Magical thinking should be explored and corrected. What is imagined may be worse than reality, and children may be blaming themselves for events beyond their control.
- 6 **Grief work and debriefing may not be therapeutic or appropriate.** The insistence on getting a child to 'debrief' or tell the story of their loss may not be therapeutic or appropriate. Not all cultures put as high a value on the ventilation of individual feelings as western culture does. The therapist's goal should be to encourage a supportive atmosphere for the children, where open communication is possible, difficult questions are answered, and distressing feelings are tolerated. This means that the child will be free to express their grief in the manner that they find appropriate to the person they most trust, and at a time of their own choosing.
- 7 **Provide symptomatic relief.** Help the family to cope with traumatic symptoms such as bedwetting, nightmares and regressive behaviour, if they occur. Give the parents information about what to expect and straightforward management advice.
- 8 **Restart normal educational and play activities as soon as possible.**
- 9 **Help the child to maintain connection with the lost parent.** Encourage the surviving parent to allow the child to choose a memento to keep, to give them access to photographs, or to let the child draw a picture, make objects, or create a memory box. Answer the child's questions about the dead parent.
- 10 **The question of justice** will be important for families in situations of political violence. Many will state that they cannot come to terms with their losses while the fate of loved ones is unknown, bodies remain unidentified, or perpetrators are still at large. These issues will affect the children, and older children may bring them up spontaneously and wish to discuss them. Healthcare workers may be asked for their own views. Stating a willingness to learn and understand, along with an acknowledgement of one's own biases and subjectivity, is the most helpful position. Political and cultural literacy are essential. The family should be put in touch with the appropriate human rights or justice agencies if they wish to give formal evidence, so that the therapeutic and confidential nature of your own work remains clear and the family are not confused about the purpose of the interview. Giving testimony to such agencies should always be at their own request. In this case it may prove therapeutic (see 'Case example: When to tell the story', below).

#### **CASE EXAMPLE: When to tell the story**

The family consisted of three surviving children (two girls and a boy) who had witnessed the death of their mother and aunt and 15 other members of their extended family. They had been physically injured in the attack and spent some time in hospital. At our first meeting, 4 months after the event, two of the children did not believe their mother was dead. They hoped she had survived as they had. We

sat together with the children's father, who told them gently that he thought that in all probability she was dead. The children cried and we did not discuss it further that day. The following week the bodies had been identified, funeral notices posted and the funeral arranged. The family had returned to the house where the massacre had occurred and appeared to be functioning well. The boy had no symptoms, although the younger girl was sad and quiet. When asked if they wanted to talk about what happened, she said no. Her brother said that he had already talked with journalists and did not feel a need to go over it again. The older girl (aged 14 years) had some intrusive thoughts and memories, and poor sleep and appetite. She wanted to walk me around the site and retell the events in detail.

The other children did not wish to join in. During the walk the older girl told me that she now knew her mother was dead. All the children then wanted to show me all their old photographs, and they participated in identifying their dead relatives and telling me stories about their life before the war. After the funeral (which only the older girl attended, at her own request) the children appeared more cheerful, and all of them were looking forward to school. The surviving family provided an extremely loving and supportive network, and although the father was extremely sad, he allowed the children to talk about their mother whenever they wanted. Later the whole family was sent to another country for medical treatment for the children. They attended local schools where they learned English, and appeared to be adjusting well.

One year after the events the International Criminal Tribunal wished to interview the family about the massacre, and the three children insisted that they would like to give their accounts. All the children made statements that were recorded on video, and gave similar detailed stories about the events surrounding the massacre. Although they found it distressing, they each obviously regarded it as significant and important, and were pleased to have had the chance to contribute in this way. This example demonstrates that children in the same family will not all deal with their grief in the same way. If given the opportunity they will find the most appropriate time to tell their own stories in the way that will give their loss significance and meaning for themselves.

## **Appendix**

The following three examples are drawn from fieldwork in various conflict and disaster situations. They illustrate the variability of responses and provide examples of practical ways to support grieving families and communities.

### **Vignette 1: Complex needs and conflict in a grieving family**

A is an 18-year-old high-school student, living in a rural area in the heart of a conflict region, the second oldest of seven children (four girls and three boys). She wanted to study medicine. Her life and health were normal until the shelling began and her family fled to the forest, where they spent 3 months. The local police, who were of a different ethnic origin, found them and separated the men from the women and elderly men and sent the latter home. They got home to find their village full of soldiers and police and themselves under siege at their home, where they were harassed and sometimes beaten. Meanwhile their invalid

pensioner father was shot in a massacre of 10 men from the village. He was buried while they were under siege. A was referred to me 1 month after this by a local doctor who was concerned about her mental state. When I first saw her she was extremely sad and frightened. She was crying all the time, and ruminating about her father being captured. She found everywhere frightening, and was too afraid to go to sleep. When she did fall asleep, she woke early. She had no appetite, and a diurnal mood swing.

I first assessed her at the doctor's home, where we had a long talk, at her instigation, about everything that had happened to her. I felt that the severity of her depressive symptoms might necessitate use of an antidepressant, but delayed making a decision until I was able to assess her at home with her family. I visited them a week later and found all seven members of the family living in one restored room of their fire-damaged home. To my surprise, A was a great deal better, her sleep and appetite having returned to normal over the course of the week. She informed me that she felt this was because she felt she had someone to talk to, and who 'wanted to come and visit'. However, all the female members of the family were preoccupied with the father's death, tearful when discussing it, and had conflicting views about how to manage the grief. The mother and one sister no longer wanted to wear the symbolic mourning clothes, but to move on. The other three sisters were wearing black mourning bands in their hair and wanted to do so for the appropriate period of 1 year. One of these sisters complained of having some panic attacks. They also all felt angry and concerned about their material circumstances. They had no access to their father's pension, as this would have meant going to a police station run by the ethnic group in power to get new identity papers (all of theirs had been burnt), and identifying themselves as from a conflict area and as being members of a family with a massacre victim. Anxiety made sleep difficult.

Interestingly, the boys in the family (aged 7, 8 and 14 years) appeared cheerful, busy and well, insisting that they were symptom free, although they missed their father. All the boys attended school regularly. The girls did not go, as there was no money for books. They therefore sat around at home with little to do.

We agreed to have family meetings to help them to resolve their conflicting views about how to grieve, and relaxation therapy to provide some symptomatic relief. We did this as a group and they practised themselves on a daily basis, with the mother running the group. Over the next weeks there was a marked improvement in the whole family. The three girls continued to wear their mourning bands, and the mother was more tolerant of this. A began to press me to help her to get an ID card so that she could go to a nearby town, get a job and earn some money. However, the security situation deteriorated too much for this to be possible. My last visit before evacuation was distressing, as there was fighting on the nearest main road and the sound of shelling of nearby villages. We all knew that they might have to flee again in the near future.

I returned to see the family 3 months later. They had spent these months internally displaced, being pushed from one village to another, and with very little to eat. During this time, the 14-year-old son, who had separated himself from the family because he believed that he endangered them, had been killed along with another male relative. The family had returned to their home to find it completely burnt to

the ground except for an outhouse. They had nothing left and were using an ammunition box as a table, and sleeping under a small piece of plastic in the garden, because the outhouse attracted snakes. As before, the healthiest members of the family appeared to be the smallest boys, who denied any symptoms except some tearfulness now and then. They appeared active and cheerful except when witnessing their mother's distress. The mother was devastated, and could not stop crying. She could not sleep, eat or function, and expressed suicidal ideas. A had moved away to live with an aunt in a nearby town, and had a number of somatic symptoms. We provided clothes for the family and basic material equipment for the house. The mother was started on antidepressant therapy.

The family then lost contact with our service for 6 months. They had been provided with materials to build a warm room, but the aid agency had failed to realise that with no adult males left in the family there was no one to build it. The family therefore moved into a grim damp refugee flat in town. The mother had found the antidepressants helpful but had run out of medication. Two daughters had escaped the situation by marriage. The boys were well and attending school. The other daughters remain trapped within the prison of their mother's unremitting grief. They spent all day in the flat with their mother talking and crying. She did not wish to be left alone. They wanted to show her how much they cared for her and insisted on doing every household task, which added to her feeling of being a useless burden. We began 'family work' again, encouraging the girls to join the free local youth club and to allow the mother to re-establish her maternal role in the family, supporting her by restarting the antidepressant medication at her request, and getting in touch with the aid agency about the family's house.

**Some reflections on this case:** For most families of this particular ethnic group, the immediate and respectful burial of the dead is crucial. This is followed by 7 days of visiting by friends and family, who sit all day with the bereaved and discuss the dead. These normal mourning processes had not been possible either for the father or for the son. It seems likely that the surprisingly sudden symptomatic relief that A gained from my initial intervention was a result of my contributing to some of this normal mourning by being an outsider who visited and listened. A family approach meant that differences could be brought out in the open in a respectful way. The family also formed a natural group so could encourage and support each other in doing relaxation work. Attending to human rights concerns such as identity papers and security was also important. However, all this was undone by the second round of conflict and loss. There is something particularly devastating about loss coming again immediately a family has begun to work its way towards recovery. Being made homeless and not being given support to rebuild their house have contributed to their sense of bereavement and powerlessness, and prolonged the period of grief. The mother told me repeatedly that if she could start rebuilding her house she would feel better.

Some families are strongly patriarchal. There are different coping strategies available to boys and girls. All the women in this family came across as strong and capable, but all of them felt that the loss, first of an invalid father and then of the oldest son, had completely destroyed the family's capacity to function. Much of the work with grieving female survivors has to address their insecurity and lack

of confidence in their own self-worth. This family required a complex approach, including participation in normal mourning, attention to basic needs, help with family communication, symptomatic relief, help with re-establishing normal family roles, and adapting to new roles in the absence of male support.

### **Vignette 2: Supporting the whole family**

Family B had lost more than 20 members, mostly female and children, in a massacre. I was asked to visit because of concerns about the mental health of the surviving children who had witnessed the attack and were all under 6 years of age. At the first session, most of the remaining extended family, including the children, had gathered to meet me in the only intact room in the house. I already knew the outline of what had happened, and used this first meeting to draw a genogram. I have found that in situations of mass violence, in a culture where the extended family is of central importance, this simple technique has a number of useful functions.

- It is a collective act, with everyone joining in, introducing themselves and explaining their connection to others.
- It is interesting for the children, who join in the actual drawing on a large sheet of paper in the centre of the room.
- By asking the family to include those who have died, it allows for a collective naming of the dead. In this family my symbolically putting a simple black line through these names took on a ritual significance, and the children were quick to point out when I missed someone out.
- The naming allows the person who has died to be identified, but how much is said about that person or what happened is up to the family. Thus it provides the opportunity for storytelling without forcing the issue.
- What is said about the dead is said in front of the whole family, so there is a collective narrative from which the children are not excluded.

Once the genogram had been drawn, the family told me their concerns about the children and their own fears about letting the children talk, as it seemed to upset them. At this meeting, I gave the simple advice about communication outlined above, and arranged to meet the family regularly and to have play therapy with the children. At the next meeting, the family informed me that they were concerned about the oldest teenage girl, who fainted regularly at the same time every afternoon, and was the most nervous and sensitive member of the family. Her sister was one of the dead, and her mother was particularly concerned about her health, but never cried herself. They wanted reassurance that the girl was not seriously ill. Having provided this, I wondered aloud if the teenage daughter was in some way grieving for the whole family and that this exhausting work might be causing her to faint. It also meant that the mother did not have time to think about her own sadness. The daughter said that she wished her mother would cry a little and not worry about her so much, in which case she could look after her.

By the next meeting, the daughter was no longer fainting and the mother was now actively grieving. I continued with family meetings and play therapy over the next 6 months. During this time the oldest child (5 years of age) of another section of the family, in which the mother had died, began to tell his father fragments of what he had seen and to ask

questions about his mother. The father had taken out photographs of his wife to show to all the children. At no point did the children tell the story to me, nor did I insist upon it, seeing my role as facilitating and supporting communication within the family. Over the following year the children became much less tearful and withdrawn, and increasingly outgoing, cheerful, communicative and energetic. They all attended the formal reburial of their family. Their father remarried and their new stepmother was well accepted. The father began on the process of rebuilding his house. They remained well at our last contact, and the oldest child had begun school without problems.

### **Vignette 3: Assisting communal mourning**

The South-East Asian tsunami that occurred on 26 December 2004 destroyed an area along the coast of Northern Sumatra 300 miles long and 6 miles wide. At least 130 000 people were killed in that country alone, and 400 000 were left homeless. In some villages more than 70% of the community were killed. One issue was the problem created by large mass graves. For example, outside the provincial capital Banda Aceh, approximately 20 000 people were buried in a small piece of land next to the main road, with no identification and no acknowledgement of their lives. Nothing grew there. Driving from the airport, one might witness a lone figure standing or sitting on the ground in quiet meditation or prayer. Our non-governmental organisation (NGO) psychosocial team talked with local community leaders in an effort to understand how to assist the Acehnese people in their mourning at this site, and took up their suggestion to collaborate in building a Quiet House. The house was built by local people in less than 10 days with NGO supervision. It overlooked the grave site and provided shelter, privacy and beauty for the relatives of the dead, without the traffic of the main road intruding. The house was designed to emphasise traditional culture, and was landscaped with flowering plants and trees. To provide comfort for the bereaved, the Imam wrote a well-known Muslim prayer: 'From him (Allah) we come and to him (Allah) we return.'

One of the local workers became tearful, explaining 'I think my family are buried here but I don't know. This is why I don't come here ... but now I can come and talk to them. It is very important for the people of Aceh to have a place where they can come and feel a sense of loss and family again.' The project led to requests for further Quiet Houses at other sites.<sup>13</sup>

## 1.24 Obstetric and paediatric anaesthesia in low resource settings

The Safe Anaesthesia Working Group of the World Health Organisation's 'Safe Surgery Saves Lives' global initiative updated the 1992 International Standards for the Safe Practice of Anaesthesia in 2010. The aim of these Standards is to contribute to decreased patient morbidity and mortality worldwide, particularly in lesser resourced countries where regions have not adopted their own standards.

The fundamental principle of these Standards is the continuous presence of an appropriately trained, vigilant anaesthesia professional. The Standards also highly recommend pulse oximetry during anaesthesia, which means it is mandatory, although compromise may be unavoidable in emergencies.

Compliance with these International Standards should be advocated by health care workers in all facilities where anaesthetics are given.

### Obstetric anaesthesia

The limiting factor is often the availability of doctors and nurses trained in anaesthesia; women, babies and children die because of the lack of trained staff.

Remember that there are two patients – the mother and the baby. The condition of the mother affects the condition of the baby. Therefore maintaining adequate oxygenation and resuscitation of the mother is the best initial way of treating and preventing fetal distress.

**All pregnant mothers after 20 weeks' gestation who are lying down must be put in the left lateral tilt position to avoid aorto-caval compression and supine hypotension.**

### Conduct of anaesthesia

Considerations in the obstetric patient in addition to routine anaesthesia include those listed below.

### 1 Physiological

#### Hypoxaemia

Pregnant women are at risk of hypoxia. They use oxygen faster than non-pregnant women, and because of the pregnancy it is more difficult for them to breathe deeply.

#### Hypovolaemia

Signs of hypovolaemia eg. due to bleeding occur later than in the non-pregnant, because blood volume increases during pregnancy. This means that blood pressure, a late sign of blood loss, may be maintained in the hypovolaemic patient until induction of anaesthesia, when there may be catastrophic hypotension. Estimation of blood loss is difficult and it may be concealed eg. placental abruption with retroplacental bleeding. Placental perfusion is compromised before blood pressure, so fetal distress may be a warning of possible maternal circulatory compromise.

#### Acid regurgitation

Hormonal effects cause relaxation of the lower oesophageal sphincter, and pressure effects from the gravid uterus contribute to an increased risk of regurgitation and aspiration if laryngeal reflexes are impaired (e.g. during anaesthesia or eclamptic fits). An H<sub>2</sub> receptor antagonist and sodium citrate or other appropriate non-particulate antacid should be given to all pregnant women beyond the first trimester before general anaesthesia, which should involve a rapid sequence induction with cricoid pressure.

### 2 Pregnancy-related disease

- Pre-eclampsia/eclampsia
  - blood pressure control
    - » Blood pressure should be controlled prior to anaesthesia if possible. Spinal anaesthesia is recommended for Caesarean section if there are no contraindications (signs of coagulopathy or raised intracranial pressure). If general anaesthesia

is needed, attempts should be made to obtund the hypertensive response to intubation (see general anaesthesia for Caesarean section).

- Treatment with magnesium
  - » Magnesium potentiates the effect of non-depolarising muscle relaxants, so smaller doses of muscle relaxant are needed if general anaesthesia is necessary.
- HELLP (Haemolysis, elevated liver enzymes, low platelets)
  - » If platelet count is less than  $100\,000 \times 10^9/L$ , a coagulation profile is indicated prior to spinal anaesthesia. If platelet count is less than  $75\,000 \times 10^9/L$ , there is a risk of a spinal haematoma and so spinal anaesthesia is contraindicated. This has to be considered against the risks to the patient of alternative anaesthesia (general or local infiltration).
- Oedema of tissues
  - » This includes facial and airway oedema. The larynx and vocal cords may be involved and a smaller than usual diameter endotracheal tube may be required eg. 6.5mm, 6.0mm.
- Risk of increased intra-operative blood loss eg. if there has been antepartum haemorrhage, placenta praevia, long labour, maternal dehydration and ketosis or blood clotting abnormality (due to pre-eclampsia and HELLP syndrome, or anticoagulant medication). Ensure IV access with 2 wide bore patent cannulae prior to induction of anaesthesia.
- Sepsis (due to ascending genital tract infection or intrauterine infection). Early recognition of sepsis may be difficult, so it is important to suspect it from the patient's history (e.g. prolonged rupture of membranes).

### 3 Underlying medical conditions

- Examples include known cardiac abnormalities, previous cardiac surgery, and diabetes, all of which may be affected by pregnancy.
- Symptoms of chest pain or dyspnoea may indicate an undiagnosed heart valve abnormality, which may be either congenital or acquired (e.g. from rheumatic fever). unmasked by the circulatory changes in pregnancy and labour.

### 4 Drugs

**Ketamine:** This causes an increase in blood pressure, so should not be given to women with hypertension, but it can be used for induction of anaesthesia for women needing general anaesthesia for Caesarean section. It may increase uterine tone, which may cause fetal distress, or difficulty delivering the baby at Caesarean section.

**Opioids:** These drugs cross the placenta, so ideally should not be given until the cord is clamped, otherwise the baby may be slow to establish regular breathing.

### 5 Equipment

It is vital to ensure that all resuscitation equipment is available and working, in order to prevent avoidable delays if there is an emergency. Check the bag-valve-mask, airway equipment, oxygen, IV fluids, suction, saturation monitor and blood pressure machine before every operation. Ensure that difficult airway equipment (e.g. stylets, bougies) is readily available.

### Choice of anaesthesia for Caesarean section

The choice of anaesthesia for major surgical procedures such as Caesarean section depends on the clinical condition of the patient, the anaesthetist's experience, and the equipment and drugs available. It should be decided after a balance of risks and benefits has been considered.

- 1 Most Caesarean sections are performed with spinal anaesthesia unless there are contraindications (see below).
- 2 General anaesthesia is used when spinal anaesthesia is contraindicated. Intubation as part of a rapid sequence induction is needed to minimise the increased risk of regurgitation and aspiration in a pregnant woman.
- 3 Local anaesthetic infiltration can be used in situations where there is no trained anaesthetist, or if the patient is moribund.

### Spinal (sub-arachnoid) anaesthesia for Caesarean section

A spinal injection gives a dense block of rapid onset (within 5–15 minutes) that lasts for about 2 hours, and can be ideal for Caesarean section. The mother remains conscious. Spinal anaesthesia can also be used perinatally for

- evacuation of residual products of conception
- manual removal of placenta
- repair of third- and fourth-degree tears.

Spinal anaesthesia causes vasodilatation with consequent hypotension. This can be prevented with fluid loading before spinal insertion, and treated with IV fluid boluses and a vasoconstrictor (e.g. ephedrine).

### Uses of spinal anaesthesia

It can be used for:

- Caesarean section
- laparotomy (not optimal)
- evacuation of residual products of conception
- manual removal of placenta
- repair of third- and fourth-degree tears.

### Precautions

- Correct hypovolaemia first.
- Be aware of the presence of a coagulation disorder (e.g. with severe pre-eclampsia, eclampsia or placental abruption), which can lead to a dangerous bleed around the spinal cord. Spinal anaesthesia should not be used in these circumstances.

### Contraindications

These include the following:

- maternal refusal
- inadequate resuscitation facilities
- uncorrected hypovolaemia
- coagulopathy (e.g. if there is spontaneous bruising)
- fixed cardiac output (e.g. aortic valve stenosis)
- allergy to local anaesthetics
- local infection around the spinal area.

### Giving a spinal anaesthetic

#### Preparation

- Explain to the patient the type of anaesthesia.
- Do not give a pre-operative sedative, as it may reduce the baby's respiration and conscious level at birth.

- Give an antacid (e.g. sodium citrate 30 mL) immediately prior to anaesthesia.

### Procedure

- Ensure that there is a **large-bore IV cannula (14 or 16G) and IV infusion running**.
- Infuse 500–1000 mL of IV fluids (Ringer-lactate or Hartmann's solution) to preload the mother and avoid hypotension. Also ensure that atropine 0.6 mg and ephedrine 30 or 50 mg diluted to 10 mL with Ringer-lactate or Hartmann's solution are immediately available.
- Check the patient's blood pressure.
- Sterility is critical. Use antiseptic skin solution to clean the patient's back over a wide area. Use sterile gloves and ideally a sterile apron. Do not touch the point or shaft of the spinal needle with your hand. Hold the needle only by its hub.
- Prepare the spinal anaesthetic (heavy bupivacaine 0.5%, 2–2.5 mL).
- Inject 1% lidocaine solution using a fine 25G needle to anaesthetise the skin over the site (L3/4 or L4/5). Do not use a space above L2/3 because the spinal cord ends at around L1/2.
- Introduce the finest spinal needle available (24G) (ideally using an introducer needle if available) in the midline through the anaesthetised skin, at a right angle to the skin in the vertical plane. Fine spinal needles greatly reduce the risk of post-dural puncture headache.
- If the **needle hits bone** it may not be in the midline. Withdraw the needle and reinsert it, directing it slightly upwards while aiming in the direction of the umbilicus. It is important to have two correct planes (i.e. midline and also not too near to the spinous processes above or below).
- Advance the spinal needle towards the sub-arachnoid space. A loss of resistance may be felt as the needle pierces the ligamentum flavum.
- Once the needle has passed through the ligamentum flavum, push the needle slowly through the dura. You may feel another slight loss of resistance as the dura is pierced.
- Remove the stylet. Cerebrospinal fluid (CSF) should flow out of the needle.
- If CSF does not come out, reinsert the stylet and rotate the needle gently. Remove the stylet to see if fluid is flowing out. If you continue to fail, try another space.
- Once CSF flows out of the needle, inject 2–2.5 mL of the local anaesthetic solution described above.

### Never proceed with the injection if the patient complains of pain on injection.

- All patients should have their head and shoulders raised on a pillow to prevent high spread of the anaesthetic. When using 'heavy' (i.e. heavier than CSF) bupivacaine, as is used in a spinal anaesthetic, the position of the patient affects where the local anaesthetic collects, and can be used to influence the height of the block. The position of the block can be brought higher by placing the table head down. Gravity can be made to influence the level of the block for up to 20 minutes after the injection.
- Lie the mother on her back. Have the operating table tilted at least 15 degrees to the left, or place a pillow

or folded linen under the mother's right lower back to decrease the risk of supine hypotensive syndrome.

- Recheck the blood pressure every 5 minutes after the spinal needle is inserted until the end of the procedure. A fall in blood pressure is likely.
- If there is significant hypotension (i.e. systolic blood pressure < 100 mmHg or a fall in blood pressure of more than 20%), or if the mother has nausea or vomiting:
  - Give the IV infusion as fast as possible.
  - Give ephedrine in 3–6 mg increments or an alternative available vasopressor until there is a response.
  - Give high-flow oxygen via face mask.
- After the spinal injection wait 5 minutes and check for weakness of the legs, then pinch the skin with forceps. Start below the umbilicus and work up on both sides of the body until pain is felt. Wait 5 minutes, and then retest the level of the spinal block until there is no pain with pinch up to the level of the nipples. Anaesthesia should now be adequate for Caesarean section.
- After surgery the mother does not have to lie flat, but may not be able to move her legs for 2 to 4 hours. The first time she mobilises after a spinal anaesthetic she should be accompanied in case she has residual weakness.

### Complications of spinal anaesthesia

- 1 Hypotension.
- 2 Sensory block: if the bladder is full it will be unnoticed by the patient.
- 3 Headache can occur following a spinal anaesthetic, but is uncommon if small gauge spinal needles are used. Headache occurs because of leakage of CSF, which causes traction on intracranial structures. A typical headache is frontal and/or occipital, and worse on sitting or standing, but better when lying down. It can be immediate or delayed. Management consists of analgesia as per the WHO pain ladder (see Section 1.15) and keeping the patient well hydrated.
- 4 If there is bradycardia, tingling or weakness in the hands, or difficulty breathing, the block is likely to be too high. Give the mother atropine 0.6 mg if she is bradycardic, increase the IV infusion rate and give ephedrine.
- 5 Rarely, intracranial spread can also occur. It produces loss of consciousness and apnoea, and is termed a total spinal block. Resuscitation is required.

### Management of spinal blocks which are too high or total

#### Call for help.

#### Airway:

- Assess and maintain patency.
- Give oxygen 15 litres/minute via face mask, and measure SpO<sub>2</sub> using a pulse oximeter (which should already be attached).

#### Breathing

- Assess and give chest inflations with a bag-valve-mask if there is apnoea or inadequate breathing.
- Ideally protect the airway by intubation if the patient is unconscious (P or U on the AVPU scale).

#### Circulation

- High or total spinal blocks can cause cardiac arrest.
- Assess pulse and blood pressure.

- Give chest compressions if the patient is in cardiac arrest or has an inadequate central pulse (the blood pressure may be unrecordable).
- Tilt the patient to the left if this has not already been done.
- Treat hypotension with IV Ringer-lactate or Hartmann's solution and ephedrine.
- Treat bradycardia < 50 beats/minute in the mother with atropine 0.6mg IV, repeated after 3 minutes as necessary.

Check the fetal heart after maternal resuscitation and consider the timing and method of delivery.

Consider and exclude other causes of unconsciousness (e.g. eclampsia, hypoglycaemia, epilepsy, opioid drugs, intracranial bleed).

Keep a chart of pulse, blood pressure, respiratory rate, SaO<sub>2</sub>, fetal heart rate and treatments given.

For management of anaphylaxis, see Section 2.7.C.

### General anaesthesia

If spinal anaesthesia is contraindicated, rapid sequence induction and intubation is the recommended anaesthetic if expertise and equipment are available. See in Paediatric anaesthesia section of this section for the '10 golden rules of anaesthesia', essential monitoring, essential drugs, essential equipment, and how to intubate steps 1–6.

General anaesthesia is indicated

- 1 If spinal fails or is refused by the patient
- 2 If there is a medical contraindication for spinal anaesthesia:
  - suspected coagulopathy,
  - raised intracranial pressure (impaired consciousness following eclamptic fits)
  - fixed cardiac output (e.g. aortic stenosis)
- 3 If there is no time for a spinal anaesthetic to be given.

### Conduct of General Anaesthesia

- 1 Minimise aspiration risk by the following:
  - restrict oral intake, especially solids for women in labour
  - give H<sub>2</sub> receptor antagonist e.g. ranitidine 150mg orally if time, or 50mg IV if emergency
  - give sodium citrate 30mL orally just prior to induction of anaesthesia
  - assess patient, with particular attention to airway.
- 2 Check drugs available:
  - Induction agents
    - Thiopentone 3–5mg/kg or
    - Ketamine 1.5–2mg/kg – causes less hypotension than thiopentone, useful if patient hypovolaemic e.g. if antepartum haemorrhage. Contraindicated if pre-eclampsia or eclampsia or suspected raised intracranial pressure.
  - Muscle relaxant – Suxamethonium 1–2mg/kg
  - Other drugs – to reduce hypertensive response to intubation, given if the patient has severe pre-eclampsia/eclampsia, magnesium 4g (2g if already receiving magnesium) or lidocaine 1.5mg/kg, and/or rapid onset opioids if available. If opioids are used, the baby may need naloxone after initial resuscitation if not breathing adequately.
- 3 Check equipment – laryngoscopes, endotracheal tubes and ensure difficult airway equipment, including stylets,

bougies, laryngeal mask and cricothyroidotomy kit are available.

- 4 Lie patient on theatre table with left lateral tilt and ensure suction is on and under pillow. Connect monitoring.
- 5 Start an IV infusion of Hartmann's solution via a large gauge (14 or 16G) cannula.
- 6 Explain to the patient and anaesthetic assistant about cricoid pressure and pre-oxygenate the patient for 3 minutes.
- 7 Give predetermined dose of induction agent and suxamethonium and support jaw until relaxed, or until fasciculations subside.
- 8 Intubate patient and inflate cuff. Check position of endotracheal tube before allowing cricoid pressure to be released.
- 9 Maintain anaesthetic with a volatile agent or intermittent boluses of ketamine.
- 10 After the baby is delivered, oxytocin is given, as requested by the surgeon, usually 5 units as a bolus, followed by an infusion. Oxytocin may cause tachycardia and hypotension, so care must be given to patients with hypovolaemia or other patients for whom tachycardia would cause cardiovascular compromise e.g. stenotic cardiac valve disease. In these patients, the oxytocin bolus can be drawn up into 20mL 0.9% saline and given slowly over 5–10 minutes. After delivery the mother can be given opioid analgesia for post-operative pain relief.

### Failed intubation

This is more likely to occur at emergency Caesarean sections, when it is often unexpected and leads to rapid oxygen desaturation. An early decision should be made to abandon repeated attempts at intubation.

The priority is to OXYGENATE the patient.

- 1 Maintain cricoid pressure. This should not interfere with bag-valve-mask ventilation if correctly placed, and may need to be adjusted.
- 2 Inform surgeon and scrub nurse to help.
- 3 Ventilate the patient with 100% O<sub>2</sub>, initially with mask.
- 4 If mask ventilation not successful,
  - a. insert oropharyngeal airway
  - b. consider using 2 hands to maintain airway with assistant squeezing bag
  - c. insert laryngeal mask.
- 5 If ventilation is still inadequate, a percutaneous cricothyrotomy should be performed.
- 6 If this is unsuccessful, either surgeon or anaesthetist should perform surgical cricothyrotomy or tracheostomy.

If ventilation and oxygenation is possible at any of the steps before cricothyroidotomy, and the Caesarean section is elective, the patient should be woken up and a spinal or local infiltration should be used.

If the Caesarean section is an emergency, you should consider whether to wake the patient up and give spinal anaesthesia, or proceed with the patient breathing spontaneously and give volatile anaesthesia or intermittent ketamine IV.

If spinal anaesthesia is not possible, intubation fails, or expertise and/or equipment is unavailable, and Caesarean section is urgently needed, the priority is to maintain oxygenation with bag-valve-mask and anaesthetise with either a volatile agent or ketamine depending on the experience of the practitioner.

### Ketamine in early pregnancy

Ketamine causes a trance-like state where patients become mentally removed from their surroundings. It causes sleep, analgesia and short-term memory loss (amnesia). The patient is unconscious, pain-free and has no memory of the time under anaesthesia. The airway protective reflexes are usually present but cannot be guaranteed. Therefore it is important that the patient is **starved and anaesthetised on a tipping table with suction available**. It can only be used as a sole anaesthetic agent in the first trimester and if there is no increased risk of regurgitation. Patients should be fasted for 6 hours prior to ketamine anaesthesia.

**Ketamine is contraindicated in patients with high blood pressure (including pregnancy-induced hypertension), eclampsia or heart disease.**

### Effects of ketamine:

**Central nervous system:** Ketamine causes sympathetic nervous system stimulation. The additional use of diazepam (after delivery if ketamine is used for a Caesarean section) will reduce the amount of sympathetic stimulation. Ketamine also raises intracranial pressure, which makes it unsuitable for patients with eclampsia.

The effects start 10–15 seconds after IV injection. Ketamine produces a 'dissociative state'. The eyes may remain open and may make quick side-to-side movements (nystagmus), and the patient may move during surgery if ketamine is the only drug used. The patient can be quite agitated, crying and distressed on waking up. This can be minimised by using diazepam with ketamine and avoiding stimulation while emerging from anaesthesia. This can also be helped by including diazepam (see below) as part of the premedication.

**Cardiovascular system:** Ketamine causes mild stimulation of the cardiovascular system. The blood pressure rises by about 25% and heart rate increases by about 20%. This increases the workload of the heart.

**Respiratory system:** If given too quickly, IV ketamine can cause the patient to stop breathing for up to a minute. If this happens, ventilate the patient until the effect wears off. The airway is usually maintained, but still needs to be monitored closely. The oxygen saturation may decrease, so give oxygen.

Ketamine causes bronchodilatation. Laryngeal spasm may occur, and may be partly caused by increased secretions resulting from ketamine use (see below for the importance of an atropine premedication in helping to prevent this). If it occurs, continuous positive airways pressure by mask with oxygen or manual ventilation with a bag and mask should relieve this potentially dangerous problem. If it doesn't relieve the obstruction and oxygen saturations are falling, or the patient is cyanosed, give a short acting muscle relaxant (suxamethonium 1 mg/kg IV) and continue bag valve mask ventilation until adequate breathing returns (usually about 5 minutes later).

**Muscle:** Ketamine increases muscle tone. This makes it an unsuitable drug for major abdominal surgery where abdominal relaxation is necessary. Some body movements can occur.

**Uterus and placenta:** Ketamine may increase the tone of the uterus. It readily crosses the placenta, so the fetus receives some of the drug.

### Premedication before ketamine

- Atropine 10–20 micrograms/kg (up to a maximum of 600 micrograms) IM 30 minutes before or IV at the time of induction of anaesthetic.
- Diazepam 100 micrograms/kg (up to a maximum of 10 mg in pregnancy) can be given IV at the time of induction to prevent hallucinations. When performing a Caesarean section after ketamine induction, give diazepam only **after** the baby has been delivered as diazepam can cross through the placenta and prevent the newborn baby from breathing.
- Give oxygen at 6–8 litres/minute by mask or nasal cannulae.

### Administration of ketamine in pregnancy

- 1 Should only be used without intubation in the first trimester.
- 2 Can be used as an induction agent as part of rapid sequence induction in 2nd and 3rd trimester if there are no contraindications, e.g. pre-eclampsia, eclampsia.

**Start an IV infusion of crystalloid** and ensure that a reliable IV cannula is in place.

Ketamine may be given by IV injection or by IV infusion. At doses of **250–500 micrograms/kg IV** ketamine is a good **analgesic**. At doses of **1–2 mg/kg IV** ketamine is an **anaesthetic**.

Giving IV diazepam 100 microgram/kg will reduce nightmares and hallucinations, but respiratory depression is more likely than with ketamine alone.

### Ketamine injection

- Check vital signs (pulse, blood pressure, respiration and temperature).
- Oxygen should be given to ensure that SaO<sub>2</sub> remains above 94%, ideally near 100%.

Induction of anaesthesia is achieved by slowly administering ketamine 2 mg/kg body weight IV slowly over 2 minutes. For short procedures lasting less than 15 minutes, this will provide adequate anaesthesia.

- Check the adequacy of anaesthesia at the operation site before proceeding with the surgery. Pinch the incision site with forceps. **If the pregnant woman feels the pinch, wait 2 minutes and then retest.**
- Monitor vital signs (pulse, blood pressure and respiration) every 5 minutes during the procedure.

Give additional IV boluses of ketamine 1 mg/kg body weight as needed.

### Ketamine infusion

- For longer procedures, infuse ketamine 200 mg in 100 mL of 5% dextrose at 2 mg/minute (i.e. 20 drops per minute with a standard giving set with a drop factor of 20) and titrate to response. More or less may be needed. Stop the infusion 10 minutes before the end of the operation. If the patient needs a blood transfusion, give it through a different IV line.
- Monitor vital signs (pulse, blood pressure and respiration) every 5 minutes during the procedure.

### Post-procedure care

**Discontinue ketamine infusion and administer a post-operative analgesic appropriate to the type of surgery performed.** The patient takes about 2 hours to wake up, and needs to be in a quiet area. Let her wake up naturally without stimulation. Maintain observations every 30 minutes until the patient is fully awake.

### Local anaesthesia for Caesarean section

In extreme situations, Caesarean section can be undertaken under infiltration with local anaesthetic. Although not ideal, this can be necessary in an extremely ill patient (e.g. if unconscious and/or eclamptic), where general anaesthetic/intubation is not available and spinal anaesthetic is inadvisable.

Up to 100 mL of lidocaine 0.5% with adrenaline 1:200 000 is used to infiltrate the layers of the abdominal wall either side of the midline from the symphysis pubis to 5 cm above the umbilicus.

### Paediatric anaesthesia

**This must only be undertaken by anaesthetic practitioners with adequate experience, preparation and equipment. If these skills and equipment are not available, the child should be referred to a more experienced hospital if at all possible.**

Ketamine anaesthesia is commonly used in children and is usually safe, but it must still be undertaken with care.

The '10 golden rules of anaesthesia' (originally defined by Maurice King in his manual *Primary Anaesthesia*) form the basis of essential safe anaesthetic practice for all cases, and are listed below.

- 1 Do an adequate pre-operative assessment.
- 2 Ensure that the patient has been nil by mouth for an appropriate time.
- 3 Use a tipping table.
- 4 Check all equipment and drugs.
- 5 Have suction ready.
- 6 Keep the airway open.
- 7 Be prepared to ventilate the patient (with oxygen).
- 8 Check the pulse, blood pressure and oxygen saturation (SpO<sub>2</sub>).
- 9 Have a vein open with a reliable venous cannula.
- 10 Have an assistant ready to apply cricoid pressure.

In addition:

- Create a non-frightening environment. If possible and appropriate, the parents should be present up to the time of induction of anaesthesia.
- Be aware of anatomical, physiological and pharmacological concepts relevant to infancy and childhood.
- Know the normal values of the main physiological variables.
- For all emergencies, remember ABC for assessment and treatment, and call for help early.
- Know the hourly fluid and blood requirements for every patient (for children these are based on their weight).
- Ensure that all equipment and drugs are available for the child.

### Pre-operative assessment

- Past medical history (including anaesthetic history), in particular any cardiorespiratory illness, and the presence

of respiratory tract infection, which increases the risk of adverse respiratory events during anaesthesia.

- Medication and allergies.
- Nil-by-mouth guidelines (if unsure, ensure 6 hours nil by mouth for all oral intake)
  - clear fluids: 2 hours
  - breast milk: 4 hours
  - food: 6 hours.
- Weigh the child.
- Note the physiological status: airway, oxygenation and ventilation, cardiovascular stability, hydration.
- Assess airway and ease of intubation. Burns, facial deformity, small chin and reduced mouth opening are all signs of a potentially difficult airway. If any problems with airway or intubation are anticipated, consider referring the child to a more experienced hospital.
- If the child is sick, consider whether the procedure is really necessary, and if it is, ensure adequate resuscitation prior to any procedure.
- Plan the fluid requirements. **Do not give hypotonic solutions such as 0.18% saline in 5% dextrose. Give Ringer's lactate or Hartmann's solution, which are best and essential intra-operatively.** Neonates, infants and sick children need glucose (dextrose) intra-operatively, and therefore a 5% or 10% solution of glucose in Ringer-lactate or Hartmann's solution is ideal. Check the blood glucose levels regularly, and give additional glucose (10%) 2 mL/kg as required.
- **Basic maintenance fluids in children:**
  - Give 4 mL/kg/hour for the first 10 kg of body weight.
  - Then add 2 mL/kg/hour for the next 10 kg of body weight.
  - Then add 1 mL/kg/hour for each kg thereafter.
- **Additional fluids:** Judge these clinically: cardiovascular status and urine output (> 0.5–1 mL/kg body weight/hour for a child).
- **Premedication:** give oral paracetamol. Avoid sedative premedications unless you are experienced in their use.
- **Explain what is to happen to the child and their family.**

### Intra-operative considerations

#### Planning the anaesthetic

- Maintenance of normal physiological status is part of balanced anaesthesia.
- **General anaesthesia** involves a reduced conscious level (sleep), muscle relaxation and analgesia. Anaesthetic drugs rarely provide all three of these (e.g. ketamine is a poor muscle relaxant, ether is not analgesic, local anaesthetics provide no fall in conscious level). Therefore modern anaesthesia uses combinations of drugs to provide balanced anaesthesia.
- **Avoid general anaesthesia wherever possible.** Most operations can be performed using one or all of the following: sedation, local anaesthesia and ketamine. These techniques should be the basis of anaesthesia for the non-specialist anaesthetist.
- **General anaesthesia is indicated** where other methods are precluded due to lack of knowledge, lack of drug, the nature of the surgical procedure (abdominal surgery) or contraindication for ketamine/local anaesthetic drug.
- Inhalation anaesthesia with or without muscle relaxant

and local anaesthetic/opioid as analgesia is the standard combination.

- Intravenous ketamine is an excellent induction agent unless it is contraindicated. Thiopentone is a useful alternative if inhalational anaesthesia is planned and intravenous induction is required.
- Induction can be achieved by inhalation of anaesthetic gases, provided that there is adequate expertise and equipment. This is not safe for patients with a full stomach, but in those with acute upper airway obstruction it must be used (intravenous induction often leads to apnoea or a worsening of airway obstruction).
- **Neonates and infants form a special group. Do not undertake anaesthesia without concern in this age group, and it should be administered only by an experienced practitioner.** Sedation and ketamine anaesthesia are more difficult to perform safely. Under general anaesthesia, neonates and infants do not breathe well (due to difficult airway maintenance, unfavourable chest wall/lung mechanics and limited reserve in the face of hypoxaemia). Therefore, in general, ventilation must be controlled. Caution must be exercised with regard to drug doses (opioids and local anaesthetics due to side effects, suxamethonium is required at a higher dose), and post-operative risks are increased. Ketamine or inhalational anaesthesia with controlled ventilation is the technique of choice.

#### For all anaesthesia:

- Remember the '10 golden rules'.
- Give oxygen if it is available (especially at altitude).
- Use all monitoring that is available. The best monitor is the anaesthesia provider closely watching the patient at all times. A pulse oximeter is the most essential basic monitor.
- Maintain normothermia (using warm fluids and high ambient temperature).
- Give fluids for maintenance with additional fluid as indicated clinically.
- The optimal haemoglobin level depends on age, but preferably should always be higher than 8g/dL. Correction of chronic anaemia is not necessary unless major blood loss is expected.
- Analgesia: paracetamol, non-steroidal anti-inflammatory drugs, local anaesthetic infiltrations and blocks, and opioids (morphine and pentazocine).
- Plan to maintain spontaneous ventilation wherever possible. Never use muscle relaxants without knowledge of and experience in how to intubate.

#### When to intubate

- **To protect the airway/lungs:** All acutely ill children and pregnant women have poor gastric emptying. If in doubt, or if there is a strong indication of a 'full stomach' (acute abdomen) you must protect the lungs with an endotracheal tube. Intravenous induction with the application of cricoid pressure prior to intubation is the technique of choice. Prolong nil by mouth times post trauma to minimise the risk of regurgitation.
- **To ensure a safe maintained airway:** In the case of a difficult airway or potentially difficult intubation, **never** give muscle relaxant until the airway is secured with an endotracheal tube (i.e. keep breathing!). Upper airway

obstruction is a contraindication to intravenous anaesthesia, including ketamine.

- **To provide positive pressure ventilation:** Prolonged surgery, where muscle relaxant is essential (abdominal surgery).
- **To improve oxygenation in neonates and infants:** You can administer 100% oxygen and maintain better lung volumes with positive end-expiratory pressure (PEEP).

#### Post-operative care

- **Basic recovery care:** attention to ABC, maintenance of normothermia, continued fluid therapy, and provision of safe and effective analgesia.
- Commence oral fluids as soon as possible.
- If intravenous fluids are required (due to ongoing losses or nil by mouth), give at 70% maintenance with additional fluids matched to losses.
- Regular oral/rectal analgesia (paracetamol, non-steroidal anti-inflammatory drugs) with opioid as rescue analgesia. Consider opioid infusion (see Section 1.6 and Section 1.15).
- Pain assessment scores to titrate analgesia (see Section 1.16).
- Family care and communication.

## Techniques

### Sedation

In pregnancy and in children should only be administered by experienced health workers; usually an anaesthetist.

- Conscious sedation through to general anaesthesia: based on loss of airway self-maintenance, gradual loss of protective reflexes and decreased responsiveness.
- All drugs can have unpredictable and prolonged effects.
- Cardiorespiratory compromise is the greatest danger.
- **Avoid sedation altogether in patients with upper airway obstruction.**
- Prepare as for general anaesthesia.
- Drugs: chloral hydrate, midazolam or diazepam.
  - chloral hydrate: 25–50mg/kg orally (infants)
  - midazolam: 200 micrograms/kg intranasally, orally or sublingually
  - diazepam: 200 micrograms/kg IV (500 micrograms/kg rectally).

### Local anaesthetic

- **Advantages:**
  - It is cheap, and minimal equipment is required.
  - Its use can avoid the need for general anaesthesia.
  - The procedures are simple and brief.
  - It can be used for post-trauma analgesia and post-operative analgesia.
- **Disadvantages:**
  - Slow onset, and prolonged effect.
  - Each block can have major complications.
  - Toxicity: central nervous system (seizures) and cardiovascular (arrhythmias).
  - All techniques can be lethal.
  - It is not sedative!
- **Safety:**
  - Always ensure sterility.

**Never exceed the maximum doses of local anaesthetics: lignocaine 3 mg/kg (7 mg/kg with adrenaline), and bupivacaine 2 mg/kg (with or without adrenaline).**

- Be very cautious with doses in neonates.
- Know the **anatomy**.
- Use blunted needles (easier to identify layers), ideally 25–29 gauge.
- Always **aspirate** before any injection (this is not a 100% guarantee of avoiding intravascular injection).
- All injections should be **easy** (i.e. there should be no resistance to injection; resistance indicates intra-neural injection).
- Be aware of the possibility of toxicity, and assess for it during and after administration of local anaesthesia (an early symptom of toxicity is tingling of the lips, which are a highly vascular area).

### Applications

This can be administered topically, by infiltration or by regional blocks.

**Do not combine local anaesthetic with adrenaline in digital or penile blocks.**

- **Topical application:** easy to do and can be very effective (e.g. Ametop or EMLA skin anaesthesia, local anaesthetic soaked dressings, eye drops).
- **Infiltration:** use a small needle, and slow injection.

### Nerve blocks

**For all blocks, first consider whether ketamine anaesthesia would be safer and more tolerable for the child.**

- Explain this type of anaesthesia to the patient and carers, and gain their consent.
- Warn the patient about motor blockade and the sensation of sensory blockade.
- Apply the principles of safe use of local anaesthetics.
- The onset of effect can be slow (30–60 minutes).
- The effect can be prolonged (up to 24 hours).
- Be aware of the distribution of analgesia for each block.

### Femoral block/‘3 in 1’

- Femoral shaft fractures, burns, grafts from anterior thigh.
- Medial calf only blocked below the knee.
- Lie the patient in a supine position. The femoral nerve lies lateral to the vascular sheath just below the inguinal ligament (the nerve, artery and vein lie laterally to medially, respectively).
- Sterilise the skin, and provide skin analgesia.
- Identify the artery. The injection point is 0.5–1 cm lateral to the artery.
- Advance a 21G blunted needle at 45 degrees to the skin until two ‘pops’ are felt (the fascia lata and fascia iliaca).
- Aspirate, inject lignocaine 1% with adrenaline (1 in 200 000), 0.5–0.7 mL/kg.
- Larger volume blocks obturator and lateral cutaneous nerves in addition, hence ‘3 in 1’.

### Brachial plexus block (axillary approach)

- This is the easiest and safest approach.
- It blocks the whole arm except for the upper arm and shoulder.
- Lie the patient supine, abduct the arm to 90 degrees, rotate it externally, forearm to 90 degrees.
- Identify the artery, sterilise the skin, and provide skin analgesia.
- Advance 1 inch with a 22 G needle, aiming for the apex of the axilla, over and parallel to the artery.

- After one pop is felt, let go of the needle. It will bounce with arterial pulsation if correctly sited.
- Support the needle, then carefully aspirate and inject 0.5 mL/kg lignocaine 1% with adrenaline 1 in 200 000. Intravascular injection is a significant risk.

### Intercostal block

- This is useful for fractured ribs and upper abdominal surgery.
- The risk of complications is high, but it is an effective block.
- Identify the postero-medial curve of the rib.
- Sterilise the skin and provide skin analgesia.
- Advance a 22–24G needle perpendicular to the skin until you hit the rib.
- ‘Walk’ the needle just under the rib, aspirate and inject.
- Repeat at each rib.
- Beware of the maximum dose, 0.5 mL/kg of 1% lignocaine with adrenaline 1 in 200 000, as intravascular uptake from this site is high.

### Intravenous regional anaesthetic (IVRA)/Bier’s block

- This is used for distal limb excisions and fracture manipulations.
- It involves intravenous injection of local anaesthetic into an arm with a tourniquet blocking off the arterial and venous supply. It is therefore dangerous and must only be performed with the appropriate equipment.
- Exsanguinate the arm by elevation.
- Apply the tourniquet (a double one if available).
- Insert two IV cannulae – one in the limb to be blocked as distal as possible, and the other for safety in another limb.
- Inflate the tourniquet (to twice the arterial pressure).
- **Inject lignocaine 1% (10 mL at 1 year, 20 mL at 5 years, 30 mL at 10 years) into the cannula in the limb to be blocked (but not with adrenaline and not with bupivacaine).**
- There is a 10-minute onset, and it is safe to release the tourniquet after 30 minutes.

### Ilioinguinal/iliohypogastric block (field block)

- This is used for hernia repair and orchidopexy.
- Lie the patient supine and identify the anterior superior iliac spine.
- This is 1 cm medial and 1 cm caudal.
- Sterilise the skin and provide skin analgesia.
- Advance a 22 G blunted needle perpendicular to the skin until one pop is felt (after the skin). Then aspirate and inject.
- Two pops are acceptable. Three pops or ‘feels too far’ runs the risk of femoral nerve block.
- Infiltrate 0.5 mL/kg 1% lignocaine with 1 in 200 000 adrenaline after aspiration.
- Withdraw to skin and infiltrate.

### Central blocks

**Central neural blockade should only be used by experienced anaesthetic practitioners in older children.** It is not appropriate to discuss central blocks for children in this textbook. Please refer to a specialist anaesthetic textbook.

### Ketamine

Ketamine anaesthesia is not always safe, and must only

ever be undertaken with great care. Remember the 10 Golden Rules of anaesthesia and ensure that adequate preparation has taken place.

Ketamine is an analgesic, dissociative anaesthetic that induces a trance-like cataleptic state dissociated from the environment.

- **Advantages:**
  - airway maintenance
  - cardiovascular stability
  - useful for short procedures, and limb and extra-cavity surgery.
- **Disadvantages:**
  - airway is not guaranteed, and interference risks laryngospasm and bronchospasm; cardiovascular stability is no alternative to good resuscitation
  - **hypoxaemia and apnoea**, especially after bolus administration
  - hypertonus, especially with prolonged anaesthesia (greater than 1 hour)
  - resistance is unpredictable except in developmentally delayed children
  - it raises the intracranial and intraocular pressure
  - emergence phenomena (e.g. hallucinations), although these are perhaps less common in children, and can be minimised with benzodiazepines.
- Use as low a dose as possible.
- Recovery may be prolonged.
- Use only with great caution in neonates (apnoea is very likely to occur).

#### **Ketamine doses**

- 1 mg/kg slow IV bolus.
- Repeat half the first dose (500 micrograms/kg) after 15 minutes.
- 7 mg/kg IM induction dose.

#### **For IV infusion:**

- Make up a solution of 1 mg/mL by placing 500 mg in a 500-mL bag of 5% glucose or 0.9% saline.
- Maintenance after the initial bolus.
- Aim for 2–4 mg/kg/hour for general anaesthesia.
- Aim for a lower dose, of 500 micrograms to 1 mg/kg/hour, for analgesia.

Marked tachyphylaxis can occur with infusions that last for more than 30–60 minutes.

#### **Inhalational anaesthesia**

**Do not undertake this unless you are trained in anaesthesia.**

- **Airway maintenance skills and the ability to recognise an appropriately anaesthetised patient are the absolute minimum requirements for safe practice.**
- The best simple guide to depth of anaesthesia is the level of sympathetic nervous system arousal.
- The equipment for this type of anaesthesia is generally more specialised.
- Spontaneous ventilation via mask or endotracheal tube and breathing system is the safest application.

**Ether** is a relatively safe drug to use, although it is no longer widely available. It can be given by an open method or by a breathing system and vaporiser, usually of the draw-over type. Induction of anaesthesia is slow and relatively predictable. Respiratory depression is late, and cardiovascular

stability is well maintained. Recovery can be prolonged. Ether has **no analgesic effect**.

**Halothane** is a potent but highly effective inhalational anaesthetic agent. It can only safely be given via a vaporiser. It is easy and dangerous to use too much.

**Trichloroethylene (trilene)** has the advantages of slow onset, high potency and an analgesic effect. Tachypnoea and post-operative nausea are seen. It is rarely if ever used alone.

#### **Essential equipment**

This should follow the World Health Organization (WHO) or World Federation of Societies of Anaesthesiologists (WFSA) standards. The minimum is Level 1 facility.

#### **Minimum equipment required for ketamine and local anaesthesia provision**

- Equipment to support the airway and ventilation (bag-valve-mask).
- Suction (foot operated or electric).
- Intravenous cannulae.
- Syringes.
- Needles.
- Pulse oximeter.

#### **Preferred equipment for ketamine, inhalational anaesthesia and resuscitation**

- Oxygen masks: with and without reservoir bags (paediatric and adult sizes).
- Oxygen supply: cylinders with oxygen flow meter or oxygen concentrator.
- Intravenous fluids (isotonic solutions such as Hartmann's, Ringers-lactate or 0.9% saline) not dextrose solutions without electrolytes, except in the first 2 days of life.
- Intravenous administration sets (ideally burettes).
- Paediatric anaesthetic face masks (ideally clear masks with inflatable rims that provide an airtight seal and have minimal dead space).
- Oropharyngeal airways (Guedel), sizes 0–4.
- Bag-valve-mask incorporating non-rebreathing valve (paediatric), reservoir tubing/bag and self-inflating bag (preterm neonatal (250 mL) and full term neonatal and child (500 mL) sizes).
- Ayre's T-piece, with Jackson-Rees modification (open-ended 500-mL bag).
- Endotracheal tubes: 2.0–9.0 mm internal diameter, cuffed and uncuffed, PVC.
- Laryngoscopes: straight-bladed and curved-bladed.
- Magill's forceps (adult and paediatric sizes).
- Fixation tape.
- Suction apparatus (manual, foot/hand pump).
- Suction catheters.
- Yankauer suckers, paediatric and adult.
- A means of administering inhalational anaesthetic agents: continuous-flow (Boyles type) require a continuous oxygen supply; simple draw-over (OMV, EMO based, triservice); or new hybrid machines, such as the Universal Anaesthesia Machine ([www.gradianhealth.org](http://www.gradianhealth.org)) or the Glostavent ([www.diamedica.co.uk](http://www.diamedica.co.uk)) (please refer to specialist anaesthetic textbooks).

#### **Essential monitoring**

- This improves patient safety, reducing morbidity and mortality.

- Use in any location and for any technique, including sedation.
- Use from induction through to recovery.
- Documentation is essential.

The best and only universally available monitor is the presence and vigilance of the person administering the anaesthetic.

Minimum monitoring includes colour, pulse rate and volume, chest wall movements, capillary refill time, respiratory rate and auscultatory findings, and pupil size. This monitoring can and should be performed repeatedly by the anaesthetist.

#### Always remember to check:

- equipment prior to use
- whether there is enough oxygen
- whether oxygen is flowing into the patient
- the patient's arterial oxygen saturation (SpO<sub>2</sub>), electrocardiogram, non-invasive blood pressure (this is extremely valuable), temperature (ideally core temperature), blood glucose levels, urine output, and capnography (expensive but useful).

#### Essential drugs

- Oxygen.
- Intravenous fluids.
- Local anaesthetics (lignocaine and bupivacaine).
- Ketamine.
- Atropine.
- Diazepam.
- Midazolam.
- Paracetamol.
- Morphine or another opiate.
- Suxamethonium bromide (if no refrigeration facilities are available), (lasts 5 minutes, higher dose is needed in neonates, salivation, hyperkalaemia, masseter spasm, anaphylaxis).
- Pancuronium (or atracurium or vecuronium); neostigmine.
- Adrenaline (resuscitation doses: 1 in 10000 = 100 micrograms/mL; 1 in 1000 = 1 mg/mL).
- Thiopentone (apnoea, hypotension).
- Inhalational agents.

#### Intubation

This is used:

- to secure the airway
- to protect the airway
- for prolonged ventilation
- for intra-operative ventilation
- for tracheo-bronchial toilet
- for the application of high airway pressures and positive end-expiratory pressure (PEEP)
- for cardiopulmonary resuscitation (all of the above)
- in patients with raised intracranial pressure to maintain normal oxygenation and normocapnia.

#### Choice of tube

- Uncuffed under 25 kg: the larynx is narrowest below the glottis at the circular non-distensible cricoid ring (modern cuffed tubes are increasingly available for infants and young children).
- The correct tube is that which passes easily through the

glottis and subglottic area with a small air leak detectable at 20 cmH<sub>2</sub>O (i.e. sustained gentle positive pressure).

- Size of uncuffed tubes: measure the tube internal diameter against the diameter of the little finger of the child:
  - preterm neonates: 2.5–3.5 mm internal diameter
  - full-term neonates: 3.0–4.0 mm internal diameter
  - infants under 1 year of age and after the neonatal period: 3.5–4.5 mm internal diameter
  - children over 1 year: internal diameter in mm = age/4 + 4  
length of tube in cm = age/2 + 12 for oral tube  
= age/2 + 15 for nasal tube.

#### Aids to intubation

- Laryngoscope: blade (straight for neonates and infants because of their long, floppy epiglottis; curved for older children and pregnant mothers), bulb and handle.
- Magill's forceps.
- Introducer (not further than the end of the tube itself).
- Gum elastic bougie (over which the tube can pass).
- Cricoid pressure (can aid visualisation of the larynx).
- Suction apparatus must be available, plus Yankauer and other catheters.
- Syringe (cuffed tube).

#### Predictors of difficulty

- Difficulty in opening mouth
- Reduced neck mobility
- Laryngeal/pharyngeal lesions
- Congenital: Pierre-Robin syndrome, mucopolysaccharidoses.
- Acquired: burns, trauma.
- **Look from the side: a small chin is a predictor of difficulty.**

#### Complications

- Displacement: oesophageal, endo-bronchial, out of larynx.
- Obstruction: kinking, secretions.
- Trauma: from the lips to larynx.
- Hypertensive response.
- Vagal response.
- Laryngeal or pharyngeal spasm.
- Aspiration of gastric contents.

#### How to intubate

- 1 Prepare and check the equipment.
  - Choose an appropriate tube size, with one size above and one size below available.
  - Get the tape ready to fix the tube.
  - Suction must be available.
  - Induce anaesthesia and give muscle relaxant unless completely obtunded. **Do not attempt this in a semi-conscious patient.**
- 2 Position:
  - Children over 3–4 years of age and pregnant mothers: 'sniffing morning air' position (head extended on shoulders and flexed at neck).
  - Children under 3 years (especially neonates and infants): neutral position (large occiput).
  - Keep in a neutral position with in-line immobilisation if there is an unstable cervical spine (e.g. due to trauma or Down's syndrome).

- 3 Pre-oxygenate every child prior to intubation.
- 4 Introduce the laryngoscope into the right side of the mouth, sweep the tongue to the left, and advance the blade until the epiglottis is seen.
  - Curved blade: advance the blade anterior to the epiglottis, and lift the epiglottis forward by moving the blade away from your own body.
  - Straight blade: advance the blade beneath the epiglottis into the oesophagus, pull back, and the glottis will 'flop' into view.
  - Recognise the glottis.
  - Insert the endotracheal tube gently through the vocal cords.
  - Stop at a predetermined length.
- 5 Confirm that placement is correct.
  - The chest moves up and down with ventilation and equally on both sides.
  - Listen to breath sounds in the axillae and anterior chest wall.
  - Confirm that there are no breath sounds in the stomach.
  - Oxygen saturations do not go down.
- 6 Secure the tube.

If you are skilled, proceed to nasal intubation. This is

**best for long-term ventilation, but is contraindicated in base of skull fracture.**

- Fresh gas flow through T-piece circuit to prevent re-breathing CO<sub>2</sub>.
- Minute ventilation (MV) is 1000 mL plus 100 mL/kg.
- For spontaneous ventilation: 3 × MV.
- For positive pressure ventilation: 1.5 × MV.
- Minute ventilation = rate × tidal volume.
- Ventilator rates and tidal volumes (by hand or mechanical).
- Tidal volume is that which is **enough to see the chest expand adequately**, or 5–10 mL/kg.
- Rates:
  - neonates: 30–40 breaths/minute
  - infants: 25–30 breaths/minute
  - children: 20 breaths/minute
  - adolescents: 15 breaths/minute.

## 1.25 Non-invasive respiratory support

### Introduction

Respiratory support is needed when the patient fails to sustain an adequate airway, oxygenation or ventilation, despite treatment of the condition leading to respiratory failure. Respiratory failure may result from:

- respiratory illnesses
- severe shock
- coma
- convulsions
- meningo-encephalitis
- neuromuscular disorders
- raised intracranial pressure (e.g. from trauma).

Infants and young children are more likely to progress to respiratory failure because:

- they are more susceptible to infection
- their airway is smaller
- their thoracic cage is more compliant
- their ribs are (nearer) horizontal
- their respiratory muscles are more prone to fatigue.

Pregnant women and girls are also more susceptible to respiratory failure. They have reduced immune function, an expanding abdominal mass which impairs lung expansion, and are more prone to gastro-oesophageal reflux and aspiration of gastric contents.

As respiratory failure progresses, it will ultimately lead to cardiorespiratory arrest and death. Thus recognition of the severity of the conditions that lead to respiratory failure, followed by appropriate treatment, will reduce morbidity and mortality.

### Use of respiratory support

The following **clinical signs** should be observed when assessing the adequacy or inadequacy of breathing:

- intercostal, sub-costal and supra-sternal recession
- respiratory rate
- inspiratory and expiratory noises
- use of accessory muscles
- adequacy of breath sounds and chest expansion
- heart rate
- skin colour
- mental status.

To help to assess the development of respiratory failure, it is necessary to assess **changes** in the clinical signs listed above. In the following situations, however, these signs are less useful because there is absent or decreased work of breathing:

- in patients with fatigue or exhaustion (e.g. after prolonged respiratory effort)

- in those with cerebral depression due to raised intracranial pressure, poisoning or encephalopathy
- in children with neuromuscular disease.

In these cases, pay more attention to the chest expansion and air entry on auscultation of the chest, heart rate, skin colour, mental status and, if available, SaO<sub>2</sub> measurement.

Pulse oximetry measures the arterial oxygen saturation through the skin (SpO<sub>2</sub> or SaO<sub>2</sub>). Values of SpO<sub>2</sub> lower than 94% in air at sea level (for values at high altitude, see Section 5.1.D) are abnormal and would warrant at least initial treatment with additional inspired oxygen. Values

of less than 85% in oxygen are very low, but even values greater than 95% in oxygen may be associated with significant hypoventilation. **It is essential to remember that, in respiratory failure, even a normal SaO<sub>2</sub> while receiving additional inspired oxygen is likely to be associated with significant hypoventilation or intrapulmonary shunting.** Measurement of transcutaneous, end-expired or blood carbon dioxide levels will confirm this.

When respiratory fatigue is severe, oxygenation is poor or deteriorating, or carbon dioxide levels are raised, respiratory support should be used, if available. The various forms of respiratory support are outlined in Table 1.25.1, along with their indications.

**TABLE 1.25.1** The various forms of respiratory support, with nursing care and medical treatment required, and examples of relevant conditions treated

Mode of respiratory support	Interface with patient	Level of nursing care	Associated medical treatment	Clinical use	Examples of relevant conditions treated
High-flow high-humidity oxygen	Nasal cannulae	Home, ward, HD	Nil	To provide a flow above the patient's needs, that helps to wash out dead space, and improves comfort and clearance of the airways. It may provide mild CPAP	Bronchiolitis, post-operative, chronic lung disease of prematurity
Continuous positive airways pressure (CPAP)	Nasal cannulae or nasopharyngeal tube	HD	Sedation or analgesia may be needed	To keep the upper and lower airways patent and maintain adequate lung volume (oxygenation)	Neonatal respiratory distress syndrome, <b>bronchiolitis*</b>
	Nasal mask or face mask	Home, ward, HD	Nil		Sleep-related upper airway obstruction
		Intensive care (IC)	Sedation or analgesia may be needed		Acute upper airway obstruction before, <b>instead of*</b> or after extubation
Intermittent positive pressure ventilation (IPPV)	Nasal mask or pillows, face mask (NIPPV)	Home to IC	Nil	To treat hypoventilation (raised CO <sub>2</sub> ) when airway control and clearance are adequate	Chronic (e.g. central, neuromuscular) Acute (e.g. after surgery)
	Endotracheal tube	IC	Anaesthesia for intubation. Sedation or analgesia will be needed	To treat hypoventilation when clearance/support of airway(s), or when close control of ventilation is needed	Procedures or surgery requiring anaesthesia Severe respiratory illnesses, raised intracranial pressure
	Tracheostomy	Home to IC	ENT surgical procedure	Long-term ventilation where day and night support is needed	Brainstem/high spinal injury or neuromuscular disease
Continuous negative extrathoracic pressure (CNEP)	Chamber or jacket	Home to IC	Nil	To keep the lower airways patent and maintain adequate lung volume	Bronchiolitis and other severe lower respiratory infections, especially where the nose is blocked by secretions
Intermittent negative pressure ventilation (INEP or INPV)				To treat hypoventilation where airway control and clearance are adequate or maintained by CPAP	Central hypoventilation (e.g. apnoea of prematurity or neuromuscular disease)

HD, high dependency; IC, intensive care.

Shaded areas are those that require a lower dependency of care (e.g. they have been used in the home setting), but may be useful in acute conditions.

\* High-risk situation, in which CPAP may be ineffective and intubation may be required.

---

**Notes on the use of positive pressure ventilation**

- 1 Monitoring of patient status and either airway or extra-thoracic pressures is necessary when undertaking any form of respiratory support except for high-flow, high-humidity oxygen (see below).
- 2 Positive airway pressure involves a flow of air or other gas mixture to the patient's airways. This flow may be continuous (as in CPAP) or intermittent (as in IPPV). It may vary with inspiration and expiration (as in BiPAP), or to accommodate the leaks or variable compliance of ventilator tubing, airways or lung units.
- 3 Mask ventilation can be well tolerated by children, but it may be more difficult for infants and young children to tolerate appliances on their face.
- 4 In the presence of excess airway secretions or an open mouth, nasal masks and nasal cannulae may not produce as effective airway pressures as ventilation with tracheal intubation (or relatively higher pressures may be needed to achieve the same effect).
- 5 The pressures used with masks and cannulae may be higher than those used with tracheal intubation, because of the greater potential for air leaks and other volume loss in compliant upper airway structures.
- 6 Infants and young children will sometimes only tolerate masks and cannulae if sedation is used, in which case close monitoring of respiratory failure must be undertaken in case full intubation and ventilation are needed.
- 7 Endotracheal intubation should be undertaken with rapid-sequence drug or gaseous induction, and subsequent analgesia, anxiolysis and sedation must be provided.
- 8 Positive pressure ventilation administered through an endotracheal tube must be accompanied by adequate humidity of the inspired gases.
- 9 Oxygen may be administered either using a built-in mixer in the ventilator, or by entraining a supply in the ventilator tubing nearer to the patient.
- 10 Positive pressure ventilators should be able to provide manipulation of either the pressure or volume administered, and the time intervals for inspiration and expiration. There should be alarms for failure to cycle, and for excessive pressure/volume administered.

# Section 2

## Pregnancy-related problems

## 2.1

## Antenatal care and the hospital

**Introduction**

For a variety of logistic and cultural reasons in resource-limited countries, the first time a woman attends a health facility during pregnancy may be because of a medical problem or because she is in labour. This often means that she is medically compromised even before giving birth, and at high risk of morbidity and mortality.

Antenatal care in such settings tends to be opportunistic, and the ways in which care is delivered must be innovative and optimised to ensure that comprehensive care reaches as many pregnant women and girls as possible. This might mean outreach teams going out to the rural areas ('trekking'), rather than the women having to make the long journey to the healthcare facility, often on foot. Usually the staff who undertake such visits are midwives and nurses, rarely doctors.

Such problems particularly affect rural areas at long distances from the nearest facility and where roads are poor. Hospital workers have a duty to ensure that they work with the community health teams to facilitate antenatal care.

**Definitions of pregnancy-related events**

**Maternal mortality is the death of any woman or girl, from any cause, while pregnant or within 42 days of the end of pregnancy.**

**Gravidity** is the number of times that a woman or girl has been pregnant. **Parity** is the number of times that she has given birth to a fetus with a gestational age of 24 weeks or more, regardless of whether the child was born alive or was stillborn.

For example, in gravida 2:para 2 (G2 + P2) the woman or girl has had two pregnancies and two deliveries after 24 weeks, and in gravida 2:para 0 (G2 + P0) the woman or girl has had two pregnancies, neither of which survived to a gestational age of 24 weeks. If these individuals are both currently pregnant again, they can be referred to as G3 + P2 and G3 + P0, respectively.

- A **nulliparous** woman or girl has not given birth previously (regardless of outcome).
- A **primigravid** woman or girl (a primigravida) is in her first pregnancy.
- A **primiparous** woman or girl has given birth once.
- A **multigravid** woman or girl (a multigravida) has been pregnant more than once.
- A **multiparous** woman has given birth more than once.
- A **grand multipara** is a woman who has already delivered four or more infants who have achieved a gestational age of 24 weeks or more. Such women are considered to be at higher than average risk in subsequent pregnancies.
- A **grand multigravida** has been pregnant four times or more.

Multiple pregnancies present a problem with regard to terminology. A multiple gestation counts as a single event, and a multiple birth, should be interpreted as a single parous event.

**Rationale for antenatal care**

Antenatal care is primarily a means of screening for, diagnosing, and treating conditions which could cause problems during the pregnancy, at delivery and after birth. These conditions may be pre-existing maternal medical disorders or obstetric or fetal complications which arise during the pregnancy itself.

**Basic antenatal care**

Two conditions are of particular importance to detect and manage antenatally, namely **pre-eclampsia** and **anaemia**, as they contribute to a large proportion of maternal and perinatal deaths.

Pre-eclampsia may vary in severity, but commonly presents with mildly raised blood pressure and proteinuria, and may progress to full-blown pre-eclampsia with dangerously high blood pressures, heavy proteinuria and generalised oedema (see Section 2.5.E). Mild and moderate pre-eclampsia is usually asymptomatic, and therefore routine testing of blood pressure and urine in pregnancy is crucial to its detection.

Severe pre-eclampsia can be associated with symptoms such as headache, visual disturbance and epigastric pain, and commonly leads to eclamptic fits, cerebrovascular accidents or HELLP syndrome (Haemolysis, Elevated Liver enzymes and Low Platelets), all of which carry a very high mortality. Timely intervention, by lowering the blood pressure, delivering the baby and treating fits if they occur, may be life-saving.

It is also vitally important to detect and treat anaemia antenatally, to reduce the woman's risk of dying should she experience a postpartum haemorrhage (see Sections 2.5.B and 2.8.D).

As far as possible there should be a structured approach to antenatal care. (A card or booklet designed and implemented by individual Ministries of Health for pregnant women or girls to keep and bring to clinics is helpful.) At the first encounter, an attempt should be made to obtain as full a history as possible, time permitting. This should include the following details:

- the date of the last menstrual period (LMP), regularity of the menstrual cycle, any contraceptive usage, the date of the positive pregnancy test (if available), and any particular complaints in pregnancy to date
- the previous obstetric history, including complications, mode of delivery and outcome
- the previous medical history
- the family history, especially with regard to hypertension, diabetes mellitus, multiple births and congenital abnormalities
- use of drugs, smoking, and alcohol consumption
- allergies.

The patient must always be examined.

- Look for signs of anaemia (pallor, leuconychia or white

nails, koilonychia or spoon-shaped nails, and angular stomatitis), malnutrition, oedema and other medical conditions unrelated to the pregnancy.

- The blood pressure must be measured, and ideally the woman should be weighed.
- The chest should be examined for cardiac and respiratory signs.
- Abdominal inspection and palpation should be done, looking for scars and checking for signs of pregnancy, including measurement of the symphysis-fundal height and feeling for the number of fetuses, fetal lie and presentation, and engagement of the presenting part (see Figures 2.1.1 and 2.1.2).
- An attempt should be made to auscultate the fetal heart with a Pinard's stethoscope, if the uterus is palpable abdominally.

Accurate dating of the pregnancy is important, as it influences decision making during the antenatal period, particularly around the timing of delivery and whether this is by Caesarean section (CS) or induction of labour. It also aids assessment of the maturity of the fetus if the mother goes into spontaneous labour early.

Bimanual examination, which must be undertaken in an aseptic and careful way (especially if there could be an ectopic pregnancy), is a useful diagnostic tool for dating an early pregnancy (in conjunction with the menstrual date), and in the absence of scanning facilities might be the only available means of calculating the estimated date of delivery (EDD).

At around 4 weeks' gestation, the cervix starts to change in colour and texture, feels soft and acquires a bluish tinge which may be visualised on speculum examination. The uterus first becomes palpable abdominally at around 12 weeks' gestation.

Prior to this an estimation of gestational age can be obtained from vaginal examination by assessing uterine size with the following comparisons:

- 6 weeks is equivalent to a plum or golf ball
- 8 weeks is equivalent to a tennis ball
- 10 weeks is equivalent to an orange
- 12 weeks is equivalent to a grapefruit
- 14 weeks is equivalent to a small melon (palpable abdominally).

The accuracy of clinical assessment may be reduced by obesity, fibroids, and if the uterus is retroverted.

Multiple pregnancy and molar change can also lead to a pregnancy larger than dates. At follow-up visits, the history

**FIGURE 2.1.1** Average size of normal gravid uterus at different gestations.

and examination can be more focused on pregnancy events since the last visit. Examination should look for signs of intercurrent problems, anaemia and oedema. At every visit, the blood pressure must be measured and the abdomen palpated to check on the progress of pregnancy.

At all visits after 20 weeks there should be direct questioning for symptoms of pre-eclampsia. If the blood pressure is elevated or rapidly progressive oedema is present, a urine sample **must** be tested for protein.

Prior to the due date, there should be a discussion about the mode and place of delivery for women with a previous Caesarean section scar. Birth attendants and family members must be informed that there is a high risk of scar rupture, and the woman must deliver in a healthcare site where emergency facilities are available if needed.

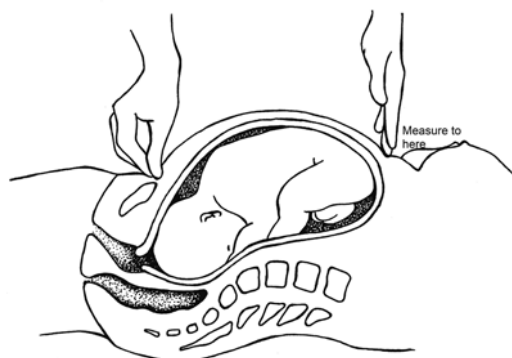

They should also be informed of any concerns you may have which might put them at risk of needing intervention at delivery (e.g. twins, a high fetal head at term). These would indicate that they must deliver at an appropriate healthcare facility.

Ideally, there should be waiting homes near the healthcare facility where comprehensive emergency obstetric care (EmOC) is available, set up by the regional health teams, to which they and their attendants can move near to the time of delivery so that they do not have to make a long and potentially dangerous journey while in labour.

**All of these details, along with the results of any investigations, should be noted on a small hand-held record ([http://eepd.org.uk/wiki/index.php?title=Hand\\_Held\\_Records](http://eepd.org.uk/wiki/index.php?title=Hand_Held_Records)) which the pregnant woman or girl is encouraged to carry with her at all times throughout the pregnancy.**

As the pregnancy progresses, the uterus continues to grow and has usually reached the level of the umbilicus by 20–24 weeks (see Figure 2.1.1). Measuring the height of the fundus above the symphysis pubis can also provide a good indication of the growth and gestation of the fetus. The woman should first empty her bladder. The measurement is then made by placing the zero point of the tape measure on the upper border of the symphysis and taking the tape along the uterus in a longitudinal direction to the upper border of the fundus, with the mother lying in the left lateral tilt position.

Between 20 and 34 weeks' gestation, the length of this measurement (in centimetres) should correspond to the gestational age in weeks of a well-grown fetus (see Figure 2.1.2).

**FIGURE 2.1.2** Measuring fundal height.

A difference of more than 2 cm too long or too short can indicate complications such as multiple pregnancy (too long), intrauterine growth retardation (too short), or inaccurate measurements of the estimated date of delivery.

It should be recognised that fundal height is not an accurate assessment of gestation or fetal size. Even in the absence of confounding factors such as multiple gestation and poly/oligohydramnios, it varies widely depending on the height and weight of the mother and lie of the fetus. In addition, the 'normal' fetal size also varies widely depending on patient build and ethnic origin.

### Antenatal investigations and interventions

- Ideally a full blood count should be done at least once during the pregnancy, to check the haemoglobin level and, if possible, the red cell indices. Portable systems for measuring haemoglobin include the haemocue and WHO colour card from a finger prick sample, or perhaps, in the future, percutaneous measurement using a transcutaneous haemoglobinometer (currently under development by Masimo).
- Urinalysis must be performed at every visit, to check for protein and glucose.
- Screening for bloodborne viruses (hepatitis B and C and HIV) is not always available (see Section 1.8). All mothers should be advised of the risks involved, and of the precautions they can take to reduce the risk of transmission. Healthcare professionals also need to be made aware of universal precautions and adhere to them at all times.
- Serum samples should be taken for blood grouping and Rhesus status.
- All women should be tested for and when appropriate treated for syphilis (see Section 2.8.H).

### ABO and Rhesus incompatibility

At a mother's first visit to the healthcare site, blood should be taken for ABO typing, determination of Rhesus (Rh) status and detecting the presence of harmful antibodies.

The main antibodies of concern are anti-D (usually acquired following fetomaternal haemorrhage), anti-c and anti-kell (which usually follow blood transfusion), all of which can cause severe haemolytic disease of the newborn. ABO incompatibility can also cause neonatal jaundice in one in 30 cases.

Potential Rh-D sensitising events for a Rhesus-negative mother include miscarriage, termination of pregnancy, ectopic pregnancy, antepartum haemorrhage, and invasive procedures such as external cephalic version. If the mother is not given anti-D immunoglobulin after such events, a second challenge will lead to a massive rise in anti-D antibodies in the mother's circulation, which can then cross the placenta and destroy Rhesus-positive fetal cells, causing fetal anaemia. The anti-D immunoglobulin should ideally be given within 3 days of the sensitising challenge, but may be effective when given up to 13 days after the challenge. The WHO recommends 125 IU per mL of fetal red blood cells found in the maternal circulation. A Kleihauer test can be performed to identify the presence and quantity of fetomaternal haemorrhage. In well-resourced countries, a dose of 250 IU of anti-D immunoglobulin is given before 20 weeks' gestation, and 500 IU after 20 weeks. (This is almost always adequate but additional units are given if the Kleihauer test indicates a larger fetomaternal haemorrhage.)

Due to limited infrastructure, blood bank facilities will not be available at all healthcare sites, but staffed laboratories should be available in district hospitals where the serum sample, taken at the healthcare site, adequately labelled and batched, can be sent for processing.

### Immunisation and antimalarial prophylaxis

Routine administration of anti-tetanus toxoid should be offered to all women to reduce the risk of neonatal and maternal tetanus. For women who have never received tetanus toxoid vaccine, or who have no documentation of such immunisation, a total of five doses is recommended – two doses given 1 month apart in the first pregnancy, then one dose in each subsequent pregnancy (or at intervals of at least 1 year), up to a total of five doses.

A single dose does not offer adequate protection, and as the highest level of antibody occurs 24 weeks following the second dose, ideally this should be given around 16 weeks' gestation, with the first dose being given at least 4–8 weeks earlier in the first trimester, if early attendance allows this.

Intermittent antimalarial prophylaxis should also be offered. Among its other advantages, this may reduce the burden of severe anaemia (see Section 2.8.D).

### Ultrasound scanning

Facilities for ultrasound scanning in this setting are usually limited. There may be no funding for a machine. If there is a machine, the staff need to be adequately trained and have the time to use it. Scanning can be useful for assessing the site of pregnancy, the period of gestation, viability, the number of fetuses, presentation and the progress of the pregnancy. If the image quality is good enough, it may also allow the detection of abnormalities, and although intervention might not be possible, this would mean that problems could be anticipated, delivery planned and the mother counselled appropriately.

### Specific antenatal problems

It is not possible to discuss the management of every antenatal condition here. Conditions such as anaemia, hypertension and diabetes, which are common complications of pregnancy and becoming increasingly so, are discussed in detail elsewhere in this textbook.

### Hyperemesis

Some nausea and vomiting is common in early pregnancy. However, in a small proportion of patients, severe vomiting (hyperemesis) can occur. This condition is more common where there is a larger than normal placental mass (e.g. in multiple pregnancy and molar pregnancy).

Signs of dehydration such as tachycardia, dry mucous membranes and a slow skin pinch can develop. The patient often develops ketoacidosis, which makes the nausea and vomiting worse. For details on managing this condition, see Section 2.6.I.

## Organising an effective antenatal care system

### Blood bank facilities

A functional and effective blood transfusion service (see Section 1.7) is a vital component of a national health system.

The WHO expects all countries to have national policies and a legislative framework for blood safety, with a centrally coordinated and quality system in place. Ideally, all donors should be unpaid volunteers, and unnecessary transfusion should be avoided. Currently there are large discrepancies between wealthy and resource-limited countries in the availability of this service.

### Antenatal care networks

One important factor in the delivery of an effective antenatal service is establishing good networks between the community and the healthcare facilities in which births occur.

As was mentioned in the introduction to this section, 'trekking' is the setting up of an outreach service by which healthcare providers go to the women, rather than vice versa. This serves to offset the problems of distance and lack of transportation, and may be the first step in facilitating these linkages, as the staff have an opportunity to offer education to the mothers, birth attendants, family and community members on the potential benefits for women of delivering in a healthcare facility. The staff can also advise on warning signs to look out for, and on emergency measures that can be taken before professional help arrives.

**Patients and their attendants need to know that they will receive the care they need regardless of whether or not they can afford it.**

Perhaps most importantly, hospital staff need to reiterate the vital role that community members can have in averting

a tragedy. This will hopefully reduce suspicion and encourage early communication when help is needed, so that critical delays in getting help to a mother can be avoided. A local emergency taxi service set up in each village, and ideally funded by the community and available at all times for women to be taken to the healthcare facility, is one way of addressing this.

One of the responsibilities of the regional health teams is to provide **waiting homes** near to a health facility, providing comprehensive EmOC, as mentioned earlier, where the high-risk expectant mother and her family members can stay for a short period prior to the birth in case an emergency arises.

If help is summoned following an emergency in the community, an emergency ambulance system, manned by personnel who have been trained in resuscitation and stabilisation, can be used for retrieval, further reducing the delay before the mother first receives skilled care (e.g. wheelbarrow ambulances, <http://niaje.com/blog/kiberas-wheelbarrow-ambulance-innovation-out-of-necessity/>).

### Conclusion

The main keys to providing effective antenatal care are education on the role that it plays and emphasis on the importance of teamwork by all of the parties involved, to ensure the best possible outcome for both mother and baby.

## 2.2

## Nursing pregnant women and girls in hospital (midwifery)

### Introduction

Irrespective of where midwifery care is provided, there are universal requirements that should govern the provision of care:

- 1 provision of a safe healthcare environment for patients and staff
- 2 respectful and compassionate care for women, the neonate(s) and the family
- 3 skilled and competent staff to provide a good standard of evidence-based care
- 4 health education and promotion.

These areas of critical importance are further considered and described concisely in the subsections below. More detailed information on each area can be found in the references listed at the end of this section.

The global human resources target for effective delivery of obstetric care is one skilled birth attendant (SBA) for every 100 expected births. SBAs are defined as midwives, nurses, health officers, medical doctors and obstetricians/gynaecologists.

### Definition of maternal death

In every action that is undertaken as part of midwifery, the prevention of maternal death must be the first priority.

According to the WHO, pregnancy-related death is defined as the death of a woman or girl while pregnant or within 42 days of the termination of pregnancy, irrespective of the cause of death.

### Safe environment

#### WHO checklist

The WHO has recently produced a helpful checklist for patient safety with regard to childbirth ([www.who.int/patientsafety/implementation/checklists/en/index.html](http://www.who.int/patientsafety/implementation/checklists/en/index.html)).

#### Infection control

The microorganisms that cause infection can be transmitted to patients and staff by several routes. These include aerosol, droplet (e.g. coughing and sneezing) and faecal-oral routes, direct contact (person to person), indirect contact (through contaminated food or water, contaminated surfaces or objects), via blood and body fluids, and via insects and parasites. It is vital that basic infection control practices

**TABLE 2.2.1 Elements of the WHO Safe Childbirth Checklist**

Checklist item		Qualifying caption
<i>On admission of the mother to the birth facility</i>		
Does the mother need referral?	<input type="checkbox"/> Yes, organised	According to the facility's criteria
	<input type="checkbox"/> No	
Partograph started?	<input type="checkbox"/> Yes	Start plotting when cervix is $\geq 4$ cm, then cervix should dilate $\geq 1$ cm/hour. Every 30 minutes, plot heart rate, contractions and fetal heart rate. Every 2 hours, plot temperature. Every 4 hours, plot blood pressure
	<input type="checkbox"/> No, will start when $\geq 4$ cm	
Does the mother need to start antibiotics?	<input type="checkbox"/> Yes, given	Give if temperature is $\geq 38^{\circ}\text{C}$ , or if there is a foul-smelling vaginal discharge, rupture of membranes longer than 18 hours, or labour longer than 24 hours
	<input type="checkbox"/> No	
Does the mother need to start magnesium sulphate?	<input type="checkbox"/> Yes, given	Give if (1) diastolic blood pressure is $\geq 110$ mmHg and 3+ proteinuria, or (2) diastolic blood pressure is $\geq 90$ mmHg and 2+ proteinuria, and any of the following: severe headache, visual disturbance or epigastric pain
	<input type="checkbox"/> No	
Does the mother need to start antiretroviral medicine?	<input type="checkbox"/> Yes, given	Give if the mother is HIV positive and in labour
	<input type="checkbox"/> No	
<input type="checkbox"/> Supplies are available for cleaning hands and wearing gloves for each vaginal examination		
<input type="checkbox"/> Birth companion encouraged to be present at birth		
<input type="checkbox"/> Confirm that the mother and/or companion will call for help during labour if the mother has a danger sign		Call for help if the mother has bleeding, severe abdominal pain, severe headache, visual disturbance, urge to push, or difficulty emptying bladder
<i>Just before pushing (or before Caesarean section)</i>		
Does the mother need to start antibiotics?	<input type="checkbox"/> Yes, given	Give if temperature is $\geq 38^{\circ}\text{C}$ , or if there is a foul-smelling vaginal discharge, rupture of membranes longer than 18 hours now, labour longer than 24 hours, or Caesarean section
	<input type="checkbox"/> No	
Does the mother need to start magnesium sulphate?	<input type="checkbox"/> Yes, given	Give if (1) diastolic blood pressure is $\geq 110$ mmHg and 3+ proteinuria, or (2) diastolic blood pressure is $\geq 90$ mmHg and 2+ proteinuria, and any of the following: severe headache, visual disturbance or epigastric pain
	<input type="checkbox"/> No	
Are essential supplies at the bedside for the mother?	<input type="checkbox"/> Gloves	Prepare to care for the mother immediately after birth: (1) Exclude the possibility of a second baby, (2) Give oxytocin within 1 minute, (3) Use controlled cord traction to deliver the placenta, (4) Massage the uterus after the placenta has been delivered
	<input type="checkbox"/> Soap and clean water	
	<input type="checkbox"/> Oxytocin 10 IU in syringe	
Are essential supplies at the bedside for the baby?	<input type="checkbox"/> Clean towel	Prepare to care for the baby immediately after birth: (1) Dry the baby and keep them warm, (2) If the baby is not breathing, stimulate and clear the airway, (3) If they are still not breathing, cut the cord, ventilate with bag and mask, and (4) shout for help
	<input type="checkbox"/> Sterile blade to cut cord	
	<input type="checkbox"/> Suction device	
	<input type="checkbox"/> Bag and mask	

Checklist item	Qualifying caption	
<input type="checkbox"/> Has an assistant been identified and informed to be ready to help at birth if needed?		
<i>Soon after birth (within 1 hour)</i>		
Is the mother bleeding too much?	<input type="checkbox"/> Yes, shout for help	If blood loss is $\geq 500$ mL, or if blood loss is $\geq 250$ mL and the mother is severely anaemic, massage the uterus, consider additional uterotonic drugs, start an intravenous line, and treat the cause
	<input type="checkbox"/> No	
Does the mother need to start antibiotics?	<input type="checkbox"/> Yes, given	Give antibiotics if the placenta is manually removed, or if the temperature is $\geq 38^{\circ}\text{C}$ and any of the following are present: foul-smelling vaginal discharge, lower abdominal tenderness, rupture of membranes longer than 18 hours at time of delivery, <i>or</i> labour longer than 24 hours at time of delivery
	<input type="checkbox"/> No	
Does the mother need to start magnesium sulphate?	<input type="checkbox"/> Yes, given	Give if (1) diastolic blood pressure is $\geq 110$ mmHg and 3+ proteinuria, <i>or</i> (2) diastolic blood pressure is $\geq 90$ mmHg and 2+ proteinuria, and any of the following: severe headache, visual disturbance <i>or</i> epigastric pain
	<input type="checkbox"/> No	
Does the baby need a referral?	<input type="checkbox"/> Yes, organised	According to the healthcare facility's criteria
	<input type="checkbox"/> No	
Does the baby need to start antibiotics?	<input type="checkbox"/> Yes, given	Give these if antibiotics were given to the mother, or if the baby has any of the following: breathing too fast ( $> 60$ breaths/minute) or too slow ( $< 30$ breaths/minute), chest in-drawing, grunting, convulsions, no movement on stimulation, <i>or</i> too cold (temperature $< 35^{\circ}\text{C}$ and not rising after warming) or too hot (temperature $> 38^{\circ}\text{C}$ )
	<input type="checkbox"/> No	
<input type="checkbox"/> Does the baby need special care and monitoring?		Recommended if more than 1 month early, birth weight $< 2500$ grams, needs antibiotics, <i>or</i> required resuscitation
Does the baby need to start an antiretroviral drug?	<input type="checkbox"/> Yes, given	Give antiretroviral drug if the mother is HIV positive
	<input type="checkbox"/> No	
<input type="checkbox"/> Started breastfeeding and skin-to-skin contact (if mother and baby are well)?		
<input type="checkbox"/> Confirm that the mother or companion will call for help if:		The mother has bleeding, severe abdominal pain, severe headache, visual disturbance, breathing difficulty, fever/chills, <i>or</i> difficulty emptying bladder
		The baby has fast breathing or difficulty breathing, fever or is unusually cold, stops feeding well, is less active than normal, <i>or</i> the whole body becomes yellow
<i>Before discharge</i>		
Is the mother's bleeding controlled?	<input type="checkbox"/> Yes	
	<input type="checkbox"/> No, treat and delay discharge	
Does the mother need to start antibiotics?	<input type="checkbox"/> Yes, given	Give if the temperature is $> 38^{\circ}\text{C}$ and any of the following: chills, foul-smelling vaginal discharge, <i>or</i> lower abdominal tenderness
	<input type="checkbox"/> No	
Does the baby need to start antibiotics?	<input type="checkbox"/> Yes, give antibiotics, delay discharge, and give special care or refer	Give if the baby is breathing too fast ( $> 60$ breaths/minute) or too slow ( $< 30$ breaths/minute), or if there is chest in-drawing, grunting, convulsions, no movement on stimulation, too cold (temperature $< 35^{\circ}\text{C}$ and not rising after warming) or too hot (temperature $> 38^{\circ}\text{C}$ ), has stopped breastfeeding well, <i>or</i> there is umbilical redness extending to the skin or draining pus
	<input type="checkbox"/> No	
Is the baby feeding well?	<input type="checkbox"/> Yes	

Checklist item	Qualifying caption	
	<input type="checkbox"/> No, help and delay discharge	
<input type="checkbox"/> Family planning options discussed and offered to mother		
<input type="checkbox"/> Confirm that the mother or companion will call for help after discharge if:		The mother has bleeding, severe abdominal pain, severe headache, visual disturbance, breathing difficulty, fever/chills, <i>or</i> difficulty emptying bladder
		The baby has fast breathing or difficulty breathing, fever or is unusually cold, stops feeding well, is less active than normal, <i>or</i> the whole body becomes yellow
<input type="checkbox"/> Follow-up arranged for mother and baby		

are adhered to in order to reduce or eliminate the sources and spread of infection (see Section 1.2).

Situations in which equipment, treatment rooms and delivery beds are covered in dirt, old blood and rat droppings, with goats and pigs wandering freely through the grounds and rats nesting in incubators and other equipment (all of which can be seen in resource-limited settings in public health facilities) are unacceptable and a source of infection. It is important to understand the reasons why women are developing serious wound infections post Caesarean section, which include, for example, overcrowded recovery rooms, with beds and surroundings not cleaned properly for months.

Washing hands between patients and after all invasive procedures is one of the infection control procedures that is of paramount importance, as dirty hands play a large part in spreading infection. Facilities for handwashing (i.e. a basin and clean towels), plus the availability of soap and water, are essential within any ward or healthcare facility.

It is also extremely important to ensure that any equipment used for the care of patients is cleaned after every use, with anything broken being replaced or mended. It is also necessary for the equipment to be stored in a clean and tidy area, so that it does not become contaminated when not in use. This will ensure that vital equipment is kept clean and in working order, ready to be used safely at any time.

An example of a situation where the above basic minimum standards are not met is the absence of clean oxygen tubing with nasal cannulae to help a baby to survive, and only dirty equipment available, with nothing to thoroughly clean it. There is then the dilemma of whether to use the unclean equipment with the associated severe risk of infection to the sick infant.

The environment in which women and babies are cared for also needs to be regularly cleaned. This includes regular cleaning of trolleys, bedding and sanitation facilities. Omission of these tasks will lead to the harbouring of infection, whether this is through direct or indirect contact or by the attraction of flies and mosquitoes to dirty surfaces or pools of fluid.

It is appreciated that, in some healthcare facilities, cleaning solutions (e.g. disinfectant) can be difficult to obtain because of lack of supplies or their cost making them unavailable. Using basic soap and water or even just cooled boiled water is better than not cleaning at all, and will remove microorganisms and the organic matter on which they thrive.

Instruments and other equipment that penetrates skin or mucous membranes or enters the vascular system or sterile spaces needs to be free of viable microorganisms, including viruses and bacterial spores. This is achieved by sterilising the equipment, usually in a hot oven or autoclave. It is important that the healthcare staff maintain the ovens and/or autoclaves in working order. They also need to fully appreciate how the process of sterilisation works. It is not appropriate for instruments to be placed in hot ovens or autoclaves without first cleaning them to remove visible blood and organic debris. Another common mistake is for healthcare staff to remove sterilised instruments and then proceed to cool them off using unsterilised water from the roof or tap.

Healthcare staff should wear protective clothing when indicated, if it is available. This includes new sterile gloves for every invasive procedure, and disposable or cleanable plastic aprons to avoid contamination of uniforms with bodily fluids during messy or potentially messy procedures.

Another extremely important element of infection control is to ensure that healthcare staff have received appropriate training in the disposal of used sharps (e.g. needles) into sharps boxes. The process for removal of these full sharps boxes from the health facility, and their incineration, also needs to be clear and robust, to prevent contaminated sharps from ending up on the local village dump, where children often scavenge and play.

### Physical safety

The safety of the physical environment in which women and their babies are cared for is also very important, and staff need to give this full consideration. Broken beds and equipment can be dangerous. The former may collapse, and the latter may have sharp edges that can cause a wound. Babies can fall off high surfaces if these are not guarded.

### Respectful and compassionate care

A good midwife or healthcare worker will treat every woman, irrespective of her personal circumstances, with compassion and respect. Pregnancy, labour, delivery and the postnatal period can all be anxious times for a woman. It is at these times that guiding, supportive and empathetic care is required. It is completely unacceptable within any society for women to be verbally and physically assaulted by their carers. Fellow staff should never tolerate this type of behaviour from colleagues towards women.

Good care will involve providing full, understandable explanations of any required interventions to the woman and her family, with the woman giving her consent to those interventions.

When in labour, women often find the intense pain of contractions easier to bear if they can be upright and moving about. This position is also better physiologically, as it promotes the progress of labour and promotes the well-being of the fetus. In most cases this is the position which should be encouraged until delivery is imminent. The position for delivery should, where possible, be the one that the woman prefers (e.g. upright or squatting), but this will also be dictated by the type of delivery and the degree of observation of the mother and her baby that is required. Women should not be instructed by their carers to lie flat on a hard trolley for almost their entire labour, as there is no necessity for them to do so, and this position is detrimental to the progress of labour and to the well-being of the fetus.

It is also important during labour and delivery to ensure that the basic care needs of women for a comfortable, safe environment are met. Light food and drinking water need to be available, with intake of water encouraged throughout labour to prevent dehydration. Ideally a relative or friend should be able to stay with the woman during labour and delivery to provide emotional support throughout. However, this may not always be possible in the very cramped, busy delivery wards that exist in some countries. If this is the case, there is all the more need for caring, empathetic staff. Strong analgesics for pain relief during labour may be unavailable in developing countries, and therefore these women often require greater resilience and coping skills, so encouragement and support from healthcare staff and the family is crucial throughout this time.

## Skilled and competent staff

### Management of emergencies

All midwives, traditional birth attendants and healthcare staff who provide maternity care need training to recognise what is normal and what is abnormal for both the mother and the fetus/neonate. Healthcare workers should know how to manage emergency situations relevant to their level of knowledge, and when and who to call for help.

In many areas within resource-limited countries there is no accessible surgical or anaesthetic care, and the nurse-midwife may well be the last point of referral. The nurse-midwife therefore needs to be trained and competent in all emergency procedures that may need to be performed within the environment in which they work. These emergency procedures are described in more detail within the relevant sections of this book.

### General care

In the antenatal period, it will be the midwives' responsibility to ensure through physical examination, fetal heart auscultation, blood pressure monitoring, urinalysis, and screening for and treatment of anaemia that the pregnancy is progressing satisfactorily (see Section 2.1). WHO recommends 4 routine antenatal visits: <16, 24–28, 30–32 and 36–38 weeks gestation, and more frequently if at any stage it is identified as a high-risk pregnancy. During the pregnancy it may be necessary for the midwife to initiate treatment and follow up any problems that are discovered (e.g. anaemia, hypertension, infections).

When a woman goes into established labour her well-being and progress should be regularly monitored by either the traditional birth attendant or ideally a skilled birth attendant. This monitoring should include a 4-hourly check of the blood pressure and body temperature, a half-hourly check of the maternal pulse and fetal heart rate, and vaginal examination 4-hourly in the first stage of labour to check that the labour is progressing appropriately. During labour, the woman should be encouraged to void urine at regular intervals and as a minimum every 4 hours to avoid having an overfull bladder which could impede descent of the fetus through the birth canal. For poor progress in labour, amniotomy and/or careful augmentation with oxytocin may be indicated.

All observations that are recorded in labour should be recorded on a WHO partograph. Use of the partograph will help healthcare staff to recognise poor labour progress and/or observations of concern.

Fetal heart auscultation with a Pinard's stethoscope or portable Doppler ultrasound device (e.g. a Sonicaid) also needs to occur regularly, although the required frequency of the latter in the first stage of labour will be determined by the availability of facilities for performing an urgent Caesarean section for fetal distress. Once the second stage of labour has been reached the woman will usually start to experience the urge to push, and the midwife should encourage pushing in normal labour once this urge is sufficiently intense. Vaginal examinations should then occur at least hourly to assess progress if delivery is not imminent. At this stage it can be possible to deliver the fetus more rapidly (if the fetal heart rate is indicating signs of distress) by using episiotomy, forceps or ventouse. The second stage of labour can be particularly stressful for the fetus and therefore in the second stage the fetal heart should be auscultated at least every 15 minutes to determine signs of distress that would necessitate an accelerated delivery.

During delivery, the nurse-midwife needs to assist the woman in having a controlled delivery in order to avoid perineal trauma and/or harm to the newborn child. Active management of the third stage of labour by a skilled birth attendant with oxytocin is essential. Sterile delivery equipment needs to be available. At the very least in the community for the traditional birth attendant this should include a sterile instrument to cut the cord, with a sterile cord clamp and/or ties.

As previously stated, the healthcare worker needs to be constantly alert for any deviation of labour and delivery away from the normal (e.g. premature delivery, twin delivery, haemorrhage, hypertension, etc.), so that care can be adapted accordingly and emergency assistance sought if it is required and available.

The healthcare worker needs to be able to perform basic resuscitation of the newborn if this is required at delivery. Therefore bag-valve-mask resuscitation equipment needs to be readily available to healthcare staff trained in its use, including traditional birth attendants.

In addition, during the postnatal period the healthcare worker will need to ensure that they have the skills and knowledge necessary to provide appropriate care for the mother and child. This will include monitoring the progress of both mother and child, again being able to recognise the abnormal and initiate and/or provide the appropriate care to address any problems. The healthcare worker will need to be able to give all necessary advice to the mother and her

family on her postnatal recovery and childcare, including advice and support with infant feeding.

### Health education and promotion

The midwife or healthcare worker should use every interaction she has with the woman and her family throughout pregnancy, labour and the postnatal period as an opportunity to provide health advice, promote good health and deliver education. This should include antenatal education and information on the recognition of danger signs occurring at any stage during the pregnancy and in the postnatal period, including haemorrhage, abdominal pain, reduced fetal movements, severe headache and any other signs and symptoms of pre-eclampsia, and the immediate action to take when these signs occur. The healthcare worker also needs to provide education on parenting and childcare, again with advice on recognising abnormalities in the child, in order to seek appropriate medical advice. There will also be an ideal opportunity to give family planning advice and advice on the necessary immunisations,

prophylactic treatments and available health screening for the whole family.

### Critical incident audit and feedback to improve perinatal and maternal mortality and morbidity

There is little doubt that this is a vital activity that should be undertaken on a regular basis, and that resources and time must be made available for this. Effective methods of preventing maternal and perinatal mortality are available, but the systems of care that should ensure they are put in place are frequently impaired. Critical incident reviews are potentially a simple cost-effective way of defining the local problems and pointing the way to local solutions.

## 2.3

## Managing normal labour and delivery

### BOX 2.3.1 Minimum standards

- WHO partograph
- Disinfectant cream for vaginal examinations
- Sterile gloves
- Fetal heart monitor (Pinard's or Doppler)
- Oxytocin and a safe way of giving it
- Amniotic hook
- Sterile vaginal speculums
- Postnatal care programmes for mother and baby

### Positions for assisting with delivery of the baby

All mothers in labour should be sitting upright or in a lateral or semi-recumbent position (see Figure 2.3.3). They should not lie flat on their back, as this causes compression of the inferior vena cava and aorta, with reduced cardiac output, as well as limited ability to push. They should be encouraged to stand and be mobile for as long as is comfortably possible.

### Basic anatomy to aid understanding of the birthing process

FIGURE 2.3.1 Basic anatomy of the pelvis.

FIGURE 2.3.2 The baby's birth path.

FIGURE 2.3.3 Good positions during the second stage.

FIGURE 2.3.6 Pushing in the wrong position.

Figure 2.3.4 shows delivery on a birth stool. A TBA is delivering this mother's baby, and the husband is helping. Sitting up like this helps the uterus to contract, and it also makes it easier for the mother to bear down. In addition, when the mother opens her legs they act as pivots to help to increase the diameter of the pelvis.

FIGURE 2.3.4 Using a birthing stool.

### The WHO partograph

See World Health Organization (2008) *Managing Prolonged and Obstructed Labour* ([http://whqlibdoc.who.int/publications/2008/9789241546669\\_4\\_eng.pdf](http://whqlibdoc.who.int/publications/2008/9789241546669_4_eng.pdf)).

The partograph is a graphic record of the progress of labour and relevant details of the mother and fetus. It was initially introduced as an early warning system to detect labour that was not progressing normally. This would allow for timely transfer to occur to a referral centre, for augmentation or Caesarean section as required. The partograph indicates when augmentation is needed, and can point to possible cephalopelvic disproportion before labour becomes obstructed.

It increases the quality and regularity of observations made on the mother and fetus, and it also serves as a one-page visual summary of the relevant details of labour.

The partograph has been used in a number of countries, and has been shown to be effective in preventing prolonged labour, in reducing operative intervention, and in improving the neonatal outcome.

It is important to ensure that adequate supplies of the form are always available.

The WHO partograph begins only in the active phase of labour, when the cervix is 4 cm or more dilated (see below).

However, it is a tool which is only as good as the health-care professional who is using it. The observations that are recorded will document the following:

- **Maternal well-being:** record pulse rate every 30 minutes, blood pressure and temperature 4-hourly, urine output and dipstick testing for protein, ketones (if available) and glucose after voiding, **and** record all fluids and drugs administered. If the findings become abnormal, increased frequency of observation and testing will be required, and intervention may be implemented.

FIGURE 2.3.5 The pushing position, pushing with healthcare worker support.

- **Fetal well-being:** record fetal heart rate for 1 minute every 15–30 minutes after a contraction in the first stage, and every 5 minutes in the second stage. If abnormalities are noted, urgent delivery can be considered.
- **Liquor:** clear, meconium stained (thick or thin), bloody or absent. Thick meconium suggests fetal distress, and closer monitoring of the fetus is indicated. Check every 30 minutes.
- **Frequency, duration and strength of uterine contractions (assessed by palpation):** record every 30 minutes.
- **Abdominal examination:** to assess descent of the fetal head.

- **Vaginal examination:** this should be done no less than every 4 hours to assess cervical dilatation, descent of the fetal head, and moulding of skull bones. More frequent examination is only undertaken if indicated.

There must be a team approach, and senior staff must oversee the care of high-risk patients. Ideally there should be one-to-one care.

**Key to partogram**

- **Amniotic fluid:** I = membranes intact, C = membranes ruptured, clear fluid, M = meconium-stained fluid, B = bloodstained fluid.

FIGURE 2.3.7 The modified WHO partogram without latent phase.

FIGURE 2.3.8 Sample partogram showing normal progression of labour.

FIGURE 2.3.9 How to record contraction frequency and length. The number of squares filled in records the number of contractions in 10 minutes. The shading shows the length of contractions.

FIGURE 2.3.10 Recording effacement: the length of the cervix. Effacement can be recorded by thickening a line with a pen as shown in the diagram, or 'percentage' effacement can be written in the squares.

- **Moulding:** 0 = bones are separated and sutures can be easily felt; + 1 = bones are just touching each other; + 2 = bones are overlapping but can be reduced; + 3 = bones are severely overlapping and irreducible.
- **Cervical dilatation:** assess at each VE and mark with a cross ×. Begin at 4 cm.
- **Alert line:** starting at 4 cm of cervical dilatation, up to the point of expected full dilatation at the rate of 1 cm per hour.
- **Action line:** parallel and 4 hours to the right of the alert line.
- **Descent assessed by abdominal palpation:** this refers to the part of the head (which is divided into five parts) palpable above the symphysis pubis; recorded as a circle (O) at every vaginal examination. At 0/5, the sinciput (S) is at the level of the symphysis pubis.
- **Hours:** this refers to the time elapsed since the onset of the active phase of labour (observed or extrapolated).
- **Time:** record the actual time at 30-minute intervals.
- **Contractions:** chart every 30 minutes; palpate the number of contractions in 10 minutes and their duration in seconds (< 20 seconds, 20–40 seconds, > 40 seconds).
- **Oxytocin:** record the amount (in units) of oxytocin per volume of IV fluids, and the number of drops per minute, every 30 minutes when used.
- **Drugs given:** record any additional drugs given.
- **Pulse:** record every 30 minutes and mark with a dot (•).
- **Blood pressure:** record every 4 hours and mark with arrows, unless the patient has a hypertensive disorder or pre-eclampsia, in which case record every 30 minutes.
- **Temperature:** record every 4 hours.
- **Urine, ketones and volume:** ideally record every time urine is passed.

### Maternal condition

Maternal vital sign observations are crucial in labour, in order to detect pre-eclampsia, haemorrhage (accompanied by a rise in heart rate, or, as it worsens, a fall in blood pressure) and sepsis (fever). A fall in blood pressure is usually a late and ominous sign. The pulse rate and respiratory rate are valuable early features of worsening maternal condition.

### Fetal condition

The fetal heart rate should be measured every 15 to 30 minutes immediately after a contraction, for 1 minute, with the mother sitting or in the lateral tilt position.

The normal baseline fetal heart rate is 110–160 beats/minute. The fetus's baseline heart rate should remain stable throughout labour. Fetal heart rate accelerations are healthy features, whereas decelerations may suggest fetal compromise. This applies particularly if the decelerations do not recover immediately after the contraction (this is described as a late deceleration). A baseline rate of > 160 beats/minute (tachycardia) or < 110 beats/minute (bradycardia) may indicate fetal distress, as can a rising baseline.

### Membranes and liquor

If the membranes are intact, write 'I'.

If the membranes are ruptured:

- if liquor is clear, write 'C'
- if liquor is meconium-stained, write 'M'
- if liquor is absent, write 'A'
- if liquor is bloodstained, write 'BS'.

If liquor is absent, or if there is meconium staining of liquor, draining, fetal distress should be considered and monitored for closely (meconium staining is present in 15–30% of all pregnancies, with a higher prevalence after 41 weeks' gestation).

### Moulding of fetal skull bones (see Figure 2.3.11)

FIGURE 2.3.11 Degrees of moulding of the bones of the fetal skull.

Increasing moulding may be a sign of cephalo-pelvic disproportion, as the fetal skull bones overlap to aid passage through the maternal pelvis.

Key: 0 = bones are separated and sutures can be easily felt, + = bones are just touching each other, ++ = bones are overlapping but can be reduced, +++ = bones are severely overlapping and irreducible.

### Stages of labour

Labour is divided into **latent** and **active** phases.

- The **latent phase** is cervical dilatation from 0 cm to 4 cm with gradual shortening of the cervix.
- The **active phase** is cervical dilatation from an effaced 4 cm cervix to full dilatation with good contractions. Progress should be at the rate of at least 1 cm/hour.

### Latent stage of labour (0 cm to 4 cm cervical dilatation)

In the latent phase of labour, contractions usually start off as irregular, establishing into regular painful uterine contractions. In the primigravida, this can take up to a few days to occur, but usually takes less time in the multigravida.

The well-being of the mother and fetus in the latent phase should be assessed without unnecessary interventions, and mobilisation should be encouraged. Adequate hydration and nutrition are important, and the woman should be enabled to empty her bladder as required. During this time it is important to check the haemoglobin level and review the notes with regard to possible future problems with delivery.

**Unnecessary vaginal examinations in the latent phase can lead to life-threatening infections in the mother and baby.**

### Active phase of labour

#### First stage

There should be regular painful contractions, and the cervix should efface and dilate at a rate of about 1 cm/hour from 4 cm to full dilatation (10 cm).

Vaginal examinations during labour must be recorded and only done by those caring for and monitoring the mother. They should not be undertaken more than 4-hourly unless there is a reason for doing so. During such examinations, the use of Hibitane cream or similar disinfectant cream can help to prevent infections. Care should be taken when diagnosing active labour as misdiagnosis can

lead to unnecessary medical intervention and risk to the mother and fetus. The cervix should be 4 cm and effaced and there should be regular contractions. It should be noted that in multiparae the cervix is often soft and easily stretchable to 4 cm and even beyond. This can be the case in the latent phase and sometimes even before the onset of contractions.

**The progress of labour**

**Measurement of cervical dilatation**

Cervical dilatation is assessed by vaginal examination, which should be performed every 4 hours, unless there are indications to do so more frequently.

The cervical dilatation can be plotted on a partograph against time. When the patient is admitted in active labour, the dilatation is immediately plotted on the alert line, the first line drawn upwards on the graph illustrating a rate of 1 cm/hour from this first plot. If subsequent progress is satisfactory, the cervical dilatation will be on, or to the left of, this alert line in later vaginal examinations.

**FIGURE 2.3.12** Measuring cervical dilatation. A cervical dilatation board shows the diameter of the cervix from 1 cm to 10 cm.

**FIGURE 2.3.13** Effacement and dilatation.

Before the onset of labour, the cervix will usually be tubular. Effacement is the process whereby the cervix subsequently loses its length, to become flattened against the fetal presenting part.

In primigravid women, effacement occurs in early labour, followed by cervical dilatation. In multiparous women, the cervix commonly dilates before full effacement.

**Diagnosis of the stages and phases of labour**

Cervix not dilated = not in labour  
 Cervix dilated < 4 cm = first stage and latent phase

Cervix dilated 4–9 cm = first stage and active phase (usually 1 cm/hour) and onset of fetal descent  
 Cervix fully dilated (10 cm) = second stage (non-expulsive phase), no urge to push and fetus continues to descend  
 Cervix fully dilated (10 cm) = second stage (expulsive phase), urge to push and fetus reaches pelvic floor  
 Delivery of the baby = Onset of third stage  
 Delivery of the placenta = End of third stage

**Bishop's Score:** The early pre-labour/early labour changes that occur to the cervix can be quantified by using the Bishop's score which assigns a score of 0 to 2 for each of the following characteristics: dilatation, effacement, consistency, position of cervix and station of the head (see below). It is useful both for assessing progress in the latent phase of labour, and also for assessing the 'favourability' of the cervix for induction of labour. A patient with a favourable cervix has a Bishop score of 6 or more and is likely to be easier to induce. It should also be possible to rupture the membranes by the time the Bishop score is 6.

Characteristic	0	1	2	3
Dilatation	Closed	1–2 cm	3–4 cm	5 cm or more
Effacement	>4 cm	3–4 cm	1–2 cm	Effaced
Consistency	Hard	Medium	Soft	–
Station of head	–3 or above	–2	–1/0	+1/+2
Position of cervix	Posterior	Mid	Anterior	–

**FIGURE 2.3.14** Measuring 'fifths'.

**FIGURE 2.3.15** Fetal head descent palpated abdominally showing 4/5 and 2/5.

**FIGURE 2.3.16** Descending fetal head showing vaginal appearance to palpation. Alongside each picture of the fetus is a view of the head from below and a partogram to show the stage of the mother's labour.

### Descent of the fetal head

Dilatation of the cervix should be accompanied by descent of the head, although this may not occur until advanced labour. Sometimes descent does not occur until full dilatation, especially with the pelvis of African women.

The descent of the head is measured in fifths (20% increments) palpable above the pelvic brim.

Abdominal examination should always be performed immediately before vaginal examination, and plotted on the partogram with the cervical dilation.

### Assessing fetal descent

#### By abdominal palpation

This method involves measuring by fifths of the head palpable above the symphysis pubis as described above.

- 5/5: head entirely above the inlet of the pelvis (head totally free)
- 0/5: head deep in the pelvis.

#### By vaginal examination

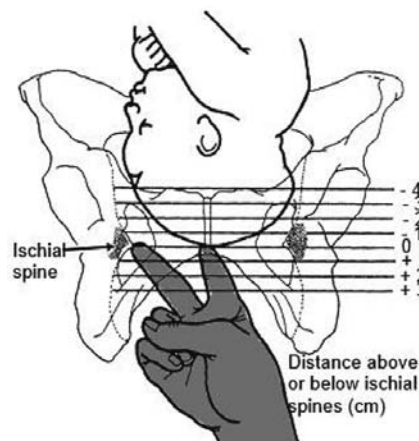

This method measures the descent of the head past the mother's ischial spines. When the presenting fetal head is at the level of the spines, this is designated '0'.

Figure 2.3.16a shows the occiput entering the brim of the pelvis on the left side, so the fetus is left occipito-lateral. Later drawings show the occiput moving round to the front so that in (d) it becomes anterior (OA). The mother was admitted soon after labour began. The baby's head is 3/5 palpable, it will soon engage in the pelvis and has started to flex. The membranes are intact, and the cervix is 2 cm long (uneffaced).

In Figure 2.3.16.b, the fetal head is now 2/5 palpable; it is more flexed and has just started to turn towards the front (anteriorly). The cervix is fully effaced but has not begun to dilate. The membranes are still intact.

In Figure 2.3.16.c, the fetal head is now 1/5 palpable; the neck is more flexed and has turned a little more. The cervix is now 7 cm dilated, so the progress line has been transferred to the alert line on the partogram. The membranes are still intact. Until now the mother has been allowed to move and walk about. She has chosen to lie down for delivery.

In Figure 2.3.16.d, the fetal head is 0/5 palpable, the occiput is anterior and the scalp is visible. The mother is almost fully dilated, so the first stage is almost over.

**FIGURE 2.3.17** Measuring the descent of the vertex using the ischial spines.

Figure 2.3.17 shows the use of the ischial spines to measure descent of the head. Feel the vertex with your index finger and feel for an ischial spine with your third finger. Is the vertex higher or lower than the ischial spines? You may only be feeling caput. Measuring fifths abdominally is more reliable but can be difficult, especially in obesity.

### Uterine contractions

For labour to progress satisfactorily there must be good contractions. They normally become more frequent and longer-lasting as labour progresses.

Uterine contractions are assessed by **palpation**, usually hourly in the latent phase, and every 30 minutes in the active phase. The frequency is measured by the number of contractions felt in a 10-minute period, and the duration is measured from the start of the contraction until it passes off (e.g. 3 in 10 minutes, each lasting for 45 seconds).

### Management of the first stage of labour

- 1 **Place an IV cannula early on in all high-risk patients.**
- 2 If a fever develops give intravenous antibiotics (ampicillin 2 grams IV/IM 6-hourly plus gentamicin 80 mg IV/IM 8-hourly or 5 mg/kg IV/IM once every 24 hours).
- 3 If the first stage is prolonged, consider the following:
  - malpositions or malpresentations
  - pelvis too small or head too big
  - contractions too weak
  - membranes need rupturing (only if there are no malpresentations or malpositions)
  - dehydration, ketosis and/or exhaustion.

### Pain control in labour

At present in low resource settings the only safe pharmacological treatment is nitrous oxide plus oxygen. Epidural anaesthesia is effective but requires careful monitoring (unlikely to be available), risks local infection, and can increase the need for Caesarean section. Opiate drugs, such as pethidine and morphine, have many potentially harmful effects on the woman and newborn infant.

Our recommendation is that, where possible, nitrous oxide plus oxygen should be made available for all women who need pain control, particularly the primigravida.

### Nitrous oxide plus oxygen

It is recommended that a maximum concentration of 50% nitrous oxide and 50% oxygen should be used.

The labour ward must be adequately ventilated and the mask fit well to avoid contamination of others in the vicinity.

The drug is always self-administered to ensure its safety (if drowsiness occurs, the woman will drop the mask).

It should not be used for more than 24 hours, and can interfere with vitamin B<sub>12</sub> metabolism if used continuously rather than intermittently (i.e. only during contractions).

The cylinder must not be mixed up with those containing 100% nitrogen. Nitrous oxide and oxygen mixture (Entonox) is supplied in a blue cylinder with white quadrants on the shoulder, whereas 100% nitrogen is supplied in a plain blue cylinder without white shoulders.

### Treatment

The woman should inhale the gas only during painful

contractions. After starting an inhalation, it takes 30 seconds to 1 minute for the nitrous oxide and oxygen mixture to act, and ideally the onset of the contraction should be anticipated, and inhaling started 30 seconds before it begins. Between contractions the mouthpiece or mask should be removed and the woman should breathe normally from room air.

Between patients the mouthpiece or mask must be cleaned and disinfected.

Side effects include drowsiness, dizziness, nausea and vomiting, and buzzing in the ears.

Nitrous oxide and oxygen is contraindicated in patients with impaired consciousness.

It does not modify uterine contractions or cause harm to the neonate.

### Prolonged pregnancy

This is defined as a pregnancy that continues for more than 14 days after the expected date of delivery. This is a particularly difficult management issue in low-resource settings, where the dates of the last menstrual period may not be recalled by the time of antenatal presentation, and where early ultrasound scanning during pregnancy is unlikely to have been performed.

Prolonged pregnancy is associated with fetal distress, shoulder dystocia, poor progress in labour, and increased fetal, maternal and neonatal mortality.

If there is reasonable evidence that a patient is at or above 40 weeks' gestation, stretching and sweeping of the membranes in a suitably equipped healthcare facility can be helpful in starting off labour, and may thus avoid the need for formal induction of labour (see below).

### Stretching the cervix and sweeping the membranes

First check the fetal position and ensure that the head is not high, and record the fetal heart rate. **If there has been any antepartum haemorrhage this procedure must not be undertaken because of the risk of placenta praevia.** The woman should empty her bladder.

A vaginal examination in the lateral tilt position using sterile gloves coated with an obstetric antiseptic cream (e.g. chlorhexidine) should be undertaken. **If there is any evidence of vaginal infection or spontaneous rupture of membranes, a membrane sweep must not be performed.**

The cervix should be assessed for effacement, whether it is soft or hard, and for dilatation. If there is no cervical dilatation or the head is not at a minimum of -3, then a sweep should not be undertaken.

If the cervix is closed but soft, it may be massaged until it allows the insertion of a finger. Once the cervical os is open (more likely post term), introduce a finger into the cervical os and pass it circumferentially around the cervix. This should separate the membranes and result in the release of local prostaglandins, increasing the likelihood of the onset of labour within 48 hours.

The whole procedure is uncomfortable but afterwards it should produce only slight pain or bleeding with irregular contractions. If pain or bleeding is marked, keep the woman under close observation in the healthcare facility.

The process can be repeated if labour does not start spontaneously after 36 hours.

## Induction or enhancement of labour

This may be required if there is prolonged pregnancy, pre-labour prolonged rupture of membranes, placental abruption, or a hypertensive disorder. Ensure induction is indicated, as failed induction is usually followed by Caesarean section.

### Artificial rupture of membranes (ARM)

This is undertaken to either induce or augment labour. Induction of labour usually also requires uterotonic drugs.

Slow progress in labour can often be corrected by ARM. However, in areas of high HIV prevalence, leaving the membranes intact for as long as possible may reduce the risk of perinatal transmission.

ARM risks infection and cord prolapse. It is contraindicated where placenta praevia is possible, in the first episode of active herpes infection, and in vasa praevia. It is more risky with a high fetal head or polyhydramnios.

### Procedure for ARM

ARM is best delayed until the cervix is 'favourable' as this will reduce the length of time the membranes are ruptured (and hence risk of chorioamnionitis), and limit the duration of any oxytocin infusion used. It is also likely to result in a reduced risk of failed inductions and thus unnecessary caesarian sections. A favourable cervix is one where softening, dilatation and effacement has started to occur, and corresponds to a Bishop score of 6 or more.

It is therefore advised to 'ripen' the cervix with one of the following before ARM: misoprostol, a Foley catheter or an oxytocin infusion (all discussed below), whichever is considered the most appropriate.

- Listen to – and note – the fetal heart rate.
- Ensure that the woman has emptied her bladder.
- Palpate the abdomen. If the presenting part is well descended, cord prolapse is less likely.
- Ideally perform an ultrasound scan to identify the position of the placenta.
- Wearing sterile gloves and with chlorhexidine obstetric cream on your fingers, examine the cervix, and note the consistency, position, effacement and dilatation. Confirm the fetal presentation.
- With the other hand (again with obstetric cream) insert an amniotic hook or a Kocher clamp into the vagina.
- Guide the clamp or hook along the fingers of your first hand towards the membranes in the vagina.
- Place two fingers against the membranes and gently rupture them with the instrument in the other hand. Allow the amniotic fluid to drain slowly around your fingers.
- Check that no cord can be felt.
- Note the colour (clear, yellow, greenish or bloody) and smell of the fluid. If thick meconium is present, suspect fetal distress. Some light bleeding may occur.
- After ARM, listen to the fetal heart during and after a contraction. If the fetal heart rate is abnormal (less than 110 beats/minute or more than 160 beats/minute), suspect fetal distress.
- If delivery has not occurred within 18 hours, give prophylactic antibiotics (IV ampicillin 1 gram 6-hourly plus gentamicin 80 mg IV/IM 8-hourly or 5 mg/kg body weight IV/IM once every 24 hours) in order to help to prevent infection in the baby and the mother. If there are no signs of infection in the mother after delivery, discontinue antibiotics.

- If the liquor is foul smelling or there is a maternal fever or other indication of uterine infection/chorioamnionitis treat with the antibiotics as above but with the addition of metronidazole 500mg IV 8 hourly.
- Regularly monitor vital signs.

### Oxytocin infusion

#### Indications

- If active labour is not established within 2–4 hours after ARM, and only if contractions are weak, begin oxytocin infusion. If there are strong contractions and no progress, look for a reason (e.g. obstructed labour).
- If labour is induced because of severe maternal disease (e.g. sepsis, eclampsia), begin oxytocin infusion at the same time as ARM.

#### Contraindications

- It is essential that obstructed labour is excluded before oxytocin is administered.
- Use oxytocin with great caution, as fetal distress can occur from hyperstimulation and, rarely, uterine rupture can occur. Multiparous women are at higher risk for uterine rupture (see below).
- Carefully observe all women receiving oxytocin. **They must never be left alone.**
- **Never use oxytocin in a woman or girl who has undergone two or more previous Caesarean sections, or who has a uterine scar for another reason, such as fibroid removal or traumatic uterine rupture.**
- If labour has been progressing and then stops in a multiparous woman there is likely to be a reason for this secondary arrest, such as cephalo-pelvic disproportion or malposition. The use of oxytocin (rather than Caesarean section) in this situation is dangerous, as uterine rupture may occur. However, in low-resource settings this concern has to be balanced against the risks associated with Caesarean section (assuming that this procedure is even available without transfer). We recommend that secondary arrest in a multiparous woman should result in urgent transfer to a facility where Caesarean section can be undertaken.
- Never use oxytocin where a previous classical Caesarean section has been performed. Provide a timed Caesarean section.

#### Concerns about oxytocin and the need for great care in its use

- If a woman has undergone one previous Caesarean section, the use of oxytocin is associated with a much increased risk of uterine rupture, and these patients must be delivered in a facility where immediate Caesarean section can be performed if required. Oxytocin may, in this latter setting, be used with great care and discontinued when adequate contractions are present.
- If more than four pregnancies after 24 weeks' gestation have been delivered, there is increased risk of uterine rupture. Oxytocin must be used with great care and discontinued when adequate contractions are present.
- Wait before starting oxytocin if misoprostol or another prostaglandin has been given within the previous 8 hours.

#### Administration of oxytocin

The individually needed effective dose of oxytocin varies greatly; so all patients must be monitored carefully.

Fluids can be calculated in drops per minute. Identify from the IV giving set what the 'drop factor' is (in standard giving sets it may be 10, 15 or 20 drops/1 mL). For micro-drop systems, (with burettes), 1 mL is 60 drops. Set the infusion rate with the flow controller below the chamber where the drops occur, and always count the rate over a full minute.

Cautiously administer oxytocin in IV fluids (Ringer-lactate or Hartmann's solution), gradually increasing the rate of infusion until active labour is established (three contractions in 10 minutes, each lasting more than 40 seconds). Maintain this rate until delivery. The uterus must relax between contractions.

A burette in-line IV giving set (see Figure 2.3.18) can help to prevent too much oxytocin being given.

**FIGURE 2.3.18** Burette for safer and more accurate administration of oxytocin.

When oxytocin infusion results in an active labour pattern, maintain the same rate until delivery.

Ensure that the woman is in the left lateral tilt or recovery position.

Record on a partogram every 30 minutes:

- rate of infusion of oxytocin (note that changes in the woman's arm position may alter the flow rate)
- duration and frequency of contractions
- fetal heart rate: listen every 30 minutes, always immediately after a contraction; if less than 100 beats/minute, stop the infusion.

Monitor pulse, blood pressure and contractions every 30 minutes. Keep a fluid balance chart. Regularly reassess for contraindications.

#### Details of oxytocin infusion

An ampoule of oxytocin usually contains 5 international units in 1 mL. Insert oxytocin 5 international units (5000 milliunits) in 500 mL of Ringer-lactate or Hartmann's solution. The concentration of this solution is 10 milliunits in 1 mL.

Start infusion at 2.5 milliunits/minute (i.e. at 5 drops/minute with a standard giving set with a drop factor of 20 drops/1 mL).

Increase infusion rate by 2.5 milliunits/minute (5 drops/minute using a standard giving set with a drop factor of 20 drops/1 mL) every 30 minutes until a good contraction pattern is established – that is, contractions lasting more than 40 seconds, and occurring 3 times in 10 minutes.

Maintain this rate until delivery is completed.

**If there are not three contractions in 10 minutes, each lasting more than 40 seconds, with the infusion rate at 20 milliunits/minute (40 drops/minute if using a giving set with a drop factor of 20 drops/1 mL):**

- In multigravida, further increases may risk uterine

rupture. The reason for this may be cephalo-pelvic disproportion or malposition. Therefore **consider Caesarean section**.

- In the **primigravida**, infuse oxytocin at a higher concentration (rapid escalation).
  - Change to a more concentrated solution with oxytocin 10 international units (10 000 milliunits) in 500 mL of Ringer-lactate or Hartmann's at a concentration of 20 milliunits/mL.
  - Give an initial infusion of 20 milliunits/minute (20 drops/minute if using a giving set with a drop factor of 20 drops/1 mL).
  - Increase the infusion rate by 5 milliunits/minute (additional 5 drops/minute if using a giving set with a drop factor of 20 drops/1 mL) every 30 minutes until good contractions are established.
  - **If good contractions are not established at 40 milliunits/minute** (40 drops/minute if using a giving set with a drop factor of 20 drops/1 mL), deliver by Caesarean section.

#### Do not use oxytocin 10 international units in 500 mL (i.e. 20 milliunits/mL) in multigravida.

If hyperstimulation occurs (i.e. any contractions lasting longer than 60 seconds or more than 4 contractions in 10 minutes), stop the infusion. The half-life of oxytocin is short (between 1 and 5 minutes), and therefore any hyperstimulation should stop with appropriate titration of the dose given. If hyperstimulation resolves, restart oxytocin infusion at half of the last dose given.

Consider terbutaline, 250 micrograms subcutaneously if the uterus does not relax.

#### Possible side effects of oxytocin infusion

These include the following:

- uterine hyperstimulation (see above).
- hyponatraemia due to water retention from vasopressin-like actions (unlikely if diluted with Ringer-lactate or Hartmann's and more likely with prolonged infusions). Monitor urine output carefully and, if possible, measure plasma sodium concentrations.
- hypotension, flushing and tachycardia if oxytocin is given as a bolus IV by mistake.

#### The use of oral misoprostol to induce labour

Because of its stability at high room temperatures and low cost, misoprostol is increasingly being used to induce labour, especially in low-resource settings. Close monitoring of uterine contractions is still essential, and misoprostol must not be used if there has been a previous Caesarean section.

Misoprostol is available as a vaginal or oral tablet or an oral solution. The latest Cochrane reviews suggest that oral misoprostol solution is the most appropriate.

#### Dose of oral misoprostol solution

A single misoprostol tablet is dissolved in drinking water (200-microgram tablet in 200 mL of water or 100-microgram tablet in 100 mL of water), and 20–25 mL of misoprostol solution (20–25 micrograms) are then given orally every 2 hours. It may be used in women with ruptured membranes, where the oral route has the additional benefit of avoiding vaginal installations with their increased risk of infection. Solutions are stable for up to 24 hours, but should then be discarded. For safety reasons it may be better to discard

unused solutions and make up a 20- to 25-microgram dose every 2 hours. Review progress by a doctor after 100 micrograms have been given although the induction can be continued with further doses if necessary.

When induction of labour is urgent and delivery indicated within a short period of time (e.g. eclampsia) consider increasing the misoprostol dose to 50 micrograms orally every 2 hours. This may increase the speed of the induction but may also increase the risk of hyperstimulation. The recent Cochrane review recommends an oral dose of 20-25 micrograms and not more than 50 micrograms every 2 hours.

**Oral misoprostol tablets**

It is possible to cut 100-microgram misoprostol tablets into quarters that are 25 micrograms in size and administer them orally every 2 hours up to a maximum of six doses. However, this is not accurate, and there is a danger of giving an incorrect dosage. The oral misoprostol solution described above is safer.

**The use of a Foley catheter to induce labour**

An effective alternative to misoprostol is to use a Foley catheter to mechanically ‘ripen’ the cervix and induce labour. The Foley catheter tip is passed through the cervical os either during a sterile digital examination, or with the use of a sterile/high-level disinfected speculum and forceps. The inflatable bulb is introduced beyond the internal cervical os and then inflated with 10ml of sterile water. The catheter tip is then left in situ for up to 24 hours to allow cervical ripening and contractions to begin. It may fall out in the interim if the cervix dilates adequately. Once removed amniotomy and oxytocin can be commenced if needed.

This method is particularly useful in women at high risk of rupture as it does not risk hyperstimulation.

**Delay in the first stage of labour**

If progress is initially good, but then slows down or stops, there may be:

- malpositions or malpresentations
- obstructed labour
- an increased risk of shoulder dystocia.

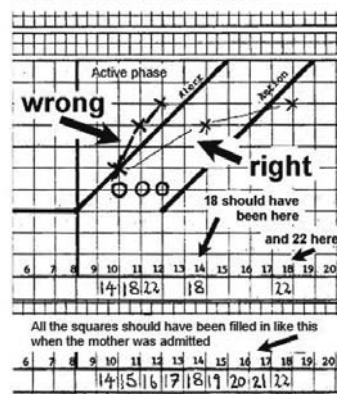

**Prolonged active phase (first stage) of labour**

If cervical dilatation crosses the alert line, this warns that labour is slow and there may be problems. If possible, transfer the patient to an obstetric unit practicing comprehensive EmOC. If the action line (4 hours to the right according

**FIGURE 2.3.19** The partogram showing the portion relating to cervical dilatation. The numbers 1 to 24 represent the number of hours since the mother was admitted, but only if she was admitted in the latent phase.

**A common mistake**

**FIGURE 2.3.20** Correct placement of data on the partogram. A common mistake is to put the next record (‘x’ and ‘o’) in the next square, and not to allow for the time that elapses between one observation and the next.

**FIGURE 2.3.21** Lines on the partogram.

to the WHO, or 2 hours to the right according to recent evidence from South Africa) is reached, the mother must be reassessed to ascertain the reason for lack of progress and further management determined.

**Other complications of the first stage of labour**

Urgent help may be required to diagnose and manage cord prolapse (see Section 2.6.G), placental separation (see Section 2.5.D.iii) or ruptured uterus (see Section 2.5.F).

**Second stage of labour**

This begins when the cervix is fully dilated. Fetal descent occurs, but initially there may be no urge to push usually occurring only when the fetal head reaches the pelvic floor. It may be helpful for the mother to stand up or squat during this time to assist pushing. She must not lie flat on her back. (Note; some patients have an urge to push early in labour with a high head, generally with an occipito-posterior presentation)

Delivery of the baby may be allowed to take 2 hours from full cervical dilatation in the primigravida, and 1 hour in the multigravida, before there is cause for concern. The mother must not push if the cervix is not fully dilated.

During delivery, trauma to the perineum should be minimised. Routine episiotomy is not indicated, but should be performed if significant perineal trauma is anticipated, or to aid more rapid delivery if indicated. Anterior episiotomy/reversal of genital mutilation may be required in some women.

Episiotomy is recommended for the following:

- complicated vaginal delivery (breech, shoulder dystocia, forceps and some vacuum extractions)
- scarring from female genital mutilation (see above) or poorly healed third- or fourth-degree tears
- fetal distress.

Sometimes contractions become less strong when the cervix becomes fully dilated. After confirming the well-being of the mother and fetus, mobilise the mother, hydrate her orally, including sufficient calories to help to prevent ketosis, and then wait for up to 1 hour for the head to descend. If the mother is unable to tolerate oral fluids, administer IV glucose and fluids. However, be alert for the possibility of cephalo-pelvic disproportion. After 1 hour encourage pushing, provided that the cervix is fully dilated.

Ensure that delivery of the head is controlled so that there is not a sudden release of pressure on it as it delivers (this may damage the neonatal brain).

If there is fetal distress, or delivery has not occurred after 2 hours in a primigravida or 1 hour in a multigravida, assisted vaginal delivery should be considered. A ventouse or forceps may be considered so long as none of the head is palpable per abdomen. **The cervix must be fully dilated.**

### Delivery of the baby

- Ask the mother to pant or give only small pushes with contractions.
- Control the birth of the head by placing the fingers of one hand against the baby's head to ensure that it does not deliver too quickly.
- Support the perineum with your other hand as it distends and the head is delivered.
- In low-resource countries, if meconium is present, suck it out of the baby's nose and mouth on the perineum as soon as the head is delivered.
- Call the paediatrician (if available) if you consider that the baby might need resuscitation.
- Once the head is delivered, ask the mother not to push.
- Feel around the baby's neck for the umbilical cord:
  - If it is round the neck but loose, slip it over the baby's head.
  - If it is so tight round the neck that it is preventing delivery of the baby's shoulders, double clamp it and cut it before unwinding it from the neck. Delivery can often be achieved with the cord left in place.
- Allow the baby's head to turn spontaneously.
- After the head has turned, place a hand on each side of the head and ask the mother to push gently without the need to wait for contractions.
- Avoid tears by delivering one shoulder at a time. Routine traction of the baby's head in an axial direction should be used and should result in delivery of the anterior shoulder.
- Lift the baby's head anteriorly to deliver the shoulder that is posterior.
- Support the baby's body as it slides out.
- After delivery of the baby, give the mother 10 units of oxytocin IM to reduce the risk of haemorrhage, **but only do this if the possibility of a second twin has been excluded by earlier ultrasound examination or by abdominal palpation.** Alternatively, 10 units of oxytocin plus 500 micrograms of ergometrine

(called Syntometrine) IM can be given, but never **give ergometrine if the mother has hypertension or pre-eclampsia**, as it can increase blood pressure and cause a cerebrovascular accident.

- Dry the baby, cover with a dry clean towel and assess the baby (see Section 3.1).
- If the baby does not need resuscitation, place on the mother's abdomen for 1 to 3 minutes to provide a transfusion of placental blood to the baby, but keep warm (for details, see Section 3.1).
- Then cut the umbilical cord and place the baby in skin-to-skin contact with the mother, ensuring that the body and head are covered to keep the baby warm. The baby may seek to suck on the breast which should be encouraged.
- If the baby needs resuscitation, cut and clamp the cord immediately, and proceed to open the airway and breathe for the baby (see Section 3.2).
- If the mother is not well, ask an assistant or relative to care for the baby.

**Always prepare for the need to resuscitate the baby, especially if there is a history of eclampsia, prolonged or obstructed labour, bleeding, preterm birth or infection. Always have a bag-valve-mask of the right size available next to the mother, and ideally on a Resuscitaire®, in case assisted ventilation is required.**

If the head retracts on to the perineum during delivery (the turtle sign), this suggests shoulder dystocia (see Section 2.5.F).

### Active management of the third stage of labour

This is advised for preventing postpartum haemorrhage (PPH), and it consists of four possible interventions:

- 1 a prophylactic uterotonic drug after delivery of the shoulders of the baby and after ensuring that another fetus is not present in the uterus
- 2 early cord clamping and cutting
- 3 controlled cord traction
- 4 uterine massage after delivery of the placenta.

Of these, a uterotonic drug (see above), is the most important, with oxytocin the first choice because it causes uterine contraction to prevent atony rapidly with minimal adverse effects. Atony is the most common cause of PPH (around 80% of cases). If oxytocin is unavailable, or does not work, other uterotonic drugs should be used, including ergometrine or misoprostol.

All uterotonic drugs should be given within 1 minute of the complete birth of the fetus, to aid separation of the placenta by enhancing uterine contractions and reducing the risk of bleeding from an atonic (relaxed) uterus. **It is essential that you are certain there is not another fetus in the uterus before such drugs are given.**

Ensure that both oxytocin and ergometrine are protected from heat damage by close attention to the cold chain and their storage, otherwise they may not be effective. Ideally oxytocin should be stored in a fridge, but it can be kept at 15–30°C for 3 months. Oxytocin must never be frozen. Always store ergometrine in a fridge at 2–8°C. Misoprostol is not affected by ambient temperature.

**Ergometrine is contraindicated in patients with heart**

**disease, hypertension, pre-eclampsia or eclampsia, as it raises the blood pressure by vasoconstriction, with the risk of cerebrovascular accidents.**

Early cord clamping and cutting (the second intervention listed above) as part of the active management of the third stage of labour is no longer recommended unless the infant needs resuscitation (see above).

Controlled cord traction (the third intervention listed above) is optional where delivery is undertaken by a skilled birth attendant, but contraindicated if a skilled attendant is not available. It must not be undertaken if a uterotonic drug has not been given.

- 1 After the cord has been clamped, use cord clamp/straight clamp to hold the cord close to the perineum.
- 2 Place the other hand just above the pubis, and counter the uterus during traction of the cord to prevent it from inverting (see Figure 2.3.22).
- 3 Keep slight tension on the cord and wait for a uterine contraction.
- 4 When the uterus becomes rounded or the cord lengthens, assume that the placenta has separated, and pull gently down on the cord to deliver the placenta. Do not wait for or expect a gush of blood before applying traction. Continue to apply counter traction on the uterus with your other hand.
- 5 If the placenta does not descend and deliver within 1 minute of cord traction the placenta is not separating. Therefore stop traction, wait for the next contraction and repeat the process.
- 6 As the placenta delivers, the membranes can tear off. To avoid this, hold the placenta in two hands and gently turn it until the membranes are twisted.
- 7 Gently pull to complete the delivery.
- 8 If the membranes do tear, wearing sterile gloves gently examine the upper vagina and cervix and use a sterile sponge forceps to remove any fragments of membrane that are present.
- 9 If the cord is pulled off the placenta, uterine contractions may still push it out, but if this does not happen a manual removal may be needed (see Section 2.13).
- 10 If the uterus is inverted, push it back immediately (see Section 2.6.H).

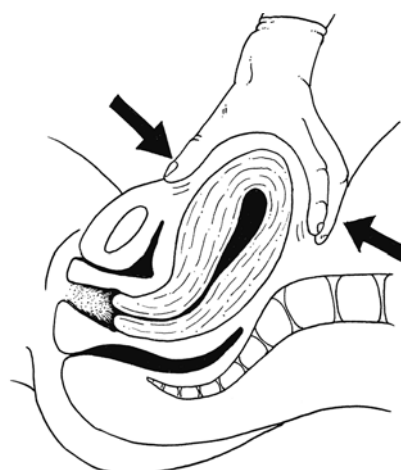

**FIGURE 2.3.22** Controlled cord traction for active management of the third stage. Reproduced with the permission of Medical Aid Films, [www.medicalaidfilms.org](http://www.medicalaidfilms.org)

In Figure 2.3.22 the operator's right hand is holding back the uterus while traction is applied to the cord.

Strong uterine massage (the fourth intervention listed above) should always be undertaken immediately after delivery of the placenta, until the uterus is contracted and remains so. Check the state of contraction of the uterus every 15 minutes for 2 hours, and repeat the massage if at any time the uterus becomes soft and relaxed.

**All postpartum women and girls must be closely**

**FIGURE 2.3.23** Strong massage applied to cause uterus to contract.

**monitored to ensure that PPH does not occur. They should be examined every 15 minutes for the first hour after delivery, and then every 4 hours until 24 hours after delivery.**

In order to prevent PPH during or after Caesarean section, oxytocin plus cord contraction is recommended in preference to manual removal of the placenta.

### **Expectant management of the third stage of labour if uterotonic drugs are not available**

Unfortunately, it is not uncommon for hospitals to run out of uterotonic drugs. In this avoidable and dangerous situation, expectant/physiological management should be undertaken.

- 1 Place the baby on the mother's breast.
- 2 Leave the cord alone.
- 3 Observe for the following signs of placental separation:
  - the uterus becomes more rounded and contracted
  - there is lengthening of the cord at the introitus
  - the mother feels uncomfortable, feels a contraction and wants to 'bear down'.
- 4 Deliver the placenta.
  - Sit the mother upright
  - Encourage her to bear down with a contraction (only after separation of the placenta).
  - Catch the placenta. If membranes are dragging behind, gently twist a few turns and with slight traction and an up-and-down movement deliver the placenta plus the membranes.

Most placentas separate within 1 hour after birth. If this does not happen, seek help.

Controlled cord traction should not be undertaken prior to the separation of the placenta in the absence of uterotonic drugs.

### **Monitoring after the placenta has been delivered by active or expectant management**

Monitor the patient's vital signs, blood pressure, pulse rate and volume, and the state of the uterus (is it contracted?) every 15 minutes for 2 hours after delivery of the placenta.

Examine the placenta for completeness.

**FIGURE 2.3.24** Examining the placenta in a sink. In this case the fetal and maternal surfaces show a piece missing, which has probably been left in the uterus.

### Checking the placenta

Check that the placenta and membranes are intact. If they are not, there are retained products of conception which may pass spontaneously or that may need to be removed manually through the vagina.

### Checking for tears

Examine the patient for tears in the cervix or vagina, and repair these as well as any episiotomy (see Section 2.13).

### Skin-to-skin contact between mother and baby

If neither the mother nor the baby need resuscitation, ensure that the newborn baby is placed in skin-to-skin contact with the mother for at least 1 hour after birth, and encourage and support the baby to attach to and suck on the breast.

This approach recommended by the Baby Friendly Hospital Initiative (step 4) improves temperature control and respiratory function, increases milk production and helps to ensure weight gain for the baby.

### Vitamin A for all recently delivered mothers

High-dose vitamin A should be avoided during pregnancy because of the risk of birth defects. A single dose of 200 000 units should be given to all postpartum mothers within 6 weeks of delivery, when the likelihood of pregnancy is very low, and when infants benefit most from its presence in breast milk.

### Discharge of mothers and their babies from hospital after uncomplicated deliveries

In high resource settings there is evidence of lower economic costs associated with early discharge (e.g. at 6 hours after delivery compared with 48 hours). However, there is no conclusive evidence for or against the policy of early postnatal discharge in resource-limited healthcare facilities. Care should be taken when extrapolating the results of studies from countries with good socio-economic conditions to communities where resources are scarce. Consideration should also be given to different settings even within the same country (e.g. urban versus rural settings), and the cultural contexts in which the trials are conducted.

### Postnatal care for mothers and their babies in resource-limited settings

In resource-limited African settings, 50% of postnatal maternal deaths occur in the first week after birth, with the majority occurring in the first 24 hours. The two most important causes of postnatal maternal death are PPH and puerperal sepsis. Mothers who are HIV positive are most at risk.

One in four deaths in childhood occurs during the neonatal period. Birth asphyxia is the most common cause, and occurs on day 1. Preterm babies most commonly die during the first week of life, and neonatal sepsis is most common after 7 days, especially in low-birth-weight/preterm babies. The origins and markers of many long-term childhood development problems occur or are seen in the first 6 weeks of life.

Despite a lack of research, mothers and their babies should remain in hospital for at least 24 hours after birth in low resource settings in order to ensure that breastfeeding is established and that any complications in the mother and baby are identified and treated. Those with high risk factors should remain in hospital for longer, and before going home all mothers should be trained to recognise danger signs in themselves and their babies.

The WHO has produced a landmark paper on postnatal care in Africa, and Tables 2.3.1 and 2.3.2 summarise their advice.

### When and how many postnatal visits should occur?

The optimum number and timing of postnatal care (PNC) visits, especially in resource-limited settings, is a subject of debate. Although no large-scale systematic reviews have been conducted to determine this protocol, three or four postnatal visits have been suggested. Early visits are crucial because the majority of maternal and newborn deaths occur during the first week, most frequently on the first day, and this period is also the key time for promoting healthy behaviours. Each country should make decisions based on the local context and existing care provision, including who can deliver the PNC package and where it can be delivered.

The following information is offered as a guide.

#### First contact

If the mother is in a healthcare facility, she and her baby should be assessed within 1 hour of birth and again before discharge. Encouraging women to stay in the facility for 24 hours, especially after a complicated birth, should be considered. If birth occurs at home, the first visit should target the crucial first 24 hours after birth.

#### Follow-up contacts

These are recommended at least at 2–3 days, 6–7 days and 6 weeks after birth.

#### Extra contacts

Babies who need extra care (LBW babies or those whose mothers are HIV-positive) should have two or three visits in addition to the routine visits.

### Where should postnatal care be provided and by whom?

The supervision and integration of postnatal care packages is essential.

**TABLE 2.3.1 Routine postnatal care (PNC): What, when, where and who?**

<b>What should be routine postnatal care?</b>
Preventive care practices and routine assessments to identify and manage or refer complications for both mother and baby, including the following:
<b>Essential routine PNC for all mothers</b>
<ol style="list-style-type: none"> <li>1 Assess and check for bleeding; check temperature.</li> <li>2 Support breastfeeding, checking the breasts and advising how to prevent mastitis.</li> <li>3 Manage anaemia, promote nutrition and insecticide-treated bed nets, and give vitamin A supplementation.</li> <li>4 Complete tetanus toxoid immunisation, if required.</li> <li>5 Provide counselling and a range of options for family planning.</li> <li>6 Refer for complications such as bleeding, infections or postnatal depression.</li> <li>7 Counsel on danger signs and home care.</li> </ol>
<b>Essential routine PNC for all newborns</b>
<ol style="list-style-type: none"> <li>1 Assess for danger signs, measure and record weight, and check temperature and feeding.</li> <li>2 Support optimal feeding practices, particularly exclusive breastfeeding.</li> <li>3 Promote hygiene and good skin, eye and cord care.</li> <li>4 If prophylactic eye care is local policy and has not been given, it is still effective up to 12 hours after birth.</li> <li>5 Promote clean dry cord care.</li> <li>6 Identify superficial skin infections, such as pus draining from the umbilicus, redness extending from the umbilicus to the skin, more than 10 skin pustules, and swelling, redness and hardness of the skin, and treat or refer if the baby also has danger signs.</li> <li>7 Ensure warmth by delaying the baby's first bath until after the first 24 hours, practising skin-to-skin care, and putting a hat on the baby.</li> <li>8 Encourage and facilitate birth registration.</li> <li>9 Refer the baby for routine immunisations.</li> <li>10 Counsel on danger signs and home care.</li> </ol>
<b>Extra care for low-birth-weight (LBW) or small babies and other vulnerable babies, such as those born to HIV-infected mothers (two or three extra visits)</b>
The majority of newborn deaths occur in LBW babies, many of whom are preterm. Intensive care is not needed to save the majority of these babies. Around one-third could be saved with simple care, including the following:
<ol style="list-style-type: none"> <li>1 Identify the small baby.</li> <li>2 Assess for danger signs and manage or refer as appropriate.</li> <li>3 Provide extra support for breastfeeding, including expressing milk and cup feeding, if needed.</li> <li>4 Pay extra attention to warmth promotion, such as skin-to-skin care or kangaroo mother care.</li> <li>5 Ensure early identification and rapid referral of babies who are unable to breastfeed or accept expressed breast milk.</li> <li>6 Provide extra care for babies whose mothers are HIV-positive, particularly for feeding support (see Section 2.8.C).</li> </ol>

**TABLE 2.3.2 Early identification and referral or management of emergencies for mother and baby**

Appropriate detection and management or referral is necessary to save the mother and the baby in the event of life-threatening complications.
<b>Danger signs for the mother</b>
<ol style="list-style-type: none"> <li>1 Excessive bleeding.</li> <li>2 Foul-smelling vaginal discharge.</li> <li>3 Fever with or without chills.</li> <li>4 Severe abdominal pain.</li> <li>5 Excessive tiredness or breathlessness.</li> <li>6 Swollen hands, face and legs with severe headaches or blurred vision.</li> <li>7 Painful engorged breasts or sore cracked bleeding nipples.</li> </ol>
<b>Danger signs for the baby</b>
<ol style="list-style-type: none"> <li>1 Convulsions.</li> <li>2 Movement only when stimulated, or no movement even when stimulated.</li> <li>3 Not feeding well.</li> <li>4 Fast breathing (more than 60 breaths/minute), grunting or severe chest in-drawing.</li> <li>5 Fever (above 38°C).</li> <li>6 Low body temperature (below 35.5°C).</li> <li>7 Very small baby (less than 1500 grams or born more than 2 months early).</li> <li>8 Bleeding.</li> </ol>

**At the hospital**

This is more likely if the mother gives birth in hospital, but even then women and babies do not necessarily receive an effective PNC contact before discharge from the health-care facility, and even if the mother comes to hospital for the birth, she may not return during the first few days after discharge. Where a waiting home is available, the mother and baby could remain there until it is considered safe for them to go home.

**Through outreach services:**

- 1 A skilled provider can visit the home to offer PNC to the mother and baby.
- 2 Home visits from a specially trained community health worker (CHW) linking to the hospital or other healthcare facilities for referral as required.
- 3 A combination of care in the healthcare facility and at home. PNC may be provided in the hospital following childbirth, and at home during the crucial first 2–3 days, with subsequent visits to a healthcare facility or clinic at 6–7 days and 6 weeks after the birth, when the mother is better able to leave her home.

## 2.4

## Pathways of care summarising the diagnosis of complications of pregnancy or delivery

(Please note that in all conditions included the presenting symptoms and clinical signs may be atypical and therefore diagnosis more difficult.)

### 2.4.A Abdominal pain in early pregnancy

**TABLE 2.4.A.1** Abdominal pain due to obstetric or gynaecological causes

Presenting symptoms	Clinical signs on presentation	Investigations	Diagnosis	Treatment
Lower abdominal pain, intermittent and very sharp Vomiting	Mass in lower abdomen or on vaginal examination <b>Warning: when performing a vaginal examination in a patient with abdominal pain who may be pregnant, consider ectopic pregnancy</b>	Pregnancy test is helpful in early pregnancy	Ovarian cyst which may become twisted (consider torsion if there is severe pain and vomiting)	Consider surgery if this is safe and available
Lower abdominal pain Signs of early pregnancy: tiredness, nausea and/or vomiting (especially in the early morning), breast swelling, increased urinary frequency Light vaginal bleeding (takes > 5 minutes for clean pad to be soaked) Shoulder pain Fainting if ruptured Amenorrhoea with perhaps only one missed period Rectal pain	Shock if ruptured (pale, sweating, fast heart rate > 100 beats/minute), weak pulse volume, low blood pressure (systolic < 90 mmHg), drowsy, irritable, unconscious) <b>Caution must be exercised when performing a vaginal examination if an ectopic pregnancy is possible, because of the risk of rupture during and due to the examination</b> Vaginal examination may show signs of early pregnancy (soft uterus), closed cervix, light bleeding, tender mass in one fornix, tenderness with cervical movement	Pregnancy test positive Ultrasound	Ectopic pregnancy which may be ruptured	Prepare operating theatre for <b>immediate</b> salpingectomy Treat shock Group and cross-match 4–6 units of blood
Pelvic pain Pain on intercourse Vaginal discharge	Fever Tender lower abdomen Tender on vaginal examination but do not undertake this if ectopic pregnancy is a possibility	Raised white blood cell count Ultrasound High vaginal swab for microscopy, culture and sensitivity	Pelvic inflammatory disease	Antibiotics IV if severe: metronidazole plus: <i>either</i> a macrolide such as erythromycin or azithromycin <i>or</i> doxycycline or ofloxacin
Lower abdominal pain History of termination of pregnancy attempted (may not be given even if this has occurred) Vaginal bleeding	Fever Vaginal bleeding (moderate to heavy) Purulent vaginal discharge If very severe, peritonitis (see above)	White blood cell count Haemoglobin Blood culture	Septic abortion	Treat shock IV antibiotics May need an intervention such as manual vacuum aspiration to remove infected products of conception, or even hysterectomy (after stabilisation)

TABLE 2.4.A.2 Abdominal pain due to coincidental causes

Presenting symptoms	Clinical signs on presentation	Investigations	Diagnosis	Treatment
Lower abdominal pain Nausea and/or vomiting Anorexia Constipation may occur	Low-grade fever (> 37.5°C) Tenderness of the right iliac fossa, sometimes with rebound Tender in the right iliac fossa on rectal examination (care is needed if ectopic pregnancy is a possibility)	Pregnancy test Raised white blood cell count Ultrasound if skilled	Acute appendicitis	Appendicectomy
Severe abdominal pain Vomiting	High fever Abdominal distension Rigid abdomen Absent bowel sounds Shock (see above for signs)		Peritonitis	Treat shock IV antibiotics Nasogastric tube <b>Immediate laparotomy in operating theatre</b>
Pain on passing urine Increased frequency of passing urine Nocturia	Fever (unusual)	Microscope urine Stick tests for infection (if available) Urine culture and sensitivity (if available)	Cystitis	Antibiotics by mouth
Pain in the lower abdomen or loin Nausea and/or vomiting Increased frequency of passing urine with or without dysuria Rigors	High fever Tenderness of one of the loins over the kidney Normal bowel sounds	Microscope urine Stick tests for infection (if available) Urine culture and sensitivity (if available)	Pyelonephritis	IV antibiotics (IV gentamicin if patient has rigors or is shocked) In the case of shock, initiate immediate treatment

## 2.4.B Abdominal pain in late pregnancy

TABLE 2.4.B.1 Abdominal pain due to obstetric causes

Symptoms	Signs	Diagnosis	Investigations	Treatment
Intermittent lower abdominal pain Vaginal fluid loss before 37 weeks' gestation suggesting premature rupture of membranes Light vaginal bleeding*	Palpable uterine contractions Cervical dilatation Check for prolapsed cord if there is rupture of membranes	<b>Possible preterm labour</b>	Partogram	Give two 12 mg doses of betamethasone or dexamethasone IM 12 hours apart Tocolysis only to give time for the steroids to work. Nifedipine 20 mg orally, followed by 20 mg orally after 30 minutes. If contractions persist, therapy can be continued with 20 mg orally every 3–8 hours for 48–72 hours, with a maximum dose of 160 mg/24 hours
Intermittent lower abdominal pain Vaginal fluid loss after 37 weeks' gestation suggesting rupture of membranes Light vaginal bleeding	Palpable uterine contractions Cervical dilatation and effacement Check for prolapsed cord if there is rupture of membranes	<b>Term labour</b>	Partogram	See Section 2.3

(continued)

Symptoms	Signs	Diagnosis	Investigations	Treatment
Lower abdominal pain, intermittent and very sharp	Mass in lower abdomen or on vaginal examination. Difficult to feel in pregnancy per abdomen or per vagina as the uterus is enlarged	<b>Ovarian cyst</b> which may become twisted (this is very rare in late pregnancy)	Ultrasound	May need laparotomy
Severe constant abdominal pain Light or heavy vaginal bleeding* Fetal movements stop	Shock Tense and very tender uterus on abdominal examination Fetal distress or absent fetal heart	<b>Placental abruption</b>	Ultrasound	<b>Call for surgical and anaesthetic help</b> Left lateral tilt or recovery position IV fluid boluses for shock Cross-match 4 units of blood and freeze-dried plasma if available Deliver fetus as soon as possible if alive
There is a change (usually during labour) from intermittent labour contractions to a constant pain which may become less after rupture has occurred Sometimes there is an oxytocin drip in place Vaginal bleeding which may be light or heavy History of a previous Caesarean section or other operation on the uterus	Shock Abdominal distension Tender over the uterus, with more easily palpated fetal parts Absent fetal movements and heart sounds	<b>Ruptured uterus</b>	Ultrasound may help diagnosis, <b>but must not delay laparotomy</b>	<b>Call for surgical and anaesthetic help</b> Treat shock if present Cross-match 4 units of blood and freeze-dried plasma if available Prepare theatre for laparotomy after patient is stable
Foul-smelling watery vaginal discharge Lower abdominal pain Premature labour or premature rupture of membranes Light vaginal bleeding	Fever Tender over the lower abdomen and uterus Possible fetal distress	<b>Chorio-annionitis</b>	White blood cell count Blood culture Discharge for microscopy, culture and sensitivity	IV antibiotics before urgent delivery, whatever the gestational age: Ampicillin 2 g IV every 6 hours <i>plus</i> gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours <i>plus</i> metronidazole 500 mg IV every 8 hours
Purulent, foul-smelling lochia Lower abdominal pain Light vaginal bleeding	Fever Tender uterus Shock	<b>Endometritis after birth (puerperal sepsis)</b>	Raised white blood cell count Blood culture Lochia for microscopy, culture and sensitivity	Treat shock IV antibiotics: Ampicillin 2 g IV every 6 hours <i>plus</i> gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours <i>plus</i> metronidazole 500 mg IV every 8 hours

(continued)

Symptoms	Signs	Diagnosis	Investigations	Treatment
Lower abdominal pain Rare in late pregnancy, but may present postnatally	Swinging fever Swelling in adnexa or pouch of Douglas Tender uterus Ultrasound	<b>Pelvic abscess</b>	Raised white blood cell count Blood culture Pus for microscopy, culture and sensitivity	IV antibiotics: Ampicillin 2 g IV every 6 hours <i>plus</i> gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours <i>plus</i> metronidazole 500 mg IV every 8 hours Surgical drainage
Upper abdominal pain	Headache Visual disturbance Oedema	<b>Severe pre-eclampsia with impending eclampsia</b>	Raised blood pressure Protein in urine > ++	Magnesium sulphate Urgent delivery of fetus

\* Light bleeding is defined as taking longer than 5 minutes for a clean pad or cloth to become soaked. Heavy bleeding is defined as taking less than 5 minutes for a clean pad or cloth to become soaked.

**TABLE 2.4.B.2 Abdominal pain due to coincidental causes**

Symptoms	Signs	Diagnosis	Investigations	Treatment
Lower abdominal pain Nausea and/or vomiting Anorexia	Low-grade fever (> 37.5°C) Tenderness of the right iliac fossa, sometimes with rebound Tender in the right iliac fossa on rectal examination	<b>Appendicitis</b>	White blood cell count elevated Ultrasound if skilled	Appendicectomy
Severe abdominal pain Vomiting	High fever Abdominal distension Rigid abdomen Absent bowel sounds Shock (see above for signs)	<b>Peritonitis</b>		Treat shock Consider immediate laparotomy: call surgeon and anaesthetist and prepare operating theatre IV antibiotics: Ampicillin 2 g IV every 6 hours <i>plus</i> gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours <i>plus</i> metronidazole 500 mg IV every 8 hours Nasogastric tube on open drainage Immediate laparotomy in operating theatre
Pain on passing urine Increased frequency of passing urine Nocturia	Rarely fever	<b>Cystitis</b>	Microscope urine Stick tests for infection (if available) Urine culture and sensitivity if available	Oral antibiotics
Pain in the lower abdomen or loin Nausea and/or vomiting Increased frequency of passing urine	High fever Tenderness in one of the loins over the kidney Normal bowel sounds	<b>Pyelonephritis</b>	Microscope urine Stick tests for infection (if available) Urine culture and sensitivity if possible	Ampicillin 2 g IV every 6 hours <i>plus</i> gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours <i>plus</i> metronidazole 500 mg IV every 8 hours

## 2.4.C Vaginal bleeding in early pregnancy

In all cases a pregnancy test must be performed.

**TABLE 2.4.C.1 Vaginal bleeding in early pregnancy**

Symptoms	Signs	Diagnosis	Treatment
Light bleeding Cramping lower abdominal pain	Closed cervix	<b>Threatened miscarriage</b>	Wait and see
Light bleeding Abdominal pain, shoulder tip pain and/or rectal pain Feeling faint on standing up, or fainting	Shock Vaginal examination should be undertaken carefully ( <i>see</i> Section 2.5.D.i)	Ectopic pregnancy	<i>See</i> Section 2.5.D.i
Heavy bleeding No history of products of conception passed Cramping lower abdominal pain	Dilated cervix Tender uterus that corresponds to dates Shock if bleeding is severe Severe anaemia if bleeding is prolonged	<b>Inevitable miscarriage</b>	Cross-match blood and freeze-dried plasma if available Treat shock if present Evacuate products of conception (ideally by manual vacuum aspiration) Give iron if the patient has anaemia
Light bleeding Mild cramping lower abdominal pain History of products of conception passed	Closed cervix Soft uterus that is smaller than expected for dates	<b>Complete miscarriage</b>	Check haemoglobin levels Give iron if the patient has anaemia
Heavy bleeding Nausea and/or vomiting Cramping lower abdominal pain Passage of some products of conception which look like grapes	Dilated cervix Soft uterus, larger than expected for dates	Molar pregnancy	Evacuate products of conception (ideally by manual vacuum aspiration). If symptoms persist and there is continued vaginal bleeding, repeat urine pregnancy test Measure HCG levels if possible Screen for pre-eclampsia (measure blood pressure, and urine for protein) Follow up for abnormal bleeding; if it occurs, perform a vaginal examination, ultrasound scan and measurement of HCG levels
A history of pregnancy and self-induced abortion may or may not be given Lower abdominal pain Prolonged light to heavy bleeding	Lower abdominal tenderness Foul-smelling vaginal discharge Pus coming from the cervix Fever Tender uterus with pain on moving the cervix Shock due to haemorrhage and/or sepsis	Induced abortion with infection	Treat shock if present IV antibiotics: Ampicillin 2 gram IV loading dose, then 1 gram IV every 6 hours <i>plus</i> gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours <i>plus</i> metronidazole 500 mg IV every 8 hours until the patient has been fever-free for 48 hours Manual vacuum aspiration (risk of uterine perforation): only when pulse and blood pressure are improving and after 24 hours of appropriate IV antibiotics and good urine output of > 30 mL/hour Correct DIC if there is a blood clotting disorder If the patient remains shocked after resuscitation and/or heavy vaginal bleeding continues, they will need earlier surgery After ensuring that there are no vaginal or cervical injuries, irrigate the vagina with sterile normal saline, Ringer-lactate or Hartmann's solution to remove any herbs or caustic substances that may have been used to induce the abortion

(continued)

Symptoms	Signs	Diagnosis	Treatment
<p>A history of pregnancy and self-induced abortion may or may not be given</p> <p>Lower abdominal pain</p> <p>Prolonged light to heavy bleeding</p> <p>Severe abdominal pain</p> <p>Urinary or faecal incontinence.</p> <p>Faecal discharge from vagina</p>	<p>Severe abdominal tenderness with rigid abdomen and ileus if there is peritonitis</p> <p>Foul-smelling vaginal discharge</p> <p>Pus coming from the cervix</p> <p>Fever</p> <p>Tender uterus with pain on moving cervix</p> <p>Shock due to haemorrhage and/or sepsis</p>	<p>Induced abortion with injuries to genital tract and to bowel or bladder</p>	<p>Stabilise if shocked</p> <p>Laparotomy to repair injuries</p> <p>Manual vacuum aspiration (high risk of uterine perforation) after checking that there are no tears in the vagina or cervix which need repair</p> <p>Appropriate IV antibiotics as above</p>

Light bleeding is defined as taking longer than 5 minutes for a clean pad or cloth to become soaked. Heavy bleeding is defined as taking less than 5 minutes for a clean pad or cloth to become soaked.

## 2.4.D Vaginal bleeding in late pregnancy

TABLE 2.4.D.1 Vaginal bleeding in late pregnancy

Symptoms	Clinical signs	Diagnosis	Treatment
<p>Severe constant abdominal pain</p> <p>Light or heavy vaginal bleeding</p> <p>Reduced fetal movements</p>	<p>Shock</p> <p>Tense and tender uterus on abdominal examination</p> <p>Fetal distress or absent fetal heart rate</p>	<p>Placental abruption</p>	<p><b>Call for surgical and anaesthetic help</b></p> <p>Left lateral tilt or recovery position</p> <p>IV fluid boluses for shock</p> <p>Cross-match 4 units of blood and freeze-dried plasma if available</p> <p>Deliver fetus as soon as possible if viable, either by inducing labour or by Caesarean section</p>
<p>Vaginal bleeding which can be light or very heavy</p> <p>Bleeding can be precipitated by intercourse or artificial rupture of membranes</p> <p>No pain</p>	<p>Soft uterus</p> <p>Presenting part may be higher than expected</p> <p>Fetus may be distressed, non-viable or uncompromised with normal movements and normal fetal heart rate pattern</p> <p>Ultrasound will show placenta praevia</p> <p><b>Do not undertake digital vaginal examination, as this may precipitate massive bleeding which can be fatal</b></p> <p>Shock may be present, depending on the severity of bleeding and its duration</p>	<p>Placenta praevia</p>	<p>Call for surgical and anaesthetic help</p> <p>Treat shock if present</p> <p>If preterm and not bleeding too heavily, give steroids, admit for bed rest, and only perform a Caesarean section if there is a further bleed</p> <p>Cross-match ideally 4 units of blood</p>
<p>Usually a change from intermittent labour contractions to constant pain</p> <p>Oxytocin may be being used to augment contractions</p> <p>Vaginal bleeding which may be light or heavy</p> <p>History of a previous Caesarean section or other surgery on the uterus</p>	<p>Shock (especially an increasing heart rate detected ideally on partograph)</p> <p>Abdominal distension</p> <p>Tender over uterus, with more easily palpable fetal parts</p> <p>Absent fetal movements and heart sounds</p>	<p>Ruptured uterus</p>	<p><b>Call for surgical and anaesthetic help</b></p> <p>Treat shock if present</p> <p>Cross-match ideally 4 units of blood</p> <p>Prepare theatre for laparotomy while resuscitating the patient</p>

(continued)

Symptoms	Clinical signs	Diagnosis	Treatment
Heavy vaginal and other bleeding	Bleeding from sites in addition to the vagina Signs of other conditions that may be responsible, such as: <ul style="list-style-type: none"> <li>• placental abruption</li> <li>• pre-eclampsia or eclampsia (high blood pressure and proteinuria)</li> <li>• retained dead fetus</li> <li>• septicaemia, including intrauterine sepsis</li> <li>• incompatible blood transfusion</li> <li>• amniotic fluid embolism</li> </ul>	Coagulation failure	Fresh blood transfusion Blood products such as platelets, fresh-frozen plasma and cryoprecipitate if available
Light vaginal bleeding Bleeding can be precipitated by intercourse or artificial rupture of membranes No pain	Fetal distress or death	Vasa praevia (placental blood vessels lying in the membranes and in front of the baby's head)	If diagnosed by ultrasound before labour, plan for Caesarean section

## 2.4.E Vaginal bleeding after delivery

**TABLE 2.4.E.1** Vaginal bleeding after delivery

Symptoms	Signs	Possible diagnosis
Immediate heavy bleeding after birth	Uterus soft and not contracted	Atonic uterus
Immediate heavy bleeding after birth	Uterus contracted	Trauma to cervix, vagina or perineum
Bleeding which may be light if clot is blocking cervix	Placenta not delivered within 30 minutes of birth	Retained placenta
Bleeding which is usually light but continues for many hours	Portion of placenta missing Uterus contracted	Retained placental parts
Bleeding for > 24 hours	Portion of placenta missing Foul-smelling lochia may be present Fever may be present Severe anaemia	Retained placental parts with or without infection
Lower abdominal pain of varying intensity Immediate but usually light bleeding	Uterus not felt on abdominal palpation Inverted uterus may be seen at vulva Bradycardia may be present Shock	Inverted uterus
Usually during labour there has been a change from intermittent labour contractions to a constant pain which may become less severe after rupture has occurred Sometimes an oxytocin drip is in place Vaginal bleeding which may be light or heavy History of a previous Caesarean section or other surgery on the uterus	Shock Abdominal distension Tender over uterus	Ruptured uterus (more likely before delivery of the baby)

## 2.4.F The diagnosis of breathing difficulties in pregnancy

All of the symptoms and signs may not be present for all of the diagnoses listed in Table 2.4.F.1, and it is difficult to distinguish between some of them; some symptoms and signs will be a diagnosis of exclusion. It is therefore important to treat the treatable.

**TABLE 2.4.F.1 Breathing difficulties in pregnancy**

Symptoms that may be present	Clinical signs that may be present	Diagnosis
Weakness Tiredness	Pale conjunctiva, nail beds, palms of hands and soles of feet	Severe anaemia
Weakness Tiredness Dyspnoea	Signs of severe anaemia Oedema of legs Basal lung crepitations Tachycardia Gallop rhythm Enlarged liver Elevated jugular venous pressure (JVP)	Heart failure due to severe anaemia
Dyspnoea	Heart murmur Irregular heart rhythm Oedema of face and legs Basal lung crepitations Tachycardia Gallop rhythm Enlarged liver Elevated JVP	Heart failure due to heart disease
Dyspnoea Cough Pleuritic chest pain	Fever Tachypnoea Respiratory distress Reduced air entry Bronchial breathing Pleural rub Rhonchi Crepitations	Acute lower respiratory tract infection (pneumonia)
Dyspnoea Cough	Respiratory distress Tachypnoea Wheezing Rhonchi Reduced air entry	Asthma
Dyspnoea	Hypertension Proteinuria Oedema of face and legs Basal lung crepitations Tachycardia Gallop rhythm Enlarged liver Elevated JVP	Pulmonary oedema due to hypertension and severe pre-eclampsia
Dyspnoea Swelling of the leg Pleuritic chest pain	Tachypnoea Haemoptysis Leg pain/swelling Cyanosis Shock Central chest pain Elevated JVP Pleural rub	Pulmonary embolus

(continued)

Symptoms that may be present	Clinical signs that may be present	Diagnosis
Collapse Dyspnoea	Shock Apnoea Cardiac arrest Cyanosis Coagulopathy	Amniotic fluid embolus

## 2.5 Life-threatening complications of pregnancy and delivery

### 2.5.A The pregnant woman or girl with shock during pregnancy and the puerperium

#### Introduction

The pregnant patient who is shocked due to hypovolaemia (the most common cause of shock; see below) will be pale, cold and clammy, have a rapid weak pulse, and may have a reduced conscious level, be confused or be unconscious. If the shock is due to sepsis, the patient's skin may become warm from vasodilatation.

Shock results from an acute failure of circulatory function. Maintenance of adequate tissue perfusion depends on the following:

- a pump (the heart): failure leads to cardiogenic shock
- the correct type and volume of fluid (blood): failure leads to hypovolaemic shock
- controlled vessels (arteries, veins and capillaries): failure leads to distributive shock
- unobstructed flow: failure leads to obstructive shock
- red blood cells: failure leads to dissociative shock.

The most common causes of shock are hypovolaemia from any cause, septicaemia, the effects of trauma and very severe anaemia.

TABLE 2.5.A.1 Causes of shock

<i>Cardiogenic</i>	Arrhythmias Cardiomyopathy <b>Heart failure</b> Cardiac valvular disease Myocardial contusion
<b>Hypovolaemic</b>	<b>Haemorrhage</b> <b>Gastroenteritis</b> Volvulus <b>Burns</b> <b>Peritonitis</b>
<i>Distributive (relative hypovolaemia)</i>	<b>Septicaemia</b> Anaphylaxis Anaesthesia Spinal cord injury
<i>Obstructive</i>	Tension pneumothorax Haemopneumothorax Flail chest Cardiac tamponade Pulmonary embolism
<i>Dissociative</i>	<b>Very severe anaemia</b> Carbon monoxide poisoning

#### Classification of causes of shock

Common causes are shown in bold type (see Table 2.5.A.1), and all causes are described in more detail in the relevant sections of this book.

#### Diagnostic pointers

During assessment and resuscitation, a focused history of the previous 24 hours and previous illnesses should be obtained. This may point to the likeliest working diagnosis for emergency treatment.

- A history of vomiting and/or diarrhoea points to **fluid loss**, either externally (e.g. **gastroenteritis**) or into the abdomen (e.g. appendicitis and peritonitis, early stages of gastroenteritis).
- A history of bleeding. This may be vaginal bleeding, or 'silent' bleeding into the abdominal cavity (as in ectopic pregnancy, placental abruption or ruptured uterus).
- Fever or a rash points to **septicaemia**.
- Urticaria, angioneurotic oedema or a history of allergen exposure points to **anaphylaxis**.
- Heart failure points to **severe anaemia** (usually with severe pallor), valve disease or cardiomyopathy.
- A history of sickle-cell disease or diarrhoeal illness and low haemoglobin levels points to **acute haemolysis**.
- **A history of major trauma points to blood loss, and, more rarely, tension pneumothorax, haemothorax, cardiac tamponade or spinal cord transection.**

- Severe **tachycardia** or signs of heart failure point to an **arrhythmia** or a cardiomyopathy.
- A history of polyuria, sighing respiration and a very high blood glucose level points to diabetes (see Section 2.7.D on **diabetic ketoacidosis**).
- A history of drug ingestion points to **poisoning**.

### Physiology of shock

**Shock is defined as an acute failure of circulatory function, leading to impaired delivery of nutrients and oxygen to, and impaired removal of waste products from, the body tissues.**

Shock is a progressive syndrome, but its effects can be divided into the following progression.

### Phase 1 (compensated) shock

**TABLE 2.5.A.2 Compensated shock**

Physiology	Clinical effects
Sympathetic reflexes maintain cardiac output by: <ul style="list-style-type: none"> <li>● increased systemic arterial resistance</li> <li>● decreased blood flow to non-essential organs</li> <li>● increased heart rate</li> <li>● constriction of the venous reservoir</li> <li>● angiotensin and renin release leading to renal preservation of salt and water and reabsorption of intestinal fluid</li> </ul>	Normal systolic blood pressure (diastolic blood pressure may be increased due to vasoconstriction) Tachycardia Cool skin and increased capillary refill time Decreased urine output (< 0.5 mL/kg/hour, or < 30 mL/hour in the mother) Confusion/agitation

### Phase 2 (uncompensated) shock

**TABLE 2.5.A.3 Uncompensated shock**

Physiology	Clinical effects
Failure of compensatory mechanisms with decreased tissue perfusion leading to: <ul style="list-style-type: none"> <li>● increased anaerobic metabolism, leading to lactic acidosis</li> <li>● acidosis impairs cardiac function and cellular homeostasis, leading to a further decline in cellular metabolic functions</li> <li>● inflammatory mediators are released which further impair cell function and vital systems such as the coagulation cascade and platelet function</li> </ul>	Hypotension Cold peripheries and markedly increased capillary refill time Acidotic breathing Absent urine output Impaired cerebral function

### Phase 3 (irreversible) shock

The diagnosis of irreversible shock is a retrospective one.

Severe damage to vital organs leads to inevitable death due to diminished energy stores which cannot be replenished even if circulatory function is restored. Therefore early recognition and effective treatment of shock are vital.

### Physiology of septic shock

Tissue perfusion is decreased through the action of bacterial toxins and host inflammatory mediators. This results in the following:

- abnormal distribution of blood in the microcirculation, sometimes with peripheral vasodilatation
- loss of intravascular fluid into the extravascular space due to capillary leakage
- depressed myocardial contractility due to toxins and acidosis
- although cardiac output may be normal or raised from baseline, it may still be too low to deliver sufficient oxygen and nutrients to the tissues, because in septic shock the cells do not use oxygen properly. There appears to be a block at the mitochondrial level in the mechanism of oxygen uptake. This progressive deterioration in cell oxygen consumption can lead to multiple organ failure.

### Early (compensated) septic shock

This is characterised by the following:

- raised cardiac output with tachycardia

- (sometimes) decreased systemic resistance, warm extremities and a wide pulse pressure
- (sometimes) increased systemic resistance with cold extremities and a raised diastolic blood pressure
- hyperpyrexia and hyperventilation
- mental confusion.

All of these signs may be minimal. Mental confusion in particular needs to be looked for carefully, if septic shock is not to be overlooked at this stage. In the group with increased systemic resistance, decreased capillary return is a useful sign in these circumstances.

**A pregnant patient may lose 1200–1500 mL of blood before showing obvious signs of shock (20% of circulating blood volume, 6–7 litres). Maternal signs of hypovolaemia are late.**

Fetal distress may be the first sign of shock in pregnancy.

### Graphs to indicate the progression of shock in relation to clinical signs

#### Stage 1

At first, with less than 1000 mL of blood loss, there are very few signs and symptoms. The patient may be slightly anxious, and the pulse and respiratory rate are slightly elevated but still within the normal range. Therefore, if this is the first recording taken, you may think it is normal for this particular patient, but it may in fact be abnormal for her (see Figure 2.5.A.1).

Note that in the anaemic mother the signs may be worse and the risks may be greater earlier than this.

FIGURE 2.5.A.1 Stage 1 shock.

**Stage 2**

After further blood loss, the perfusion to organs is maintained by the body's stress response. This increases the diastolic pressure, with a resultant reduction in the pulse pressure, and the pulse rate continues to rise, reaching over 100 beats/minute (see Figure 2.5.A.2).

Meanwhile, urine is not being produced and the mother's respiratory rate starts to increase.

Note that in the anaemic mother the signs may be worse and the risks may be greater earlier than this.

FIGURE 2.5.A.2 Stage 2 shock.

**Stage 3**

When 2000 mL of blood have been lost, a drop in blood pressure is observed, along with other signs and symptoms of hypovolaemia. It must be emphasised that

hypotension, which is commonly used as an indicator of the severity of blood loss, is in fact a very late sign.

Generally, the pulse rate should be lower than the systolic blood pressure. If the pulse rate is higher than the systolic pressure, the patient is in grave danger (see Figure 2.5.A.3).

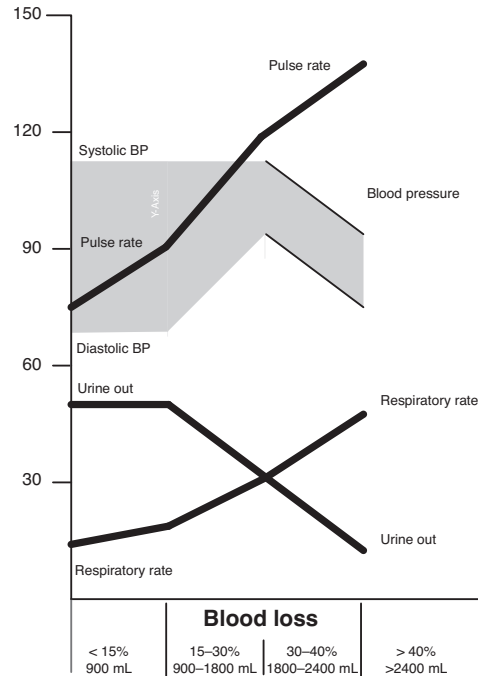

FIGURE 2.5.A.3 Stage 3 shock.

Note that in the anaemic mother the signs may be worse and the risks may be greater earlier than this.

**Stage 4**

If more than 2000 mL of blood are lost, this is an uncompensated very late stage of hypovolaemia, which could very rapidly result in death if emergency measures are not initiated immediately (see Figure 2.5.A.4).

Note that in the anaemic mother the signs may be worse and the risks may be greater earlier than this.

In late (uncompensated) septic shock:

- hypotension occurs as a result of decreased vascular resistance, and even with a normal or raised cardiac output, shock develops
- the cardiac output may fall gradually over several hours, or precipitously within minutes
- as tissue hypoxia develops, plasma lactic acid levels increase
- survival depends on the maintenance of a hyperdynamic state.

**Choice of fluid for volume replacement**

Crystalloid or colloid fluids are appropriate for volume replacement in shock (see Section 2.8.B).

However, dextrose/glucose infusions (particularly hypotonic ones such as 5% glucose or 0.18% saline in 5% glucose) do not constitute appropriate fluid resuscitation, and can be dangerous because they lower serum sodium levels, which can result in seizures and brain swelling.

Compared with colloids, crystalloid fluids:

- diffuse more readily into the interstitial space

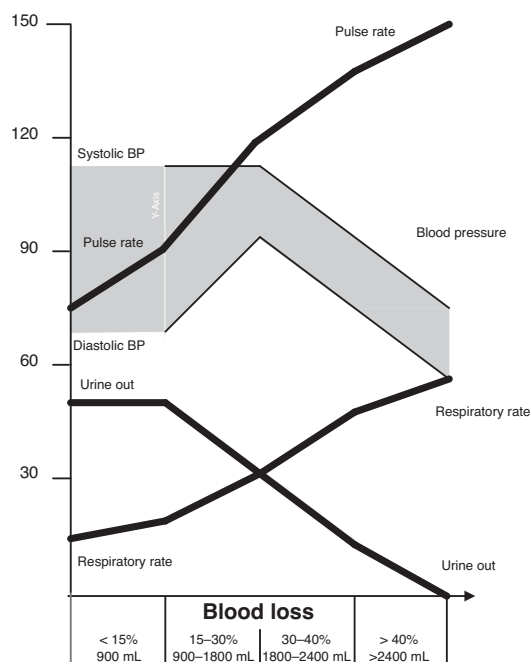

FIGURE 2.5.A.4 Stage 4 shock.

- may be associated with more peripheral oedema
- where capillary leak exists, allow more water to enter the interstitial space, because of the lower osmotic pressure
- need two to three times the volume of colloids to expand the vascular space
- have been reported to be associated with lower mortality.

Nevertheless, the use of both crystalloids and colloids is appropriate, although crystalloids (e.g. Ringer-lactate or Hartmann's solution or normal saline) are more likely to be available.

### Choice of crystalloid

The fluid that was traditionally infused into the circulation for the management of shock was normal saline (0.9% sodium chloride). This fluid has increasingly been shown to be dangerous, especially in the sick patient. An infusion of normal saline causes a hyperchloraemic acidosis (a high chloride concentration leading to an acidosis) which, in the shocked patient, who is already acidotic, causes a deterioration in the health of cells in vital organs, even though perfusion of the cells has been improved by the increased circulating volume.

There are sodium-containing alternatives to normal saline that are safer as they approximate more closely to human serum/plasma in content (see Table 1.6.1), although they are slightly more expensive. We recommend the use of either of these alternatives – **Ringer-lactate and Hartmann's solution**, which are widely available – for all fluid replacement. Hospitals are advised to change their standard crystalloid from 0.9% ('normal') saline to Ringer-lactate or Hartmann's solutions as soon as possible.

As not all hospitals will have access to these solutions immediately, there may sometimes be no alternative but to start fluid replacement with normal saline. However, if more than 20mL/kg needs to be given, then one of the safer alternatives should be used in very sick patients if at all possible.

### Blood

If there is significant blood loss or pre-existing severe anaemia in the face of any blood loss, blood will be needed. Full cross-matching takes about 1 hour to perform. For urgent need, type-specific non-cross-matched blood (which is ABO- and rhesus-compatible, but has a higher incidence of transfusion reactions) takes about 15 minutes to prepare. In dire emergencies, O-negative blood must be given.

Fluids should be warmed, especially if they are needed in large volumes. In the absence of heaters, bags of fluid or blood can be warmed by placing them under the clothes next to the skin of a relative. Even this takes time, and another method is to pass the tubing of an IV set through a bowl containing warm water.

### Primary assessment and resuscitation

**Suspect or anticipate shock** if at least one of the following is present:

- bleeding in early pregnancy (e.g. miscarriage, induced abortion, ectopic pregnancy or molar pregnancy)
- bleeding in late pregnancy or labour (e.g. placenta praevia, abruptio placentae, ruptured uterus)
- bleeding after childbirth (e.g. ruptured uterus, uterine atony, tears of genital tract, retained placenta or placental fragments)
- infection (e.g. induced or septic miscarriage/abortion, chorioamnionitis, endometritis, pyelonephritis)
- trauma (e.g. injury to the uterus or bowel during induced abortion, ruptured uterus, tears of the genital tract).

### Primary assessment indicating shock

- Fast, weak pulse ( $\geq 100$ –110 beats/minute).
- Pallor (especially of the inner eyelids, palms or around the mouth).
- Sweatiness or cold clammy skin.
- Rapid breathing ( $> 30$  breaths/minute).
- Anxiety, reduced conscious level, confusion or unconsciousness.
- Low blood pressure (systolic pressure less than 90mmHg is a late sign).
- Reduced urine output ( $< 30$  mL/hour).

### Resuscitation

**If heavy bleeding is the suspected cause of shock**, take simultaneous steps to stop the bleeding. These consist of uterotonic drugs such as oxytocin or misoprostol, uterine massage, bimanual compression, aortic compression and condom catheter, and anti-shock garment in postpartum haemorrhage. Urgent surgical intervention may be required (e.g. for ruptured ectopic pregnancy).

### Airway

Try at the same time to stop bleeding by surgical or specific medical treatments as urgently as possible.

- Use an opening manoeuvre if the airway is not open or is partially obstructed. Keep the airway open. If there is improvement but the airway closes without active opening support, consider airway adjuncts to maintain the airway if the patient is unconscious (P or U on the AVPU scale).
- **Suction** if necessary.
- The airway may need to be maintained and protected by **intubation**, using experienced senior help (if available).

### Breathing

- Provide a high concentration of oxygen through a face mask with a reservoir bag if there is adequate spontaneous respiration.
- For patients with inadequate ventilation, respiration should be supported with oxygen via a **bag-mask**, and experienced senior help should be summoned (if available).

### Circulation

- Gain IV access.
  - Use a short, wide-bore (16- to 18-gauge) IV cannula if possible for IV access.
  - Access via the internal or external jugular veins is a good option if peripheral access is impossible. Long saphenous vein cut-down may also be considered, and the new intraosseous drill can be used if all else fails (see Section 8.4.B).
  - **Applying pressure on the site of the bleeding can be valuable in many circumstances, including postpartum haemorrhage (see Section 2.5.D.iv) and external haemorrhage from major trauma.**
  - Try to obtain two vascular access sites to give large volumes quickly, and in case one line is lost.
  - A blood pressure cuff can be used to speed up infusions in emergency situations. Wrap the cuff around the blood/fluid bag and place it inside a non-compressible bag. (see Figure 2.5.A.5).
- Use the left lateral tilt position or recovery position to minimise aortic and vena caval compression, and to reduce the risk of aspiration in patients after 20 weeks' gestation.
- Elevate the legs by raising the foot of the bed.
- Consider using a non-pneumatic anti-shock garment (NASG).
- Give **an initial rapid bolus of 500 mL to 1 L of Ringer-lactate or Hartmann's solution or blood if the patient is haemorrhaging. A colloid at the same dose can also be given, if available.** It is essential that the bolus is given as rapidly as possible. In the absence of syringe pumps, it should be manually pushed in using a 20- to 50-mL syringe (using a three-way tap and link to an IV giving set).
- Further boluses of 500–1000 mL will usually be required in the first hour. Once more than 2 litres have been given IV, complications such as pulmonary or cerebral oedema may occur. Expert help, including CVP monitoring, is very valuable if it is available.

The concept of 'targeted crystalloid fluid-resuscitation' is important and requires urgent research into shock due to obstetric haemorrhage. Here the initial boluses of IV crystalloids required to treat shock would only be given to keep the vital organs (especially the brain, heart and kidneys) perfused before blood becomes available and, of most importance, surgery and specific medical treatments to stop the bleeding have started to take effect. The administration of too large a volume of IV crystalloids fluids may increase the blood pressure, damage clotting and disrupt early clot formation.

If this approach is used when giving boluses of crystalloid in shock due to bleeding (before blood is available and before procedures undertaken to stop haemorrhage are effective), only the amount necessary to keep the blood

pressure at a level sufficient to perfuse the vital organs is given. There is no clear evidence to indicate the precise blood pressure that should be achieved in a woman in shock due to haemorrhage. However, **adequate perfusion of vital organs** may best be indicated by **a radial pulse which can be palpated and an alert conscious level.** During pregnancy, the adequacy of the fetal heart rate may also be helpful.

Our personal practice, especially in low resource settings, is to start with IV boluses of 500mL of crystalloid and reassess after each bolus, always aiming to stop haemorrhage and obtain blood for transfusion as soon as possible. In situations where there is brisk active blood loss and delay in obtaining blood or effective intervention to halt the bleeding, several boluses of crystalloids may be required. The importance of undertaking measures to halt the bleeding and obtaining blood for transfusion rapidly cannot be overstated.

### Tranexamic acid

If bleeding is the cause of shock, this inexpensive and safe drug can be helpful. The drug should be started as soon as possible after the onset of major haemorrhage, in order to be effective.

The loading dose is 1 gram over 10 minutes followed by an IV infusion of a further 1 gram over a period of 8 hours. The slow IV bolus dose is given by injecting 1 gram of tranexamic acid into a 100-mL bag of 0.9% saline and letting it run through over a period of about 10–20 minutes (the exact timing is not crucial). The 8-hour infusion is given by injecting 1 gram of tranexamic acid into a 500-mL bag of 0.9% saline and giving it over a period of 8 hours (approximately 60 mL/hour).

Keep the patient warm but do not overheat.

**FIGURE 2.5.A.5** Pressure bag over the bag of Ringer-lactate or Hartmann's solution to increase infusion rate.

**Transfuse blood as soon as possible to replace blood loss.**

**Determine the cause of bleeding**

- If bleeding occurs **before the first 24–28 weeks of pregnancy**, suspect miscarriage, induced abortion, ectopic pregnancy or molar pregnancy.
- If bleeding occurs **after the first 24–28 weeks or during labour, but before delivery**, suspect placenta praevia, abruptio placentae or ruptured uterus.
- If bleeding occurs **soon after childbirth**, suspect atonic uterus, retained placental fragments, ruptured uterus, tears of the genital tract or occasionally an inverted uterus.
- In all cases consider the possibility of a primary or secondary blood clotting disorder.

**Cases where infection is the suspected cause of shock**

- Collect appropriate samples (blood cultures, urine, pus, swabs) for microbial culture before starting antibiotics, if facilities are available but do not delay giving antibiotics because of specimen collection.
- Give a combination of antibiotics to cover aerobic and anaerobic infections, and continue until the patient has been fever-free for 48 hours:
  - benzyl penicillin 2.4 grams initially, then 1.2 grams IV 6-hourly *or* ampicillin 2 grams initially, then 1 g IV/IM every 6 hours *plus* gentamicin 80mg IV/IM 8-hourly *or* 5 mg/kg body weight IV/IM once every 24 hours *plus* metronidazole 500mg IV every 8 hours
  - *or* ceftriaxone 2–4 grams IV once daily *or* cefotaxime 2 grams 12-hourly IV *plus* metronidazole 500mg IV every 8 hours.
- **If the patient is in shock, do not give antibiotics by mouth or IM, as they will not be absorbed.**
- Reassess the patient's condition for signs of improvement.

**Cases where haemorrhage due to trauma is the cause of shock**

- Try and stop haemorrhage and if appropriate prepare for surgical intervention.
- Give 500mL IV crystalloid fluid resuscitation boluses and reassess circulation after each bolus until blood is available (see above).

**General issues**

Avoid giving IV boluses of 5% dextrose or dextrose saline (4%/0.18%), as they cause hyponatraemia, and may result in cerebral oedema and death.

An antibiotic such as cefotaxime or ceftriaxone should always be given IV when a diagnosis of septicaemia is made obvious by the presence of a purpuric rash (suspect meningococcal infection).

**BOX 2.5.A.1 Whole blood clotting time**

If laboratory clotting tests are not available:

- Transfer 2 mL of venous blood into a small dry clean plain glass test tube (approximately 10 mm × 75 mm).
- Hold the tube in your closed fist to keep it warm (+ 37°C).
- After 4 minutes, tip the tube slowly to see if a clot is forming. Then tip it again every minute until the blood clots and the tube can be turned upside down.
- **Failure of a clot to form after 7 minutes, or formation of a soft clot that breaks down easily, suggests a blood clotting disorder.**

Take blood for the following investigations (if available): full blood count (FBC), renal and liver function tests, blood culture, cross-matching, blood clotting, glucose stick test and glucose laboratory test.

- Catheterise and monitor urine output.
- If peritonitis is possible, add metronidazole IV.

**Cases where a blood clotting disorder is present and fractionated blood products are not available**

- Use fresh whole blood (straight from the donor if possible). In general, in obstetric emergencies, volume overload is not a problem.
- If volume overload is a concern, allow the unit of fresh whole blood to stand for 30 minutes. The red blood cells will drop to the bottom, and the fluid/plasma above them containing clotting factors can be drawn off with a syringe and needle, and plasma alone can be given.

**Central venous access**

This can be valuable provided that the healthcare workers present have the skills needed to do this safely as it is potentially hazardous. The catheter should be inserted in the intra-thoracic inferior vena cava or superior vena cava via the femoral, internal jugular or subclavian vein routes. However, **it is essential that resuscitation is not delayed by trying to insert a central venous catheter. If there is a clotting disorder, never use the subclavian route.**

A normal central venous pressure (CVP) is 4–10 cmH<sub>2</sub>O, and optimising the CVP can improve cardiac output with less risk of inducing heart failure. Take great care if the CVP is > 12 cmH<sub>2</sub>O, as cardiac failure may be induced by excessive IV fluids, especially if severe anaemia, malnutrition or a primary cardiac disorder is present.

Reassess ABC **on a regular basis.**

Reassess the response to fluids to determine whether the woman's condition is improving. Signs of improvement include the following:

- decreasing pulse rate (a rate of ≤ 100–110 beats/minute)
- increasing blood pressure (systolic pressure ≥ 90–100 mmHg)
- improving mental status (less confusion or anxiety)
- increasing urine output (≥ 30 mL/hour).

Continue monitoring to ensure that the pulse rate and blood pressure do not deteriorate after improvement, indicating the return of shock.

**If the mother's condition improves**, adjust IV fluids to 1 litre over 6 hours, and continue management for the underlying cause of shock.

If more than 3 litres have been given IV in a mother, and if shock is still present, call for anaesthetic assistance.

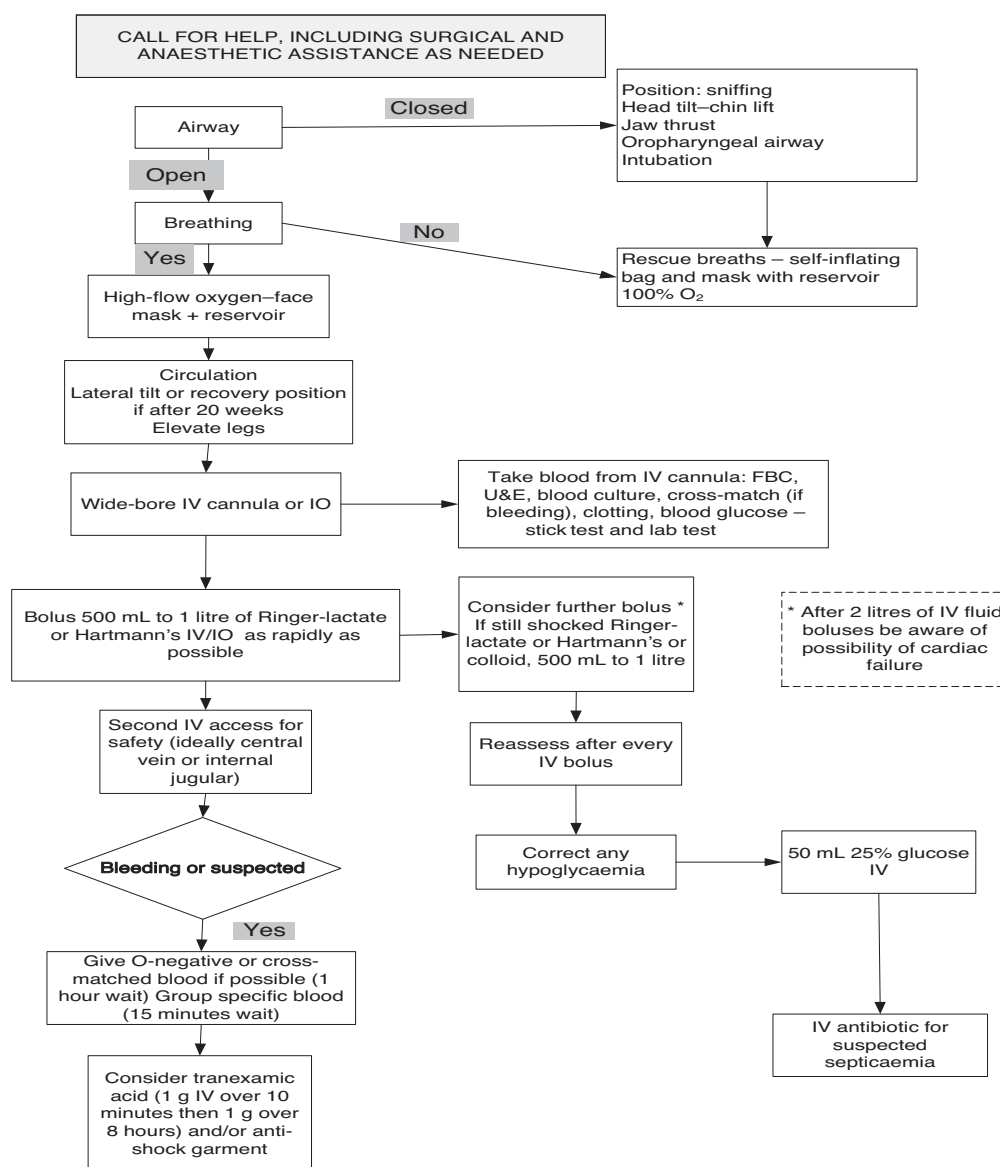

**Correct any hypoglycaemia.**

**Inotropes**

An IV infusion of dobutamine and/or dopamine at 5–20 micrograms/kg/minute should be considered, especially if a third bolus of fluid is required. Sometimes adrenaline by IV infusion at 0.05–2 micrograms/kg/minute may be required.

These infusions can initially be given **carefully** through a peripheral vein until central venous access is obtained.

Patients who require ventilation and inotropic support should be cared for in a high-dependency or intensive-care unit with invasive monitoring (if available). Seek early advice.

**FIGURE 2.5.A.6** Shock in pregnancy or the puerperium: pathway of care. IV, intravenous; IO, intra-osseous; U&E, urea and electrolytes; PPH, postpartum haemorrhage.

## 2.5.B Severe anaemia, including sickle-cell disease

### BOX 2.5.B.1 Minimum standards

- Oral and parenteral iron.
- Folic acid.
- Blood transfusion.
- Antimalarial drugs.
- Anthelmintic drugs.
- Haemoglobin measurements at healthcare facilities in the community.

### Introduction

In normal pregnancy there is an increased total blood volume and a marked increase in plasma volume, so the haemoglobin concentration falls. Pathological anaemia is

mainly due to iron deficiency, associated with depleted iron stores before pregnancy and poor diet. Malaria is another major cause of anaemia in pregnancy. Anaemic women cope poorly with blood loss at delivery. Where amoebiasis and other hookworms are endemic, these may worsen the anaemia.

### Prevention of anaemia

Oral iron supplementation is advised during all pregnancies. It is particularly important in the mother who is anaemic before pregnancy or who has a poor diet. The WHO recommends an iron supplement of 60mg/day for mothers with adequate iron stores, and 120mg/day for those women without adequate iron stores. Give ferrous

sulphate or ferrous fumarate 120 mg by mouth *plus* folic acid 400 micrograms by mouth once daily throughout pregnancy. Continue for 3 months postpartum. The mother may take the tablets after meals rather than in the morning if she prefers to do so.

In an endemic area, look for hookworm ova in the stools, and treat them if you find them. If a laboratory is not available to identify them, assume that they are present. Wait until around 16 weeks of pregnancy and then treat with mebendazole ('Vermox') 500 mg as a single treatment.

If the mother has a large spleen and is anaemic, this is probably caused by malaria, which should be treated.

In areas where malaria is endemic, institute intermittent preventive treatment (IPT) with antimalarial drugs (see Section 2.8.D).

**Severe anaemia is present if haemoglobin levels are less than 5.0 g/dL or if there are signs of heart failure and haemoglobin levels are less than 7.5 g/dL. This condition is very dangerous for both mother and baby.**

Haemoglobin can be measured using either small drops of capillary blood or a venous sample. A portable battery-operated haemacue ([www.biomedcentral.com/content/pdf/1472-6890-11-5.pdf](http://www.biomedcentral.com/content/pdf/1472-6890-11-5.pdf)) or a paper chart method can be used in rural areas where clinics are held.

**FIGURE 2.5.B.1** WHO test strip with colour scale for measuring haemoglobin in a rural area.

### Presentation of severe anaemia

- The patient will be weak, with near white palms, soles and tongue, and **signs of heart failure** if the anaemia is severe (see below).
- In haemolysis, the urine may be **dark brown in colour** and there may be signs of jaundice.

### Treatment of severe anaemia

If heart failure is not present, give ferrous sulphate 200 mg orally three times a day, vitamin C 1000 mg daily (this can increase haemoglobin levels by 1 gram/litre per week) and folic acid 5 mg once daily. If vitamin C is not available, iron tablets may be taken with orange juice to aid absorption.

**Parenteral iron:** parenteral administration produces a larger and more rapid rise in haemoglobin levels, and is more effective in replenishing ferritin levels, so might be

necessary for patients who cannot tolerate oral preparations or who are non-compliant, or if the anaemia is diagnosed late and rapid correction is required.

Parenteral iron is best given IV. Intramuscular injections are painful and may stain the skin. Do not give parenteral iron during the first trimester.

**IV preparations:** the side effects of intravenous iron preparations are less common with iron sucrose than with iron dextran. Side effects of iron dextran include arthralgia, myalgia, pyrexia, flushing and hypotension. Serious hypersensitivity is observed in approximately 1 in 200 patients with iron dextran (low-molecular-weight dextran) and 1 in 50 000 with iron sucrose.

**Iron sucrose (Venofer®):** 200 mg (elemental iron). For IV infusion, dilute 10 mL of iron sucrose (200 mg) in 100 mL of 0.9% saline and infuse immediately after dilution. The first 10 mL (20 mg) should be given slowly over 10 minutes and the remainder over 1 hour. No test dose is required for iron sucrose, as anaphylaxis is rare with this preparation. However, adrenaline must be available. A fall in blood pressure is possible if the iron infusion is given too quickly. IV infusions can be repeated weekly if the required rise in haemoglobin levels is not achieved, up to a maximum total dose of 1000 mg.

**Do not overdose with iron**, as this can affect the absorption of other essential elements from the diet and increase the oxidative stress of pregnancy.

**Treat for malaria, give prophylaxis** (see Section 2.8.D), and prevent future inoculations with impregnated bed nets.

**Treat any chronic parasitaemia** (e.g. hookworm, schistosomiasis).

Where hookworm is **endemic** (prevalence of 20% or more), give one of the following antihelmintic treatments:

- albendazole 400 mg by mouth once; **this must not be given in the first trimester** because it causes fetal anomalies
- or mebendazole 500 mg by mouth once or 100 mg twice a day for 3 days
- or levamisole 2.5 mg/kg body weight by mouth once daily for 3 days
- or pyrantel 10 mg/kg body weight by mouth once daily for 3 days.

Where hookworm is **highly endemic** (prevalence of 50% or more), repeat the antihelmintic treatment 12 weeks after the first dose.

### Treatment of severe anaemia where there is heart failure

Give a high concentration of oxygen, bed rest and sit the patient upright (with lateral tilt as well if she is more than 20 weeks pregnant).

- Consider transfusion with packed cells if the haemoglobin concentration is less than 5.0 g/dL (with IV furosemide of 40 mg for each unit of packed cells). If blood cannot be centrifuged, let the bag hang until the cells have settled. Infuse the cells slowly and dispose of the remaining serum (see Section 1.7 on blood transfusion).
- Partial exchange transfusion may be helpful. Use a cannula in a large vein in the antecubital fossa, withdraw 20 mL of the patient's anaemic blood and infuse 40 mL of new blood (ideally packed red blood cells) over 5 minutes and repeat 5–10 times.

**If labour occurs when the patient is severely anaemic:**

- Deliver with the patient sitting up.
- Cross-match blood and have it available in case of postpartum haemorrhage (PPH).
- Avoid a prolonged second stage as this increases the risk of PPH.
- If there are signs of heart failure or maternal exhaustion shorten the second stage with a ventouse if possible.
- Manage the third stage actively (give oxytocin), and suture any tears without delay.
- **The mother is in great danger for at least 48 hours after delivery. Prescribe iron and folate during the puerperium.**

**Sickle-cell anaemia in pregnancy**

Sickle-cell anaemia is a disease in which the patient's red cells form sharp points when they lack sufficient oxygen. These pointed red cells are destroyed by the body, and as a result the patient becomes anaemic. Sickle-cell anaemia is harmful to pregnant mothers. It causes miscarriage and perinatal deaths. It also causes painful crises, which may be life-threatening. Infections, especially urinary and chest infections, are also more common.

**BOX 2.5.B.2 Minimum standards**

- A multidisciplinary team that includes an obstetrician, a midwife and a haematologist.
- Blood pressure and urinalysis monitoring.
- A facility for haemoglobin estimation and electrophoresis, and other laboratory tests.
- Analgesia, including paracetamol, NSAIDs and morphine.
- Blood transfusion.
- Oxygen.
- Penicillin prophylaxis.
- **Pneumococcal (PCV and Pneumovax), hepatitis B and *Haemophilus influenzae* vaccines.**
- Ultrasound scanning.

**Before pregnancy**

Ideally, women with sickle-cell disease (SCD) should be seen before pregnancy so that they can be told about how pregnancy and SCD can interact, and how to achieve the best outcomes. This is also an opportunity to screen for end-organ damage or manage existing problems, and perhaps to discuss contraception. These activities could be undertaken in the context of a regular specialist sickle-cell review.

Women should be encouraged to have their partner tested for haemoglobinopathy before becoming pregnant, so that the risk of having a child with SCD can be assessed. Prenatal diagnosis and possible termination of pregnancy may need to be discussed with the couple.

A history of previous Caesarean section and uterine curettage should be obtained because of the increased risk of placenta praevia.

An adequate nutritional assessment should be undertaken. The patient's pre-pregnant weight, height, and optimal weight gain in pregnancy should be recorded.

Women who are planning to conceive should be told about:

- the role of dehydration (from nausea and vomiting),

cold, hypoxia, overexertion and stress in the genesis of sickle-cell crises

- the increased risk of worsened anaemia, crises, acute chest syndrome (ACS) and infection (especially urinary tract infection) during pregnancy
- potential effects on the baby, such as prematurity, growth restriction and fetal distress. The rate of complications may depend on the type of SCD that is present
- the increased risk of induction of labour and Caesarean section
- the chance of their baby being affected by SCD
- the outcome of pregnancy in SCD is usually favourable. Smith *et al* (1996) reported that 99% (283 of 286) of pregnancies delivered after 28 weeks' gestation and resulted in live births, a rate that compares favourably with the rate of 99.29% for live births to African-American women in the same country (see Further reading at end of the section).

**Tests for chronic disease complications and other relevant issues**

These include:

- echocardiogram: used to screen for pulmonary hypertension that is associated with increased mortality. A tricuspid regurgitant jet velocity of more than 2.5 m/second is associated with a high risk of pulmonary hypertension
- blood pressure and urinalysis: identifies women with hypertension and/or proteinuria
- full blood count with a reticulocyte index
- haemoglobin electrophoresis
- serum iron, total iron binding capacity (TIBC) and ferritin levels
- renal and liver function tests: performed annually to identify sickle nephropathy and/or deranged hepatic function
- red cell antibodies: may detect an increased risk of haemolytic disease of the newborn
- measurement of antibodies to hepatitis A, B and C, and HIV
- rubella antibody titre
- tuberculin skin test
- pap smear, cervical smear, and gonococcus culture and screening for other sexually transmitted diseases; bacterial vaginosis testing should also be performed
- retinal screening (if an ophthalmologist is available); proliferative retinopathy is common in patients with SCD
- T2-star (T2\*) cardiac magnetic resonance imaging: this screens for iron overload in the multiply transfused who have a high ferritin level; aggressive iron chelation before conception is advisable in iron-loaded women.

**Medication and vaccination**

- Penicillin (or erythromycin) prophylaxis: there is limited evidence of its effectiveness in pregnant women with SCD, although some authorities recommend it.
- Folic acid (5 mg daily) is useful both before and throughout pregnancy.
- Hydroxycarbamide (hydroxyurea) is helpful in severe SCD, but it is teratogenic in animals. Women on this medication should use contraception and stop hydroxycarbamide 3 months before attempting to conceive. If they become pregnant, the medication should be stopped and an ultrasound scan performed to look for structural abnormality. Termination is not indicated just

because of exposure to hydroxycarbamide, as it is still possible to deliver an unaffected baby.

- Angiotensin-converting enzyme inhibitors or angiotensin-receptor blockers are used in patients with SCD with significant proteinuria (a protein:creatinine ratio of more than 50mg/mmol), but they are not safe in pregnancy and should be discontinued prior to conception.
- Chelation therapy (e.g. desferrioxamine) should be stopped prior to conception.
- Vaccination against the following is recommended before pregnancy (if not previously given): *Haemophilus influenzae* type b, conjugated meningococcal C, and pneumococcus, hepatitis B and influenza.

### Antenatal care

Antenatal care should ideally be delivered by a multidisciplinary team that includes an obstetrician and a midwife with experience of high-risk antenatal care, and a haematologist with an interest in SCD.

Discussion about pregnancy, SCD and vaccination should cover the points listed under 'Before pregnancy' above. Providing information and education about SCD, improving the mother's nutritional status, malaria prevention and early detection of bacterial infection have a positive impact on SCD-related morbidity and mortality in Africa.

SCD may increase the risk of pre-eclampsia, so it is advisable to give low-dose aspirin (75 mg daily) from 12 weeks' gestation (unless there is an allergy). Because of the effects on fetal development, **non-steroidal anti-inflammatory drugs (NSAIDs) should only be given between 12 and 28 weeks' gestation.**

Iron supplements should only be given if there is laboratory evidence of deficiency (haemoglobin level less than 11 g/dL). Live attenuated vaccines should not be given until after delivery.

The woman's partner should be offered testing for haemoglobinopathy. If the partner is a sickle-carrier or has SCD, the risks of delivering an infant with SCD should be discussed. This should ideally occur within 10 weeks of conception, so that prenatal diagnosis and discussion about termination can be offered. Factors to be considered include coping skills for caring for a child with a serious illness, personal and cultural values with regard to childbearing, religious beliefs, the need and desire to have children, feelings and attitudes about abortion, and beliefs about self-determination versus fate as determinants of adverse events.

Pregnant women with SCD are likely to have an increased risk of venous thromboembolism, and their management should be tailored. Graduated **compression stockings** are an option. For hospital admissions, low-molecular-weight heparin is recommended (see Section 2.5.H).

Blood pressure and proteinuria assessment should occur at each visit because of the increased risk of pregnancy-induced hypertension in SCD. Any pre-existing proteinuria or renal impairment should be monitored more frequently. Women should be observed closely if their blood pressure rises above 125/75 mmHg, if their systolic blood pressure increases by 30 mmHg, or if their diastolic blood pressure increases by 15 mmHg, in association with oedema and proteinuria in the second trimester.

Urinalysis for protein should be performed at each antenatal visit, and midstream urine sent for culture and

sensitivity if symptoms of urinary tract infection are present and routinely if resources allow microscopy.

Ultrasound scanning should ideally occur as follows:

- Women should be offered a viability scan at 7–9 weeks' gestation.
- They should be offered the routine first-trimester scan (at 11–14 weeks' gestation) and a detailed anomaly scan at 20 weeks' gestation. In addition, they should be offered serial fetal biometry scans (growth scans) every 4 weeks from 24 weeks' gestation.

### Transfusion in women with SCD who are pregnant

- Routine transfusions are not required.
- Red cell units should ideally be matched for Rhesus (C, c, D, E, e) and Kell type.
- Ideally, cytomegalovirus seronegative units should be used.
- Decisions about transfusion should be made by an experienced haematologist (if available) and an obstetrician. One approach is to consider initiation of transfusions for women who have complications such as pre-eclampsia, severe anaemia, or increasing frequency of pain episodes.
- Each woman should have an individualised care plan that takes into account her previous sickle-cell and pregnancy history.
- Treatment of acute painful crisis is the same as that for non-pregnant patients, with hydration, oxygen and analgesics, although doses of the latter may be higher. Reassurance should be given that morphine use during pregnancy does not jeopardise the baby's health. However, if large doses of morphine are needed in late pregnancy, the newborn may require opioid weaning.

### Intrapartum care

No randomised controlled trials are available to guide the timing of delivery. If there is a normally growing fetus, offer elective birth through induction of labour, or by elective Caesarean section if indicated for other reasons, between 38 and 40 weeks' gestation. In low resource settings the risks of induction and the uncertainty about due date must be balanced against the potential increased risk of late pregnancy complications such as abruption and pre-eclampsia in SCD. SCD is not a contraindication to attempting vaginal delivery, or vaginal birth after previous Caesarean section.

A 'group and save' for possible transfusion is acceptable for delivery unless there are atypical antibodies, when a cross-match should be requested (to reduce delays).

In women who have hip replacements it is important to discuss suitable positions for delivery.

During labour the following measures are recommended:

- Inform the multidisciplinary team (the senior midwife in charge, senior obstetrician, anaesthetist and haematologist) when labour is confirmed.
- Maintain warmth and hydration.
- Maintain continuous intrapartum electronic fetal heart rate monitoring if available, as there is an increased risk of fetal distress which may necessitate operative delivery. There is also an increased rate of stillbirth, placental abruption and compromised placental reserve.
- Intravenous fluids should be administered if oral hydration is inadequate. A fluid balance chart should be kept.

**Changes during the intrapartum period:**

- There is an increased frequency of sickle-cell crises and ACS.
- Cardiac function can be compromised because of chronic hypoxaemia and anaemia.
- There is an increased risk of painful crises with protracted labour (more than 12 hours). If the woman is well hydrated and labour is progressing, the labour should be carefully supervised. Caesarean section should be considered if labour is not progressing well and delivery is not imminent.
- There is an increased oxygen demand. Use of pulse oximetry to detect hypoxia is appropriate. If the oxygen saturation is 94% or less, oxygen should be given by nasal cannula.

Routine antibiotic prophylaxis in labour is not supported by evidence, but hourly observations of vital signs should be performed. A raised temperature (> 37.5°C) requires investigation. The clinician should have a low threshold for commencing broad-spectrum antibiotics.

Women should be offered anaesthetic assessment in the third trimester of pregnancy, as general anaesthesia should be avoided where possible. Regional (epidural) anaesthesia during labour where available may reduce the need for both general anaesthesia for delivery and high doses of morphine with lower body sickle pain. Regional analgesia (spinal) is recommended for Caesarean section.

**Avoid pethidine because of the risk of seizures.**

Morphine is the most appropriate drug.

**Postpartum care**

- If the baby is at high risk of SCD (based on parental haemoglobinopathy results), early testing for SCD should be offered.
- Maintain maternal oxygen saturation above 94% and adequate hydration based on fluid balance until discharge.
- Low-molecular-weight heparin (or unfractionated heparin if former not available) should be administered while

the woman is in hospital and for 7 days post-discharge following vaginal delivery, or for a period of 6 weeks following Caesarean section.

- Anti-thrombotic stockings are recommended in the puerperium.
- The risk of sickle-cell crisis is increased. Hydration and oxygenation should be maintained and early mobilisation encouraged. Crises should be managed as for non-pregnant women. NSAIDs can be given in the postpartum period and during breastfeeding. Breastfeeding should be encouraged.
- Postpartum contraceptive advice should be given. Progestogen-containing contraceptives, injectable contraceptives and the levonorgestrel intrauterine system are safe and effective in SCD. Oestrogen-containing contraceptives should be used as second-line agents.
- Barrier methods are as safe and effective in women with SCD as in the general population.

## 2.5.C Septic abortion or miscarriage

**Introduction**

Septic abortion is defined as abortion complicated by infection. Sepsis may result from infection if organisms rise from the lower genital tract following either spontaneous miscarriage or induced abortion. Sepsis is more likely to occur if there are retained products of conception and evacuation has been delayed. Sepsis is a frequent complication of unsafe abortion involving instrumentation.

**Diagnosis**

Consider the possibility of septic abortion in any woman or girl with a history of termination of pregnancy or attempted termination. Presentation is typically with some of the following symptoms and signs: lower abdominal pain, prolonged

vaginal bleeding, tender uterus, foul-smelling vaginal discharge, purulent cervical discharge, fever and malaise.

**Treatment**

If septic shock is present, this will be shown by some of the following signs and symptoms:

- fast, weak pulse ( $\geq 100$ –110 beats/minute)
- pallor (especially of the inner eyelid, palms or around the mouth)
- sweatiness with cold or warm (vasodilated) skin
- rapid breathing (> 30 breaths/minute)
- anxiety, confusion or unconsciousness
- low blood pressure (systolic pressure < 90 mmHg is a late sign)
- reduced urine output (< 30 mL/hour).

Resuscitation then proceeds as described below.

### **Airway**

- Use an opening manoeuvre if the airway is not open or is partially obstructed. Keep the airway open. If there is improvement but the airway closes without active opening support, consider airway adjuncts to maintain the airway if the patient is unconscious (P or U on the AVPU scale).
- Suction if necessary.
- The airway may need to be maintained and protected by intubation, using experienced senior help (if available).

### **Breathing**

- Provide a high concentration of oxygen through a face mask with a reservoir bag if there is adequate spontaneous respiration.
- For patients with inadequate ventilation, respiration should be supported with oxygen via a **bag-mask**, and experienced senior help summoned (if available).

### **Circulation**

- Gain IV access.
  - Use a short, wide-bore (16- to 18-gauge) IV cannula if possible for IV access.
  - The internal jugular and external jugular veins are good options for access if peripheral access is impossible. Long saphenous vein cut-down may also be considered.
  - Try to obtain two vascular access sites to give large volumes quickly, and in case one line is lost.
- Elevate the legs by raising the foot of the bed.
- Give an initial rapid IV/IO bolus of 500 mL to 1 litre of Ringer-lactate or Hartmann's solution. It is essential that the bolus is given as rapidly as possible.
- Further boluses of 500–1000 mL will usually be required during the first hour. Once more than 2 litres have been

given IV, complications such as pulmonary or cerebral oedema may occur. If available, expert help, an anaesthetist, and the use of inotropes, sodium bicarbonate, and intermittent positive pressure ventilation (IPPV) with positive end-expiratory pressure (PEEP) are all potentially valuable.

- A fresh blood transfusion may also be important.

### **Antibiotics after taking specimens for culture if facilities are available (blood cultures, high vaginal swab and urine)**

All patients, whether shocked or not, must be given the following antibiotics without delay:

- **ampicillin 2 grams IV every 6 hours**
- **plus gentamicin 80 mg IV/IM 8-hourly or 5 mg/kg body weight IV/IM every 24 hours**
- **plus metronidazole 500 mg IV every 8 hours.**

**All of these should be continued until the woman has been fever-free for 48 hours.**

Patients who do not appear to be shocked on first examination must still be frequently observed for the early signs of shock during the first 6–12 hours. The frequency of observations can then be reduced.

Start antibiotics as soon as possible and ideally before attempting manual vacuum aspiration (MVA).

The woman or girl may also need the following:

- MVA to remove infected products of conception. This is preferable to curettage, because perforation may already have occurred, or could easily do so because of the friable nature of the uterine wall
- hysterectomy after stabilisation if the infection cannot be controlled.

## **2.5.D Obstetric haemorrhage**

### **2.5.D.i Ruptured ectopic pregnancy**

#### **Introduction**

An ectopic pregnancy is defined as the implantation of the fertilised ovum outside the uterus, usually within the Fallopian tube.

When it is a few weeks old it ruptures the tube, resulting in bleeding into the peritoneal cavity.

If the fetus is expelled ('tubal abortion') it leaves from the fimbrial end of the Fallopian tube with blood collecting as a haematoma, usually at about 8 week's gestation.

If the Fallopian tube ruptures, there is generally severe abdominal pain, with or without shock, depending on the amount of bleeding. Rupture usually occurs from 8 weeks' gestation onwards, but the timing can vary depending on the exact site of the pregnancy and the rate of growth of the pregnancy tissue. As a result rupture is possible before 8 weeks and beyond 12 weeks' gestation.

#### **Cause of ectopic pregnancy**

This is not known, but associated factors include the following:

- pelvic inflammatory disease leading to salpingitis (especially as a result of gonococcus, chlamydia or TB infection)
- if pregnancy occurs with an intrauterine contraceptive device in place (a rare occurrence)
- previous tubal surgery resulting in tubal ligation or tubal re-anastomosis
- previous ectopic pregnancy
- previous intra-abdominal infection (peritonitis).

#### **Sites of implantation**

Implantation in the Fallopian tube is most common (over 90% of cases), usually at the ampulla. Less common but

more dangerous is implantation at the interstitial end. The fetus can also rarely implant on the bowel, pelvic peritoneum, cervix or ovary.

### Clinical presentation: symptoms and signs

- Abdominal pain that is lower abdominal (which tends to be unilateral), cramping or stabbing, due to distension of the tube and peritoneal irritation from blood in the abdominal cavity. Rupture results in generalized abdominal pain, often associated with distention, guarding and rebound tenderness (peritonism).
- Shoulder tip pain, caused by blood irritating the diaphragm.
- Rectal pain or perineal discomfort caused by the presence of blood in the pouch of Douglas.
- Diarrhoea is an atypical symptom and can rarely be the main presenting complaint.
- Hypovolaemic shock occurs as soon as sufficient blood has been lost. Often there will be fainting or a feeling of faintness that requires the patient to lie down.
- A fast weak pulse (heart rate  $\geq$  100 beats/minute).
- Hypotension (a late sign after much blood has been lost: systolic pressure  $<$  90 mmHg).
- Vaginal bleeding, which can mimic a normal menses (75%):
  - usually dark, and not heavy
  - may be irregular.
- Signs and symptoms of early pregnancy are unusual. They include tiredness, nausea and/or vomiting (especially in the early morning), breast swelling and urinary frequency.
- Anaemia if there is chronic slower bleeding.

In all women and girls of reproductive age with diarrhoea and/or dizziness or fainting, do a pregnancy test and consider the possibility of ectopic pregnancy.

Abdominal examination reveals muscle guarding and rebound tenderness and probably fever. The differential diagnosis is appendicitis. There may be abdominal distension with shifting dullness if there is free blood in the abdomen.

Pelvic examination: **caution must be exercised when performing a bimanual vaginal examination if an ectopic pregnancy is possible, because of the risk of rupture during and due to the examination.** Vaginal examination may show general pelvic tenderness, sometimes with a mass in the fornix, or increased tenderness on one side. There may be cervical excitation, bluish discoloration of the vagina and cervix and/or slight uterine enlargement.

### Diagnosis

Consider this diagnosis in particular if any anaemia, shock or abdominal pain is greater than expected for the amount of vaginal bleeding. Check whether the woman or girl has any risk factors for an ectopic pregnancy.

**Differential diagnosis:** threatened miscarriage, acute or chronic pelvic inflammatory disease (PID), torsion or rupture of an ovarian cyst, acute appendicitis or peritonitis.

**Tip test:** Tilt the head down. If there is blood in the peritoneal cavity it will irritate the diaphragm; this is manifested

as shoulder tip pain. This test is useful if it gives a positive result, but a negative result does not exclude haemorrhage.

**Do a pregnancy test in all potentially fertile women and girls with abdominal pain, fainting or shock. If they are unable to provide a urine specimen, consider using a urinary catheter to obtain one.**

### Ultrasound examination

If there is a positive pregnancy test but no intrauterine pregnancy is seen on the ultrasound scan, an ectopic pregnancy is likely. The likelihood of ectopic pregnancy increases if free fluid and/or an echogenic mass is seen.

**Culdocentesis is not recommended, as it may delay surgery and introduce infection.**

### Primary assessment and resuscitation of shocked patients

**Call for help. A surgeon and anaesthetist must be urgently requested, and the operating theatre must be prepared.**

#### Airway

- Use an opening manoeuvre if the airway is not open or is partially obstructed. If there is an improvement, use airway adjuncts to support the airway or ask an assistant to hold it open.
- Suction if necessary.
- The airway may need to be maintained and protected by intubation using experienced senior help (if available).

#### Breathing

- Provide a high concentration of oxygen through a face mask with reservoir bag for patients with adequate spontaneous respiration.
- For patients with inadequate ventilation or depressed conscious level (P or U on the AVPU scale), respiration should be supported with oxygen by bag-valve-mask inflations and experienced senior help obtained, including an anaesthetist.

#### Circulation

- Elevate the legs and consider using a non-pneumatic anti-shock garment.
- Gain IV access.
- Use a short wide-bore IV cannula if possible (14- to 16-G).
- External jugular vein access is a good option if peripheral access is impossible. Long saphenous vein cut-down may also be considered, and, if the operator is adequately trained, central venous access ideally via the internal jugular vein can be extremely helpful, or the intraosseous route if this is not possible (see Section 8.4.B).
- Try to obtain two vascular access sites in order to give large volumes quickly, and in case one line is lost.
- Take blood for cross-matching of 4–6 units, full blood count, renal function tests (if available) and blood clotting.
- Give 500mL to 1 litre of Ringer-lactate or Hartmann's solution by rapid bolus while awaiting blood for transfusion.
- Remember that young healthy women and girls can lose a lot of blood before they become shocked, especially if it is a slow leakage rather than a sudden large loss of blood.

The concept of **targeted crystalloid fluid resuscitation** is important in management. Here the initial boluses of IV crystalloids required to treat shock would only be given to keep the vital organs (especially the brain, heart and kidneys) perfused before blood and, most important of all, surgery have become available.

The administration of too large a volume of IV crystalloid fluids by increasing blood pressure and damaging the coagulation system could increase bleeding by disrupting early clot formation.

If this approach is adopted when giving boluses of crystalloid to patients who are in shock due to bleeding, before blood becomes available and here, of most importance, surgical intervention, only the amount needed to keep the blood pressure at a level sufficient to perfuse the vital organs would be given. There is no clear evidence to indicate the precise blood pressure that should be achieved in a woman in shock due to a ruptured and bleeding ectopic pregnancy. However, **adequate perfusion of vital organs may best be indicated by a radial pulse that can be palpated and an alert conscious level.**

Our personal practice is to start with IV boluses of 500 mL of crystalloid or ideally blood and reassess after each bolus always aiming for urgent surgical intervention and blood transfusion. Several boluses of crystalloids may be required before these actions are possible.

### Disability

Conscious level on AVPU scale.

### Central venous access

This is valuable if skilled staff are available to undertake it. Ideally it should be achieved using a multi-lumen catheter coated with heparin, if available, with the catheter placed in the intra-thoracic inferior vena cava (IVC) or superior vena cava (SVC).

A normal central venous pressure (CVP) (see Section 2.7.A for details of measurement) is +4 to +10 cmH<sub>2</sub>O, and optimising the CVP can improve cardiac output with less risk of inducing heart failure. Take great care if the CVP is greater than 12 cmH<sub>2</sub>O, as cardiac failure may be induced by excessive IV fluids, especially if severe anaemia, malnutrition or primary cardiac disorders are present.

## 2.5.D. ii Miscarriage

### Types of miscarriage

Consider miscarriage or induced abortion in any woman or girl of reproductive age if more than 1 month has elapsed since her last menstrual period, and one or more of the following is present: bleeding, lower abdominal pain, partial expulsion of products of conception, dilated cervix, or smaller uterus than expected for gestation.

### Spontaneous miscarriage

This is the loss of a pregnancy before fetal viability (28 weeks' gestation in low-resource settings). It occurs in at least 15% of pregnancies.

The stages of spontaneous miscarriage may include the following:

- **threatened miscarriage:** pregnancy may continue

### Emergency treatment

**If the diagnosis is ruptured ectopic pregnancy with shock, order blood for transfusion and immediately prepare the operating theatre. Obtain a surgeon urgently, and proceed to urgent laparotomy while resuscitation is under way. Do not wait for blood.**

**At laparotomy, perform salpingectomy. Repair of the tube carries a major risk of future ectopic pregnancy, and should not be undertaken in resource-limited settings.**

### Autotransfusion

**If blood is unquestionably fresh and free from infection**, it can be collected after the abdomen has been opened and transfused.

When the woman is on the operating table prior to surgery and the abdomen is distended with blood, it is sometimes possible to insert a needle through the abdominal wall and collect the blood in a donor set.

Alternatively, open the abdomen and proceed as follows:

- Scoop the blood into a basin and strain it through gauze to remove all clots.
- Clean the top portion of a blood donor bag (containing anticoagulant) with antiseptic solution and open it with a sterile blade.
- Pour the mother's blood into the bag and infuse it through a filtered set in the usual way.
- If a donor bag with anticoagulant is not available, add 10 mL of 0.3 molar sodium citrate to each 90 mL of blood.

### Advice post salpingectomy for ruptured ectopic pregnancy

- If the other tube was macroscopically normal there is good chance of further successful pregnancy.
- The risk of a recurrent ectopic is 10% or more; that is 10 times the background risk therefore an early ultrasound scan is recommended (if available) as soon as a new pregnancy is suspected.
- Offer family planning advice.
- Consider treatment of pelvic inflammatory disease for the patient and her partner if there was intra-operative evidence of pelvic infection and no clear history of previous treatment.

- **inevitable miscarriage:** pregnancy will not continue and will proceed to incomplete or complete miscarriage
- **incomplete miscarriage:** products of conception are partially expelled.
- **complete miscarriage:** products of conception are completely expelled.
- **missed miscarriage:** is not associated with symptoms but found incidentally on routine ultrasound scan or when ultrasound is performed to investigate a pregnancy that is not growing as anticipated. The time from fetal demise to expulsion from the uterus varies widely and it is not uncommon for a miscarriage to remain *in situ* for many weeks.

Miscarriages can be complicated by infection (see Section 2.5.C).

### **Threatened miscarriage**

Here there is light vaginal bleeding and sometimes cramping lower abdominal pain. On examination there is a soft uterus corresponding in size to the date of the last menstrual period, and the cervix is closed.

Ideally in the presence of bleeding the viability of the pregnancy should be assessed by sonicaid/Pinnard stethoscope (if gestation permits) or by ultrasound. However, if the bleeding is light and self-limiting and ultrasound is not easily available then a conservative approach can initially be followed. Advise the woman to avoid strenuous exercise and sexual intercourse but bed rest is not necessary. Follow her up in the antenatal clinic. If the bleeding continues, assess for fetal viability and if the equipment is available perform an ultrasound scan. There is no medication that can prevent progression to a complete miscarriage.

### **Inevitable miscarriage**

This can be diagnosed clinically by the findings of an open internal cervical os and/or the passage of products of conception per vagina. If in doubt the diagnosis should be confirmed by ultrasound.

### **Incomplete miscarriage**

Here there is a history of significant bleeding (greater than menstruation), often with passage of clots and fetal tissue and varying degrees of lower abdominal pain secondary to uterine contraction. Bleeding can vary in severity and the cervix may be open or closed. Often the bleeding has reduced and almost stopped in which case, a complete miscarriage is an important differential diagnosis.

Diagnose by visualisation or palpation of products of conception in or through the cervical os, or by visualisation of retained products of conception on ultrasound.

### **Management of miscarriage**

There are three broad methods for managing miscarriage:

- 1 Expectant: No medical or surgical intervention is made but the patient is monitored for spontaneous resolution. This relies on ready access to emergency treatment and careful follow-up, and is therefore not commonly used in resource poor settings.
- 2 Medical: Medication is used to expedite or induce expulsion of the retained products of conception. In resource poor settings this is generally used only for later mid-trimester miscarriages (below).
- 3 Surgical: The uterus is surgically evacuated of the products of conception.

### **Surgical Management**

If pregnancy is less than 16 weeks this is the preferred management method where access to care and follow-up are restricted.

If the pregnancy is 12 to 16 weeks gestation with an unfavourable cervix that is likely to be difficult to dilate, then consideration should be given to:

- 1 'ripening' the cervix with misoprostol 200 to 600 micrograms around 3 to 24 hours prior to the procedure
- 2 Using medical induction as for gestations of 16 weeks and over (below).
- 3 Expectant management – especially if the patient appears to be contracting and is otherwise stable
- 4 Performing the surgery under optimal conditions: in an operating theatre with local anaesthetic, the availability

of a general anaesthetic, and with an experienced practitioner available.

If the cervix is open and/or some products have already been expelled a sponge forceps can be used to remove products of conception if they are visibly protruding through the cervix. A manual evacuation of the uterus can then be performed to ensure evacuation is complete.

- Manual vacuum aspiration (MVA) (see Figures 2.5.D.ii.1, 2.5.D.ii.2 and 2.5.D.ii.3) is the preferred method of evacuation. **Evacuation by curettage should only be used if MVA is not available.**
- If evacuation is not immediately possible and there is significant bleeding, give ergometrine 200–500 micrograms IM or misoprostol 200 micrograms orally, sublingually or rectally.
- Proceed to evacuation as soon as possible.

### **If the pregnancy is more than 16 weeks; a late miscarriage:**

A detailed account of how this can be managed is given on pages 182–3.

In summary management, as above, can be divided into Expectant, Medical and Surgical approaches.

Expectant management is most appropriate when the miscarriage is progressing on its own.

Medical management includes oxytocin, mifepristone and misoprostol.

Surgical management for retained placental tissue either by Manual Vacuum Aspiration/curettage or, after 24 weeks, manual removal of the placenta is sometimes required. It is very important that this complication, which can cause chronic vaginal bleeding, is recognised.

### **Safe evacuation of retained products**

- 1 Explain the procedure and the reasons for undertaking it, and obtain consent.
- 2 This must be a surgically aseptic procedure, with the use of sterile gloves and gown. Apply antiseptic solution (such as 0.5% chlorhexidine) to the vagina and cervix (especially the os) by first inserting a high-level disinfected or sterile speculum into the vagina and then using a sterile or high-level disinfected sponge forceps with a cotton or gauze swab and giving three applications of antiseptic.
- 3 Where possible perform the procedure in the operating theatre. This is especially indicated if there is a risk of heavy bleeding (e.g. molar pregnancy, suspected coagulation disorder), if the procedure is poorly tolerated by the patient or if the cervical os is difficult to dilate or difficult to access.
- 4 Even when bleeding is not heavy, give oxytocin 10 units IM or ergometrine 200 micrograms IM before MVA to make the uterus firmer and reduce the risk of perforation.
- 5 Prepare the MVA syringe by closing the pinch valve and pulling back on the plunger until its arms lock. In the case of large amounts of retained products (e.g. molar pregnancy), prepare two or three syringes.
- 6 Bimanually examine the uterus to assess whether it is anteverted or retroverted prior to instrumentation and to access its size.
- 7 Provide an oral analgesic, paracetamol 1 gram, and if the cervix is not dilated sufficiently to pass the MVA

catheter, prepare 20 mL of 0.5% lignocaine (**without adrenaline**) with a 3.5 cm long 22- or 25-gauge needle to perform a paracervical nerve block.

- 8 Using a Cusco's or Sims' speculum or vaginal retractor, visualise the cervix. You will need an adequate light source.
- 9 Inject 1 mL of 0.5% lignocaine into the anterior or posterior lip of the cervix, whichever has been exposed, if a tenaculum is to be used.
- 10 Apply either a tenaculum or sponge (ring) forceps (the latter do not require administration of local anaesthetic, and are less likely to tear the cervix in incomplete miscarriage) to the lip of the cervix.
- 11 If the cervix is insufficiently dilated for the MVA catheter to be passed, perform a paracervical nerve block following slight traction applied to the cervical lip to identify the junction between the cervix and the vaginal wall where injections of lignocaine are to be made. Inject 2 mL of lignocaine just under the epithelium (no deeper than 3 mm) at 3, 5, 7 and 9 o'clock positions. **Ensure that the needle is not in a vein with each injection by drawing back the needle before injection, as IV injection of lignocaine is dangerous and can cause convulsions and cardiac arrest.** Wait 2 minutes and check that the cervix is anaesthetised by pinching it gently with forceps. If the pinch is felt, wait for another 2 minutes.
- 12 Grasp the lip of the cervix with the sponge forceps and apply gentle traction. Cervical dilatation with Hegar dilators is only needed where the cervical os is not dilated and is firm. Slowly introduce the dilators (the smallest one first) into the cavity, checking carefully whether the uterus is anteverted or retroverted, until the resistance felt on passage through the closed internal os is released and the dilator is felt to pass through it into the uterine cavity. Usually a dilatation of 10–12 mm is sufficient. Ensure that the cervix is not torn or a false passage created by the dilators.

**FIGURE 2.5.D.II.1** Manual vacuum aspiration kit including cannulae of different sizes.

**FIGURE 2.5.D.II.2** Inserting the MVA cannula.

**FIGURE 2.5.D.II.3** Evacuating the uterine contents.

- 13 Pass the MVA cannula gently with a rotating movement through the cervix into the uterine cavity just beyond the internal os.

Slowly push the cannula into the uterus until it touches the fundus. Measure the depth by dots visible on the cannula and then withdraw the cannula by about 0.5 cm. Note the depth of the cavity and do not pass instruments beyond this. The risk of uterine perforation is higher in cases complicated by sepsis, or in a postpartum uterus with retained products of conception (see Section 2.5.D.iv). Also be aware that as it is evacuated the uterus generally contracts and thus the cavity will be smaller by the end of the procedure. Attach the prepared MVA syringe to the cannula and release the pinch valves, allowing the vacuum to transfer to the cannula and the inside of the uterus.

Evacuate the uterine contents by gently rotating the syringe from 10 to 12 o'clock and moving the cannula back and forth within the uterus. Do not allow the cannula at this stage to be withdrawn past the cervical os into the vagina, as the vacuum will be lost. If the vacuum is lost or the syringe is more than half full, empty it and then re-establish the vacuum. Do not hold the syringe by the plunger arms while the vacuum is present, as they may become unlocked and the plunger will then slip back into the syringe, pushing materials back into the uterus.

- 14 To ensure that all products of conception have been removed, check that red or pink foam but no tissue is seen in the cannula. The uterus will have a 'gritty' feel when the cavity is empty, and haemostasis should be achieved. The uterus may contract around the cannula. Always examine the syringe contents after the procedure. An absence of products of conception in a patient with signs of pregnancy or a positive pregnancy test and continued bleeding suggests three possibilities. Either the miscarriage was complete before evacuation, or the products are still in the uterus (in which case evacuation needs to be repeated), or there is an ectopic pregnancy. Be very careful about the third possibility.
- 15 If MVA is not available and a curette is used, undertake the procedure up to Step 11 above. Apply the curette with firm but controlled movements in all four quadrants of the uterus (anterior wall, left lateral, posterior wall and right lateral). The uterus will have a 'gritty' feel when the cavity is empty, and haemostasis should be achieved. If there is ongoing bleeding ensure that the cavity is empty with additional gentle curettage.
- 16 IV antibiotics should be given as a single dose unless

there are signs of sepsis, in which case a full course of antibiotics should be given (see Section 2.5.C). All patients should be treated prophylactically for *Chlamydia trachomatis* with either azithromycin 1 g orally stat or doxycycline 100 mg orally twice daily for 7 days.

- 17 Anti-D immunoglobulin prophylaxis, if available and affordable, should be given to women with a Rhesus-negative blood group. In well-resourced countries, a dose of 250 IU of anti-D immunoglobulin is given before 20 weeks' gestation, and 500 IU after 20 weeks' gestation.
- 18 Give paracetamol, 500 mg to 1 gram orally, if needed for pain.
- 19 If an unsafe induced abortion is suspected, examine the woman for signs of infection and uterine, vaginal, bladder or bowel injury, and thoroughly irrigate the vagina with sterile Ringer-lactate or Hartmann's solution to remove any herbs, local medications or caustic substances before MVA is undertaken (see Section 2.5.C).

### Follow-up and management after a miscarriage, especially where evacuation has occurred

Uncomplicated evacuations may not require follow-up. The patient should be encouraged to eat and drink and be mobile. She should be aware of the potential complications of miscarriage that include: retained tissue (sometimes requiring repeat evacuation), infection and haemorrhage. She should be advised to seek help if there are any symptoms suggestive of these complications, such as ongoing bleeding beyond 2 weeks, very heavy bleeding at any time, severe abdominal pain, offensive-smelling vaginal secretions, fever or malaise. Rigors or fainting potentially indicate severe complications, and the woman must return immediately to the hospital if these symptoms occur. Family planning must be discussed, and the woman advised to avoid pregnancy for at least 3 months.

In the case of mid-trimester miscarriages (>12 weeks' gestation), consideration should be given to the cause of the miscarriage as it is less common at this time and more likely to be secondary to a treatable factor. As a minimum, malaria (where endemic), syphilis and urinary tract infection should be excluded or treated.

### Uterine perforation

Uterine perforation may occur following evacuation of the uterus in either a medical or non-clinical setting. The risk of complications, such as infection, perforation, and damage to visceral organs such as bladder and bowel, is high where procedures are performed in non-clinical settings, and in such cases a laparotomy will be required along with high-dose intravenous antibiotics (see Section 2.5.C).

In most perforations where only the uterus has been damaged, the hole will heal spontaneously. Keep the woman under close observation for at least 48 hours.

### Symptoms and signs of perforation when it has occurred in a non-medical setting

These include severe abdominal pain, vaginal bleeding, weakness, and dizziness or fainting. On examination of the abdomen there will be guarding, rebound tenderness or a rigid abdominal wall. Frequently there will be signs of septic shock (see Section 2.5.A).

### Complete miscarriage

Evacuation of the uterus is not needed. Observe closely for evidence of bleeding, and follow up the woman in the clinic.

### Miscarriage beyond 16 weeks' gestation

Spontaneous miscarriage will generally result in expulsion of the complete fetus (this is also usually the case between 12 and 16 weeks' gestation) and placenta. These may be expelled together within the gestational sac or separately after rupture of the fetal membranes.

The patient may present with bleeding, pain, loss of liquor or a history of having already expelled the fetus before arrival. The examination may reveal an effacing and/or dilated cervix, bulging membranes, or fetal parts. The cervix may also be closed and the patient relatively asymptomatic despite a finding of fetal death on ultrasound. Ultrasound may reveal fetal cardiac activity despite evidence of an inevitable miscarriage.

Management of late miscarriage can be divided into Expectant and Medical management with Surgical management reserved for retained placental tissue after fetal expulsion and the rare cases where life-threatening haemorrhage occurs and delivery is not rapidly achievable by any other means.

If there are no signs of labour and especially if the cervix is unfavourable then the use of mifepristone is beneficial, but not essential if unavailable.

### Expectant management

This is best reserved for patients where the delivery/miscarriage process is clearly ongoing and is likely to occur spontaneously without medical intervention. If the delivery is urgent due to the maternal condition, the patient must be monitored closely to ensure the labour is progressing so that it can be medically augmented promptly if required.

### Medical management

If spontaneous delivery is not expected or delayed then delivery can be expedited medically. If chorioamnionitis is suspected then delivery is urgent and induction should be started without delay and the patient treated appropriately with antibiotics and other measures as indicated during the process.

The patient needs to be assessed for evidence of infection, bleeding or other associated disorders and treated accordingly.

The following investigations should be performed as a minimum: blood group and cross match, Hb, malaria RDT +/- malaria smear, urine analysis for possible infection.

If there are no signs of labour and especially if the cervix is unfavourable, then the use of mifepristone is beneficial if available but can be omitted. If the delivery is urgent then either the interval between mifepristone and misoprostol treatment can be reduced or they can be administered together.

- 1 Give mifepristone 200 micrograms orally.
- 2 Observe the patient in hospital for a period of 36 to 48 hours.
- 3 Obtain intravenous access and give misoprostol 100 micrograms vaginally or orally every 3 hours up to a total of 5 doses. Oral administration is advised following initial vaginal installation of the first dose of misoprostol and assessment, especially, in the presence of ruptured

membranes, to reduce the risk of ascending infection. A sterile technique must be followed whenever vaginal assessments are performed.

- 4 Review by a doctor if delivery has not occurred within 3 hours of the final dose.

Note: The dose of misoprostol should be reduced to 100 microgram beyond 27 weeks' gestation and to 50 microgram in women at higher risk of perforation e.g. grand-multiparae and after previous Caesarean section.

If mifepristone or misoprostol are not available, infuse oxytocin, 40 units in 1 litre of IV fluid (Ringer-lactate or Hartmann's solution) over 4 hours until expulsion of the products of conception occurs.

Following delivery, oxytocin 10IU intramuscular should be given and the patient monitored for bleeding.

If the placenta is not expelled with or immediately following the fetus, retained tissue is likely even if the placenta is eventually expelled. Have a low threshold for exploration and evacuation.

Where gestation is around 24 weeks it may be safer to remove the placenta manually as after a term pregnancy. If not possible then MVA/curettage can be used.

### Abortion

This is the deliberate termination of pregnancy before the fetus is viable.

- **Unsafe abortion** is a procedure performed by individuals who lack the necessary skills and/or in an environment that does not meet minimal medical standards. It may be attempted by 'medically' inducing the abortion or by 'surgically' expelling or removing products. The terms medical and surgical are used loosely here as 'medicines' used include highly toxic herbs as well as over-the counter medicines taken in overdose.

Likewise 'surgical' is used to describe anything from unskilled use of routine surgical instruments to self-insertion of sticks or other objects into the uterus to disturb the pregnancy. Unsurprisingly, complications following unsafe abortion are common and unsafe abortion is a major contributor to maternal mortality.

- **Septic abortion** is abortion complicated by infection. Sepsis may result from ascending infection from the lower genital tract, and is more likely to occur if there are retained products of conception and evacuation has been delayed. It is a frequent complication of unsafe abortion involving instrumentation.

### Molar pregnancy/gestational trophoblastic disease

This is relatively uncommon. Gestational trophoblastic

disease refers to molar pregnancy (complete and partial moles), choriocarcinoma and placental site trophoblastic tumour.

Complete and partial molar pregnancies are distinguished by the presence of a fetus in the partial group. Complete moles usually result from duplication of a single sperm following fertilisation of an empty ovum. There is no evidence of fetal tissue. Partial moles usually result from dispermic fertilisation of an ovum. There is generally evidence of a fetus or fetal red cells. Only complete molar pregnancy is likely to progress to choriocarcinoma.

Signs of pregnancy are exaggerated. The uterus increases in size more rapidly than normal, vomiting is often but not always severe and constant, there may be pre-eclampsia in the early part of the second trimester, and  $\beta$ HCG levels are very high. The symptoms and signs that are typically present include heavy bleeding, a dilated cervix, uterus larger than dates and softer than normal, and partial expulsion of products of conception that resemble grapes. MVA is required to evacuate the uterus (with anti-D prophylaxis in Rhesus-negative women if available and affordable). Diagnosis in low-resource settings is very difficult, and requires good-quality ultrasound and ability to monitor blood  $\beta$ HCG levels before dilatation and curettage. The products of conception should be examined visually and ideally histologically.

### Management of molar pregnancy

This is difficult and requires referral to hospital, ideally with expert facilities if these are available.

MVA will usually be required. There is a higher risk of bleeding, and therefore it is essential to cross-match blood prior to MVA.

Follow-up  $\beta$ HCG measurements, regular ultrasound and possibly chemotherapy will be needed (see below).

Chest X-ray and ideally liver function tests will also be required.

The woman should be strongly advised not to become pregnant within the next year, and family planning advice is particularly important.

**Choriocarcinoma**, a malignant condition, is the most serious form of mole. It may follow a normal pregnancy and be manifested as continuing vaginal bleeding. Metastasis may occur to the lungs and other organs, and specialist care will be required, including chemotherapy.

World Health Organization (2012) *Safe Abortion: technical and policy guidance for health systems*, 2nd edn. [http://apps.who.int/iris/bitstream/10665/70914/1/9789241548434\\_eng.pdf](http://apps.who.int/iris/bitstream/10665/70914/1/9789241548434_eng.pdf)

## 2.5.D.iii Antepartum haemorrhage

### Introduction

Antepartum haemorrhage (APH) is defined as bleeding from the uterus or vagina occurring after potential viability from 24–28 weeks' gestation. The main causes of APH are placenta praevia, placental abruption, and bleeding from cervical or vaginal lesions.

Bleeding from the cervix is common but is not usually heavy. It may be due to rapid cervical dilatation, cervical

ectropion or polyps. Ectropions and polyps may become more vascular and friable in pregnancy, predisposing to bleeding. Endo-cervical and vaginal infections such as *Chlamydia*, *Neisseria*, *Trichomonas* and *Candida* can give rise to bleeding. Cervical carcinoma is another cause of APH.

Speculum examination should be performed in order to visualise the cervix and help to assess the likely cause

**TABLE 2.5.D.III.1 Causes of major (> 500 mL) or massive (> 1500 mL) antepartum haemorrhage**

Symptoms	Clinical signs	Diagnosis	Treatment
Severe constant abdominal pain Light or heavy vaginal bleeding (or non-visible bleeding in concealed abruption) Reduced or absent fetal movements Dizziness Shortness of breath Confusion	Shock Tense and tender uterus on abdominal examination Fetal distress or absent fetal heart rate	Placental abruption	Call for surgical and anaesthetic help Oxygen Left lateral tilt or recovery position IV fluid boluses for shock + blood Cross-match 4 units of blood and freeze-dried plasma if available; transfuse prior to delivery if possible, to try to correct any clotting abnormality Deliver the fetus as soon as possible if it is viable, either by inducing labour or by Caesarean section
Vaginal bleeding that may be light or very heavy Bleeding can be precipitated by intercourse or vaginal examination No pain	Soft uterus Presenting part may be higher than expected. Malpresentation is more common Fetus may be distressed, non-viable or uncompromised with normal movements and normal fetal heart rate pattern Ultrasound will show placenta praevia <b>Do not undertake digital vaginal examination, as this can puncture the placenta and precipitate massive bleeding which may be fatal</b> Shock may be present, depending on how heavy the bleeding is and for how long it has been occurring	Placenta praevia	Call for surgical and anaesthetic help Treat shock if present, including the lateral tilt or recovery position (see above) <b>Do not undertake digital vaginal examination, as this can puncture the placenta and precipitate massive bleeding which may be fatal</b> If preterm and not bleeding too heavily, give steroids, admit for bed rest and only go for Caesarean section if there is a further bleed Cross-match ideally 4 units of blood
Continuous abdominal pain Vaginal bleeding that may be light or heavy History of a previous Caesarean section or other surgery on the uterus	Shock (especially an increasing heart rate) Tense, distended and tender abdomen Easily palpable fetal parts Absent fetal movements and heart sounds Malpresentation – transverse lie Signs of cephalo-pelvic disproportion Scar from previous surgery Haematuria	Ruptured uterus	Call for surgical and anaesthetic help Treat shock if present Cross-match ideally 4 units of blood Prepare operating theatre for laparotomy while resuscitating patient Stop oxytocin infusion if <i>in situ</i>
Heavy vaginal and other bleeding	Bleeding from sites in addition to the vagina Signs of other conditions that may be responsible, such as: <ul style="list-style-type: none"> <li>● placental abruption</li> <li>● pre-eclampsia or eclampsia (high blood pressure and proteinuria)</li> <li>● retained dead fetus</li> <li>● septicaemia, including intrauterine sepsis</li> <li>● incompatible blood transfusion</li> <li>● amniotic fluid embolism</li> </ul>	Coagulation failure	Fresh blood transfusion Blood products such as platelets, fresh-frozen plasma and cryoprecipitate if available Antibiotics if appropriate
Vaginal bleeding that is light Bleeding can be precipitated by intercourse or artificial rupture of membranes No pain	Fetal distress or death	Vasa praevia (placental blood vessels lying in the membranes and in front of the baby's head)	If diagnosed by ultrasound before labour, plan for Caesarean section

of bleeding, as well as to aid evaluation of the severity of bleeding.

Bleeding from the vagina or vulva may result from local trauma or infection. Vulval bleeding may be due to vulval varices, and may be heavy.

## Diagnosis

Important points in history taking include the following:

- Is the bleeding provoked or unprovoked?
  - Bleeding due to placenta praevia is likely to be unprovoked. However, bleeding may be precipitated by intercourse or vaginal examination.
  - Abruptio is more likely after abdominal trauma.
  - Intercourse may cause bleeding from cervical or vaginal lesions.
- Is the bleeding painful or painless?
  - Bleeding due to placenta praevia is usually painless.
  - Bleeding due to placental abruption is initially painless, but as it continues contractions will occur and eventually become tonic with constant severe pain and a woody feel to the uterus.
- Is it fresh or old blood?
- Is the bleeding light or heavy?

## Management of APH

This can be summarised as follows:

- ABC.
- Monitor vital signs.
- Gain IV access and give fluid resuscitation.
- Send blood for urgent haemoglobin, grouping and cross-matching, as well as Kleihauer test (if available).
- Catheterise the patient.
- Perform an abdominal examination: assess uterine tone, tenderness, presence of contractions, auscultation of the fetal heart.
- Do a speculum examination: assess for vaginal and cervical lesions, and severity of bleeding. If the placental site is unknown ideally an ultrasound scan should be performed first. If not possible, caution must be taken as bleeding from a placenta praevia may be exacerbated by vaginal assessment.
- Listen to the fetal heart.

Insert a venous cannula if any of the following are present: active bleeding, contractions, tenderness or increased tone of the uterus. If the patient is shocked, proceed to assessment and resuscitation (see below).

**Investigations:** haemoglobin, platelet count, clotting tests, urea and electrolytes, liver function tests. Cross-match 4 units if there is major (> 500 mL) or massive (> 1500 mL) haemorrhage or if the bleeding is rapid; group and save if there is loss of < 500 mL and the bleeding is not ongoing. Perform a Kleihauer test, if available, if the woman is Rhesus negative or if there is major abdominal trauma.

## Management of the different causes of APH

### Placenta praevia

Placenta praevia is an abnormally situated placenta in the lower uterine segment. It presents with painless bleeding,

often with no precipitating factor. Bleeding may be heavy and is bright red.

FIGURE 2.5.D.III.1 Increasing levels of low implanted placentas.

### Prevention and protection

- Early detection of placenta praevia is very important to prevent serious bleeding.
- **Any bleeding during pregnancy must be investigated by an ultrasound scan.**
- Mothers with placenta praevia should have immediate access to an obstetric unit with facilities for Caesarean section.
- Mothers over 28 weeks pregnant with a placenta praevia and bleeding should stay in hospital until delivery by Caesarean section, or live very near to an obstetric unit that can perform Caesarean section.

**Never allow a digital vaginal examination to be undertaken on a patient with known or suspected placenta praevia, as it can precipitate massive vaginal bleeding.**

**Careful speculum examination can help to exclude bleeding from the cervix or vagina but if placenta praevia is known to be present then undertake with extreme caution, ideally in the operating theatre.**

### Placental abruption

- Placental abruption refers to the premature separation of a normally situated placenta. The bleeding may be concealed or revealed, or mixed. It may be partial or complete (if complete, the fetus will be dead).
- The characteristic initial symptom is painless bleeding, which can be concealed or be associated with vaginal bleeding. As abruption becomes worse, contractions will occur and eventually become tonic with constant severe pain and a woody feel to the uterus. At this stage there will usually be shock, severe abdominal pain, and tenderness over the uterus. In early bleeding the uterus may still be soft to touch, but as the bleeding progresses it has a hard 'woody' feel due to uterine contraction. It may be difficult to palpate the fetal parts, the uterus may be large for dates and there may be signs of fetal distress or intrauterine fetal death. It is possible for large bleeds to be asymptomatic and even small bleeds can occasionally result in fetal death.
- Disseminated intravascular coagulation (DIC) is a common complication. A large placental abruption can occur without any visible vaginal blood loss (concealed haemorrhage).
- Remember that blood loss is invariably underestimated. Young healthy women will compensate and maintain their blood pressure until they lose around 20% of their circulating volume.

- The main risk factor for placental abruption is a previous abruption. Increased maternal age, maternal hypertension and trauma also increase the risk.

### Ruptured uterus

Uterine rupture is full-thickness separation of the uterine muscle and the overlying visceral peritoneum, sometimes associated with extrusion of the fetus, placenta or both into the abdominal cavity.

- Bleeding from a ruptured uterus can occur either before (rare) or after the onset of labour, although the vast majority occur during labour itself.
- Risk factors for rupture include, obstructed labour due to cephalo-pelvic disproportion, multiparity (especially grand-multiparity), previous uterine surgery (including myomectomy and Caesarean section), and use of uterotonics (including misoprostol and oxytocin).
- A previous Caesarean section scar may rupture during labour. However, obstructed labour even without a uterine scar, particularly in a woman of high parity, may also cause uterine rupture.
- Excessive doses of oxytocin during labour can precipitate uterine rupture and oxytocin should be used with particular caution in multiparous women, especially if it is being used to augment rather than induce labour. Any mother who is receiving this drug during labour should be assessed closely for contraindications before its administration, and should not be left alone.
- **Extra careful consideration must be given to the administration of oxytocin in labour to a woman with a uterine scar, because of the increased risk of uterine rupture. This applies to women with previous myomectomy as well as to those with a previous Caesarean section.**
- **In any setting, including resource limited settings, women with uterine scars should only receive oxytocin before delivery when a high level of supervision is available.**
- Ideally, always use a burette in-line giving set to administer IV oxytocin, to avoid over-dosage.
- Rupture of the uterus can also occur following violence or major trauma.

### Symptoms and signs

- Characteristically there is pain and tenderness over the uterus, with blood loss vaginally and cessation of contractions.
- Uterine rupture usually presents with shock, which is partly due to blood loss and partly due to increased vagal nerve stimulation (so there may be a slow pulse rather than a fast one). The baby is usually dead or has severe fetal distress.
- There may be a change in the nature of the pain in labour, from severe intermittent pain to a constant pain.
- Vaginal bleeding may or may not be present. Bleeding from a ruptured uterus can fail to drain vaginally due to an impacted fetal head, and usually the majority of bleeding is intra-abdominal in this situation.
- Maternal shock can be made worse by dehydration, exhaustion and acidosis if prolonged obstructed labour has preceded the rupture.
- The abdomen is tender to palpation, and the fetal parts can be too easily palpable.
- On vaginal examination, the presenting part may be

high or impacted; the fetal head may have retreated into the uterus.

- There may be a marked maternal bradycardia (< 60 beats/minute) due to increased vagal tone.
- The main differential diagnosis is placental abruption.

### Management

- 1 Suspect uterine rupture in any patient with risk factors such as previous Caesarean section.
- 2 Primary assessment, resuscitation and emergency treatment for shock (see below).
- 3 Call the obstetrician and anaesthetist.
- 4 Obtain consent and prepare the operating theatre.
- 5 Perform urgent laparotomy.
- 6 Give prophylactic IV antibiotics (ampicillin, gentamicin and metronidazole).

For a discussion of the dangers of oxytocin during labour, and its management and contraindications, see above (and see Section 2.5.F).

### Vasa praevia

- This is an uncommon but life-threatening condition for the fetus or neonate. In vasa praevia, fetal blood vessels run over or close to the cervix beneath the presenting part, unprotected by Wharton's jelly or placental tissue. These vessels are vulnerable to laceration and compression, most commonly at the time of delivery.
- Fetal or neonatal death can occur due to exsanguination or asphyxiation.
- Antenatal diagnosis can be made only by skilled ultrasound examination. Caesarean section is then needed to reduce the high mortality rate.

### Failure of blood clotting

This may be due to a pre-existing coagulation problem, or to complications of the pregnancy causing excessive bleeding and disseminated intravascular coagulation (DIC) (consumption of the clotting factors).

Obstetric causes include the following:

- placental abruption
- pre-eclampsia or eclampsia
- retained dead fetus
- septicaemia, including intrauterine sepsis
- incompatible blood transfusion
- amniotic fluid embolism.

### Primary assessment and resuscitation and secondary assessment and emergency treatment for bleeding in pregnancy

In any patient with vaginal bleeding and known or possible placenta praevia, a vaginal assessment should be avoided and performed with extreme caution if deemed to be essential. Ideally an ultrasound should be used to confirm the placental site.

The aims are as follows:

- to prevent shock and disseminated intravascular coagulation
- to achieve intact fetal survival if viability is possible in the circumstances.

**Call for experienced obstetric and anaesthetic assistance (if available) and ensure that the operating theatre is ready**

### Airway

- Open the airway using chin lift or jaw thrust techniques if it is closed or partially obstructed. If there is an improvement, keep the airway open using either an assistant or an oropharyngeal airway if the patient is unconscious and this is tolerated without gagging.
- Suction if necessary.
- The airway may need to be secured by intubation using experienced senior help (if available).

### Breathing

- Normal respiratory rates in a pregnant mother at rest are 15–20 breaths/minute. Tachypnoea can be due to acidosis.
- Provide high-flow oxygen by face mask with reservoir bag for adequate spontaneous respiration regardless of SaO<sub>2</sub>. This increases fetal oxygen delivery as well as improving maternal tissue oxygenation.
- If ventilation is inadequate, especially when there is a depressed conscious level (P or U on the AVPU scale), airway and breathing should be supported by bag-valve-mask inflations with high-flow oxygen, and experienced senior help should be called, including an anaesthetist if available.

### Circulation

- Normal heart rates in a pregnant mother at rest are 60–90 beats/minute.
- Normal blood pressure in a pregnant mother at rest is 95/60–135/85 mmHg.
- Remember to put the patient in the left lateral tilt position and elevate the legs.
- Monitor the heart rate and blood pressure, and reassess regularly. Aim to keep the heart rate at  $\leq 110$  beats/minute and the systolic blood pressure at  $\geq 100$  mmHg.

**Recognise the signs of hypovolaemia.** These include the following:

- tachycardia
- tachypnoea
- cold, pale, sweaty and possibly cyanosed skin
- alteration of mental state: confusion or unconsciousness
- fall in urine output to less than 30 mL/hour
- narrowed pulse pressure
- hypotension (this is a late sign).

Healthy women and girls who are pregnant can maintain a normal blood pressure when large volumes of blood are lost. Most, but not all, will demonstrate tachycardia if they are bleeding significantly, but bradycardia may also be observed.

**Remember that young healthy women can lose a lot of blood before they become shocked, especially if it is a slow trickle rather than a sudden large loss.**

### Restore circulating volume

- Put the mother in the left lateral tilt or recovery position to minimise the effects of compression of the inferior vena cava or aorta. Lateral tilt can be achieved by using a pillow, blanket or rolled up towel. A wedge may be

used during obstetric procedures. Assistants can also manually displace the uterus.

**FIGURE 2.5.D.III.2** Manual displacement of uterus and left lateral tilt.

- Gain IV access and take blood for full blood count, cross-matching and blood clotting measurement. If IV access is not possible, consider intra-osseous needle insertion (see Section 8.4.B).
  - Use a short wide-bore IV cannula if possible, either 14G (usually orange) or 16G (usually grey).
  - External jugular vein access is a good option if peripheral access is impossible. Long saphenous vein cut-down may also be considered. If adequately trained personnel are available, central venous access, ideally via the internal jugular vein, can be extremely helpful. If access is not possible, consider intra-osseous needle insertion (see Section 8.4.B).
  - Try to obtain two vascular access sites to give large volumes quickly, and in case one line is lost. Do not waste time, and as soon as the first IV cannula is in place, give an IV fluid bolus.
  - Take blood for cross-matching (ideally 4–6 units), full blood count, renal function tests (if available), and blood clotting.
- Elevate the legs.
- Give an initial IV bolus of 500 mL to 1 litre of Ringer-lactate or Hartmann's solution as fast as possible using a three-way tap and 20- to 50-mL syringes to push in as rapidly as possible. If reassessment of the circulation shows little or no improvement, then a further 500 mL should be given and followed by blood transfusion as soon as this is available. (A normal adult has a circulatory blood volume of 5 litres, and during pregnancy this increases by 40% to 7 litres.)
- Apply an anti-shock garment (if available) to help maintain adequate central circulation.

Tranexamic acid can be of benefit in patients with continued bleeding. The loading dose is 1 gram over 10 minutes followed by an IV infusion of a further 1 gram over 8 hours. The slow IV bolus dose is given by injecting 1 gram of tranexamic acid into a 100-mL bag of 0.9% saline and letting it run through over about 10–20 minutes (the exact timing is not crucial). The 8-hour infusion is given by injecting 1 gram of tranexamic acid into a 500-mL bag of 0.9% saline and giving it over 8 hours (approximately 60 mL/hour).

- Ensure adequate transfusion; the best way to resuscitate the fetus is to resuscitate the mother. Inadequate

transfusion is common, especially in cases of placental abruption.

- A central venous pressure (CVP) line can aid the decision as to whether more fluid is needed. However, insertion should not delay initial resuscitation, and must be undertaken by a competent person. If peripheral access is inadequate, this route may be used for volume replacement. If DIC is established, CVP insertion is more hazardous and the subclavian vein should be avoided, because it is not externally compressible.
- If shock is accompanied by a bradycardia of less than 60 beats/minute (e.g. in a patient with a ruptured uterus), give atropine 500–600 micrograms as an IV injection.

**Blood products**

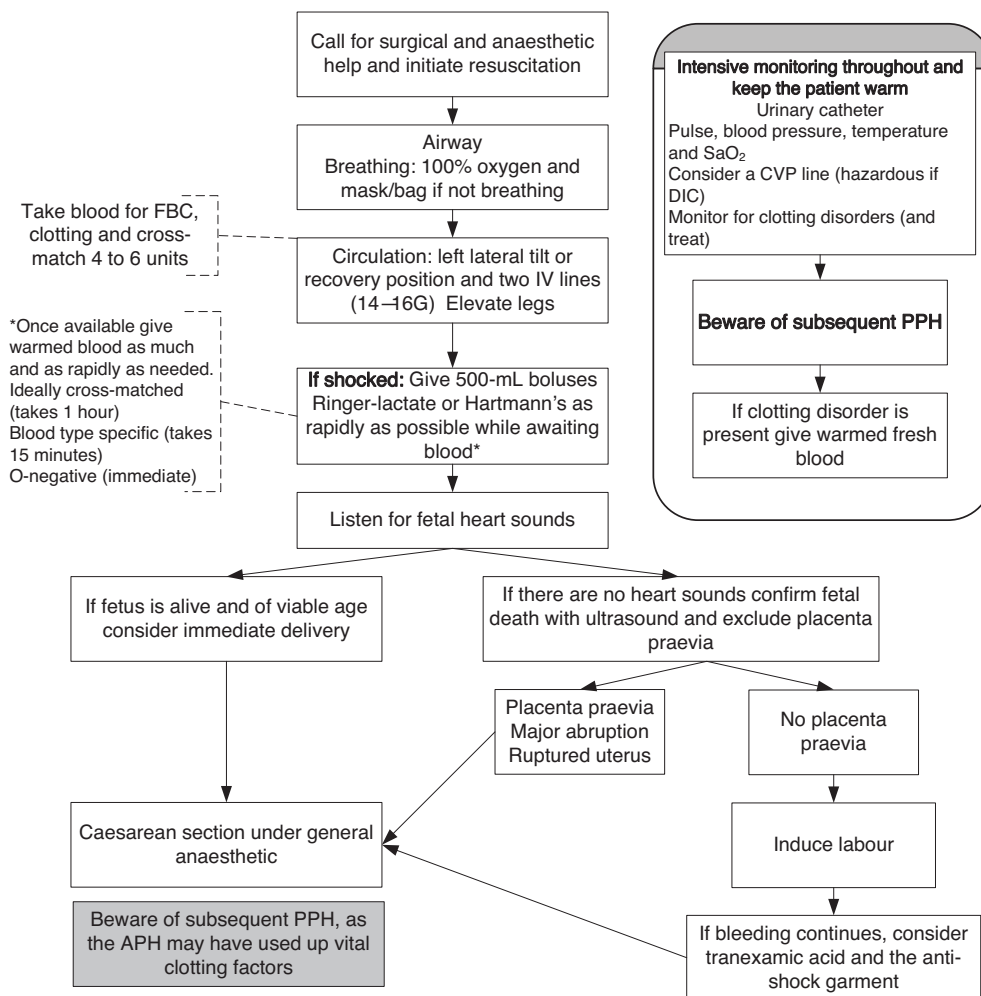

- Fresh whole blood is preferable for managing obstetric haemorrhage.
- Use cross-matched blood where available except in an immediately life-threatening emergency, when group-specific blood should be used, as cross-matching may take up to an hour.
- The patient’s blood group should be established during pregnancy, to facilitate the provision of blood when it is needed.
- All large-volume infusions should be warmed. In

particular, do not infuse cold fluid through a CVP line. The patient should also be kept warm, as hypothermia will exacerbate poor peripheral perfusion, acidosis and coagulation abnormalities. Any benefits of blood filters may be outweighed by their deleterious effect on the speed of transfusion. A good way of warming blood is to place the cold bag under the clothes of a relative next to their skin until the blood is warmed.

- Hand-inflated pressure bags are effective for giving blood and other fluids quickly (see Figure 2.5.A.5 on p. 170).

**Identify and treat any blood clotting disorders.**

- Assess bedside clotting: coagulopathy is defined as failure of a clot to form after 7 minutes, or formation of a soft clot that breaks easily (see Section 7.5 for details of whole blood clotting time measurement). Suspect and aggressively treat blood clotting disorders using warmed fresh blood, platelets (if the platelet count is  $< 50\,000 \times 10^9$ ), fresh-frozen plasma (15 mL/kg) and cryoprecipitate as appropriate and if available.
- Freeze-dried plasma is being used in the military in adverse conditions, as it is shelf stable for 2 years and easily reconstituted with sterile water within minutes. It would be a very useful addition to the emergency stores

**FIGURE 2.5.D.III.3** Pathway of care for massive antepartum haemorrhage (APH). FBC, full blood count; CVP, central venous pressure; DIC, disseminated intravascular coagulation; PPH, postpartum haemorrhage.

in resource-limited countries where the use of fresh or frozen plasma presents major storage problems.

- Urinary catheterisation is needed for measurement of hourly urine output. Aim for a rate of more than 30 mL/hour.

When the patient is stable, move her to a place where there is adequate space, light and equipment to continue resuscitation and treatment.

### Fetal assessment

When the mother has been resuscitated:

- listen for fetal heart sounds
- if significant haemorrhage has occurred and the fetus is considered viable after birth in the prevailing circumstances, consider immediate delivery **only if this is safe for the mother.**

### Anaesthetic issues

Cardiovascular instability is a relative contraindication to spinal anaesthesia.

- Rapid sequence induction agents with minimal peripheral vasodilator action, such as ketamine 1–2 mg/kg, should be considered.
- Adrenaline and atropine should be readily available in case cardiovascular collapse occurs on induction. Ventilation with high oxygen concentrations may be needed until the bleeding is controlled.
- Volatile agents have been associated with increased blood loss due to their relaxant effects on uterine muscle. Anaesthesia should be maintained with IV agents (usually ketamine) if uterine atony is a problem.
- If spinal anaesthesia is used, compensatory lower limb vasoconstriction is abolished, so profound hypotension may occur.

## 2.5.D.iv Postpartum haemorrhage

### Introduction

The definition of a postpartum haemorrhage (PPH) is blood loss of more than 500 mL from a vaginal birth and more than 1 litre after a Caesarean section. It is common, occurring in 1–3% of all pregnancies. **Globally it causes 25–50% of maternal deaths, and is the leading cause of death in low-resource settings.**

Estimates of blood loss are inaccurate and tend to be low, often around half the actual loss. Blood is mixed with amniotic fluid and sometimes with urine. It is also dispersed on sponges, towels and linen, in buckets and on the floor.

The importance of any given volume of blood loss varies depending on the mother's haemoglobin level. A mother with a normal haemoglobin level will tolerate blood loss that would be fatal for an anaemic woman. This is why it is essential to ensure that every woman who reaches labour has an adequate haemoglobin level.

**Even healthy non-anaemic women can have catastrophic blood loss.**

Bleeding may occur at a slow rate over several hours, in which case the condition may not be recognised until the mother is shocked. Previously healthy women can compensate for substantial blood loss until a relatively late stage.

### Delivery options

- Diagnose and treat the source of bleeding.
- Perform Caesarean section for major abruption or placenta praevia.
- Induce labour if the fetus is dead, there is no placenta praevia, the mother is stable and there is no significant ongoing blood loss.
  - Urine output should be monitored hourly and Caesarean section considered if labour does not become established fairly quickly. The longer the dead fetus remains *in utero*, the greater the likelihood of development of DIC.
  - **Expect and be prepared for massive postpartum haemorrhage, whether the baby is delivered vaginally or by Caesarean section.** In cases of severe APH that require surgery, discuss the possibility of hysterectomy.

**It is often APH that weakens and PPH that kills, because APH uses up the clotting factors and platelets, leaving the woman in danger if PPH follows soon afterwards.**

If no safe operating theatre facilities for Caesarean section are present, give oxygen, transfuse fresh blood and transfer the patient as soon as she is safe and stable. Ensure that IV fluids are in place, catheterise the patient, and ensure that she is nil by mouth.

### Monitoring

Essential monitoring should include pulse rate and volume, blood pressure, respiratory rate, oxygenation (SaO<sub>2</sub> if available), temperature and fluid balance (with a urinary catheter). Regular checks of the haematocrit, clotting studies and blood gases will help to guide resuscitation.

Monitor blood glucose levels and treat any hypoglycaemia.

Risk assessment in the antenatal period does not necessarily predict women who will have PPH. However, identification and treatment of anaemia antenatally will allow women to better withstand life-threatening PPH.

### Prevention of PPH

#### Active management of the third stage of labour

This is essential for prevention of PPH, and it consists of four possible interventions:

- 1 a prophylactic uterotonic drug after delivery, after checking that there is not a second twin present.
- 2 early cord clamping and cutting
- 3 controlled cord traction
- 4 uterine massage after delivery of the placenta.

#### Prophylactic uterotonic drug after delivery

This is the most important intervention. Oxytocin 10 IU IM or, especially if the mother is shocked, 5 IU by slow (over 1–2 minutes) IV injection is the first choice because it causes uterine contractions to prevent atony rapidly and with minimal adverse effects. Atony is the most common cause of PPH (around 80% of cases). Where oxytocin is

unavailable or does not work, other uterotonic drugs should be used, including:

- ergometrine 200 or 500 micrograms IM or misoprostol 600 micrograms sublingually or orally if the mother is fully conscious
- misoprostol 800 micrograms rectally if the mother is drowsy or unconscious.

All uterotonic drugs should be given within 1 minute of the complete birth of the fetus, to aid separation of the placenta by enhancing uterine contractions and reducing the risk of bleeding from an atonic (relaxed) uterus. **It is essential that, before giving such drugs, you are certain there is not another fetus in the uterus.**

Ensure that both oxytocin and ergometrine are protected from heat damage by paying close attention to the cold chain and their storage, otherwise they may not be effective. Ideally oxytocin should be stored in a fridge, but it can be kept at 15–30°C for 3 months. Oxytocin must never be frozen. Ergometrine should always be stored in a fridge at 2–8°C. Misoprostol can be stored at ambient temperature.

**Remember that ergometrine is contraindicated in heart disease, hypertension, pre-eclampsia and eclampsia, as it raises the blood pressure by vasoconstriction, which increases the risk of cerebrovascular accidents.**

#### Early cord clamping and cutting

This is not an essential part of the active management of the third stage of labour, and it is no longer recommended unless the infant needs resuscitation.

#### Controlled cord traction

This is optional where delivery is undertaken by a skilled birth attendant, but contraindicated if a skilled attendant is not available. Details are given in Section 2.3.

#### Strong uterine massage

This should always be undertaken immediately after delivery of the placenta until the uterus is contracted and remains so. Check the state of contraction of the uterus every 15 minutes for 2 hours, and repeat the massage if at any time the uterus becomes soft and relaxed.

**FIGURE 2.5.D.IV.1** Strong massage applied to cause uterus to contract.

#### The third stage

**FIGURE 2.5.D.IV.2** The third stage.

**FIGURE 2.5.D.IV.3** The uterus during the puerperium.

In order to prevent PPH during or after Caesarean section, the use of oxytocin plus cord traction is recommended in preference to manual removal of the placenta.

#### How to manage the third stage of labour if uterotonic drugs are not available

Unfortunately it is not uncommon for hospitals to run out of uterotonic drugs. In this avoidable and dangerous situation, expectant and/or physiological management should be undertaken.

- 1 Place the baby on the mother's breast.
- 2 Leave the cord alone.
- 3 Observe for the following signs of placental separation:
  - a small gush of blood
  - a lengthening of the cord at the introitus
  - the mother feeling uncomfortable, feeling a contraction and wanting to 'bear down'.

Most placentas separate within 1 hour of birth. If this does not happen, seek help.

- 4 Deliver the placenta.
  - Sit the mother upright.
  - Encourage her to bear down with a contraction (only after placental separation).
  - Catch the placenta. If membranes are dragging behind it, gently twist a few turns and with slight traction and an up-and-down movement deliver the placenta plus membranes.

Controlled cord traction should not be undertaken prior to

TABLE 2.5.D.IV.1 Diagnosis of causes of PPH

Symptoms	Signs	Possible diagnosis
Immediate heavy bleeding after birth	Uterus soft and not contracted	Atonic uterus
Immediate heavy bleeding after birth	Uterus contracted	Trauma to cervix, vagina or perineum
Bleeding which may be light if clot is blocking cervix	Placenta not delivered within 30 minutes of birth	Retained placenta
Bleeding which is usually light but continues for many hours	Portion of placenta missing Uterus contracted	Retained placental parts
Bleeding for more than 24 hours	Portion of placenta missing Foul-smelling lochia may be present Fever may be present Severe anaemia	Retained placental parts with or without infection
Lower abdominal pain of varying intensity Immediate but usually light bleeding	Uterus not felt on abdominal palpation Inverted uterus may be seen at vulva Bradycardia may be present Shock	Inverted uterus
Usually during labour there has been a change from intermittent labour contractions to a constant pain which may become less after rupture has occurred  Sometimes an oxytocin drip is in place Vaginal bleeding which may be light or heavy History of a previous Caesarean section or other operation on the uterus	Shock Abdominal distension Tenderness over uterus	Ruptured uterus (more likely before delivery of the baby)

the separation of the placenta in the absence of uterotonic drugs.

### Monitoring after the placenta has been delivered by active or expectant management

- 1 Monitor the blood pressure, pulse and state of the uterus (i.e. whether it is contracted) every 15 minutes for 2 hours after delivery of the placenta.
- 2 Examine the placenta for completeness.

## Causes of PPH

### Primary PPH

This occurs within 24 hours of birth, and in around 80% of cases is due to uterine atony.

**Remember the 4 T's: Tone, Tissue, Trauma, Thrombin.**

- **Tone:** atonic uterus – failure to contract after birth.
- **Tissue:** retained placenta or placental fragments.
- **Trauma:** ruptured uterus, or trauma to the cervix, vagina or perineum.
- **Thrombin:** clotting defects, notably disseminated intravascular coagulation (DIC).

Remember also the following:

- **Haemorrhage may be concealed within the uterus or within the abdominal cavity.**
- **A ruptured uterus** can cause concealed bleeding, as can **bleeding following Caesarean section.**
- **An inverted uterus is associated with PPH.**
- **Any degree of PPH is dangerous if there has been severe anaemia before delivery.**

### Secondary PPH

Secondary PPH (occurring from 24 hours or more after delivery up to 6 weeks after birth) is commonly associated with retained products of conception that undergo necrosis, become infected and prevent involution (sustained contraction) of the uterus. A **fever** suggests an infective component.

See p. 198 for details of the management of this problem.

### Factors that predispose to PPH

These include the following:

- previous APH
- retained products of conception
- trauma to the uterus or birth canal (e.g. from instrumental delivery)
- uterine over-distension (e.g. due to multiple pregnancy or polyhydramnios)
- grand multiparity
- prolonged labour.

### Management of PPH

**First call for help (this must include a surgeon and an anaesthetist), palpate the uterus and massage it strongly and immediately, as it is most likely that an atonic uterus is the cause (see Figure 2.5.D.iv.1 and below).**

### Airway and breathing

- Ensure that the airway is open and remains so.
- Provide **high-flow oxygen** through a face mask with reservoir bag if there is adequate spontaneous respiration.

Give 100% oxygen (using a mask with reservoir and high flow rate).

- For patients with inadequate ventilation or depressed conscious level (P or U on the AVPU scale), respiration should be supported with oxygen via a **bag-valve-mask**, and experienced senior help should be summoned (if available).

## Circulation

### Primary assessment denoting shock

- Fast, weak pulse ( $\geq 100$ –110 beats/minute). Normal heart rates in a pregnant mother at rest are 60–90 beats/minute. Tachycardia is an early sign of shock.
- Low-volume (weak) pulse.
- Pallor (especially of the inner eyelid, palms or around the mouth).
- Sweatiness or cold clammy skin.
- Prolonged capillary refill time ( $> 3$  seconds).
- Rapid breathing ( $> 30$  breaths/minute). Normal respiratory rates at rest are 15–20 breaths/minute; tachypnoea can be due to acidosis.
- Low blood pressure (systolic pressure  $< 90$  mmHg) is a **very late sign**. Healthy women and girls can maintain a normal or even high blood pressure while losing large volumes of blood.
- Nausea with or without vomiting.
- Anxiety, confusion or unconsciousness.
- Reduced urine output ( $< 30$  mL/hour). Urinary catheterisation is needed for measurement of hourly urine output if the patient is shocked (normal output is  $> 30$  mL/hour).

**Procedures for stopping haemorrhage must be started immediately and then undertaken in parallel with IV fluid resuscitation.**

### Measures to stop further haemorrhage due to uterine atony

#### Rubbing up a contraction

Poor contraction of the uterus after delivery is the commonest cause of PPH. **Rub up a contraction of the uterus (do not just pinch the skin).**

**FIGURE 2.5.D.IV.4** Contraction of uterine muscle fibres squeezes blood vessels shut.

As the muscle fibres are stimulated to contract, they compress the blood vessels running between the muscle fibres and help to stop bleeding.

### Abdominal massage of the uterus

If the uterus is atonic, a contraction may be rubbed up by abdominal massage.

- Massage the fundus in a circular motion with the cupped palm of your hand until it is contracted.
- When it is well contracted, place your fingers behind the fundus and push down in one swift action to expel clots.

### Uterotonic drugs

These drugs make the uterus contract.

Give 10IU of oxytocin IM or 5IU IV slowly, especially if the patient is already shocked, and repeat after 5 minutes if they are still bleeding and/or the uterus is not contracted. This is the drug of first choice.

Oxytocin starts to work 2–3 minutes after IV injection, but has a relatively short duration of action, and an infusion will be needed to maintain a contracted uterus. Following an oxytocin bolus, give an IV infusion of oxytocin 40IU in 500 mL (60 drops/minute with a standard IV giving set where 20 drops = 1 mL) or 1 litre (120 drops/minute) of Ringer-lactate or Hartmann's solution over 4 hours.

Side effects include hypotension (due to vasodilatation when given as a rapid IV bolus) and fluid retention.

If the mother does not have eclampsia, pre-eclampsia or hypertension, **ergometrine** 200 to 500 micrograms IM in addition may help uterine contraction. If the first dose of oxytocin does not stop bleeding within a few minutes, give **misoprostol** (which, unlike oxytocin and ergometrine, does not need to be kept in a refrigerator). It is given rectally as 4 × 200 microgram tablets or pessaries (800 micrograms in total) or, if the patient is conscious, orally as 3 × 200 microgram tablets or 2 × 200 micrograms of powder sublingually.

Ergometrine, either as part of Syntometrine (oxytocin 5IU and ergometrine 500 micrograms IM) or alone, is contraindicated in pre-eclampsia, as its hypertensive action increases the risk of convulsions and cerebrovascular accidents.

### Urinary catheterisation

This may help the uterus to contract.

### Bimanual uterine compression

If heavy PPH continues despite uterine massage, and with the placenta already delivered, this procedure can be very effective. If the placenta is still in place priority should be given to removing it as soon as possible.

- You must wear sterile or disinfected gloves (ideally long versions up to the elbow).
- Introduce your right hand into the vagina, clench your fist with the back of your hand positioned posteriorly and your knuckles in the anterior fornix.
- Place your other hand on the abdomen behind the uterus and squeeze the uterus firmly between both hands.
- Continue compression until the bleeding stops (i.e. there is no bleeding when compression is released), and the uterus is contracted.

Although this procedure is painful, it is highly effective and can significantly reduce or even successfully treat uterine

haemorrhage. Therefore, if the bleeding is profuse, and the number of staff attending the patient allows, it is a good idea for one member of the team to commence bimanual compression while uterotonic drugs are prepared and given, and initial fluid resuscitation commenced.

Bimanual compression

FIGURE 2.5.D.IV.5 Bimanual compression.

### Aortic compression

If bleeding still persists, apply aortic compression.

- Apply downward pressure with a closed fist (with your thumb outside the fist) over the abdominal aorta directly through the abdominal wall.
- The point of compression is just above the umbilicus and slightly to the left.
- Aortic pulsations can be felt through the anterior abdominal wall in the immediate postpartum period. Press the aorta down on to the vertebral column.
- With your other hand, palpate the femoral pulse with four fingers parallel to and just below the inguinal ligament to check the adequacy of compression.
- **If the pulse is palpable during compression, the pressure exerted by the fist is inadequate.**
- **If the femoral pulse is not palpable, the pressure exerted is adequate.**

FIGURE 2.5.D.IV.6 Aortic compression.

Continue until the bleeding stops. If it does not stop, continue to exert pressure while transferring the mother to a facility where expert help is available.

### Uterine tamponade

Uterine packing with a hydrostatic balloon such as a Rusch balloon or condom over a simple in–out urinary catheter can

help to control haemorrhage from an atonic uterus that does not respond to the above measures. The uterus may also be packed with a sterile pack or gauze, although it is important to ensure any gauze used is tied together, counted carefully, and extended into the vagina to facilitate removal.

A condom catheter, which is inserted into the uterus as a sterile procedure and filled with 250–500 mL of sterile Ringer-lactate or Hartmann's solution or 0.9% saline to create a uterine wall tamponade, is an effective way of stopping uterine bleeding that is continuing despite the use of uterotonic drugs and procedures (see Figure 2.5.D.iv.7). **It is important to check that the balloon is fully inside the uterus as it is inflated, and to take measures to ensure that it does not become displaced into the vagina.** This can be done by packing the vagina with a pack or gauze swab.

FIGURE 2.5.D.IV.7 Condom catheter inflated with sterile IV fluid.

Leave the balloon in position until the bleeding has stopped for up to 24 hours (the exact time needed is unclear). Before removing it, ensure that at least 1 unit of cross-matched blood for possible transfusion is available, with the possibility of making more available if required. Theatre staff and an anaesthetist should be warned in case bleeding occurs when the catheter is removed. One approach is to remove 50 mL every 30 minutes until it is fully emptied. Observe the patient closely for 4 hours after removal of the catheter, looking at vaginal blood loss and vital signs. IV antibiotics should be given when the catheter is put in place, and should be continued for 48 hours.

An alternative new approach (the EgAr device from The Gambia) useful in low resource settings involves inflating a condom with air rather than IV fluids (see Figure 2.5.D.iv.8). It includes the following components:

- a firm type of urinary catheter (used for temporary insertion and drainage of urine) rather than an indwelling Foley catheter, which is easily constricted
- a latex male condom from a sterile and unbroken pack
- the inflator (with its tube) of an aneroid blood pressure machine
- a surgical suture (preferably black silk) for tying the condom to the catheter
- a piece of sterile thread for tying the end of the condom after inflation to stop the escape of air

- sterile gauze to pack the vagina and maintain the inflated condom in the uterine cavity.

**FIGURE 2.5.D.IV.8** Condom catheter inflated with air.

Using a sterile procedure throughout, the catheter is inserted into the condom, with the end part of the condom touching the tip of the catheter. The lower part of the condom is tied to the catheter using suture thread and inserted into the uterine cavity. The condom is then held in place inside the uterine cavity using the non-dominant hand, the lower end of the catheter is connected to the inflator of the blood pressure machine (with the valve closed), and the condom is then inflated with air until the bleeding is either arrested or greatly reduced. Pneumatic pressure is rapidly achieved after a few inflations. The uterus gradually increases in size (this can be seen abdominally) as the condom is being inflated, and the woman should experience no more than slight discomfort. Excessive inflation of the condom must be avoided, and pain indicates that too much air is being forced into the condom. If this happens, the volume of air can be easily reduced by loosening the valve of the inflator.

Compared with inflating the condom with fluid (assuming that IV fluid is available, which is not always the case), this technique is much faster and easier, and good control is achieved by using the valve on the inflator.

### Fluid resuscitation

The aim of fluid resuscitation is to maintain perfusion of vital organs (the brain, heart and kidneys) during the manoeuvres described above.

- Elevate the patient's legs (raise the foot of the bed).**
- Try to obtain two vascular access sites in order to give large volumes quickly, and in case one line is lost. Insert a wide-bore IV cannula (ideally two) (14- to 16G) and send blood for a full blood count, cross-matching (4–6 units) and clotting. If peripheral veins are difficult to access, the external jugular vein or long saphenous vein cut-down are good alternatives. If a skilled person is available, an internal jugular vein central line can be helpful, especially if the central venous pressure can be measured.
- If venous access is not possible, consider inserting an intra-osseous line using the newly available drill system (see Section 8.4.B).
- Give 500 mL of O-negative blood if it is immediately available. If not, standard practice is to give an initial **rapid** IV bolus of 1 litre of Ringer-lactate or Hartmann's solution (or of 0.9% saline if the former are not available) while waiting for blood for transfusion. It is essential that the IV bolus is given as rapidly as possible, with the aid of pressure bags or manual pressure. A blood

pressure cuff that is wrapped around the fluid bag and inflated can be used to speed up infusions (see Figure 2.5.D.IV.9). An alternative is to push the boluses in using a 20- to 50-mL syringe (with a three-way tap linked to the IV giving set).

- As soon as it is available give 1 unit of blood (500 mL) as rapidly as possible**, and repeat as required. Fresh blood is particularly useful for combating the coagulopathy that occurs in major blood loss if specific coagulation components such as platelets are unavailable. Remember that blood loss is usually underestimated.
- Further 500- to 1000-mL boluses of IV crystalloid or blood, if available, will usually be required in the first hour. Once more than 2 litres have been given IV, complications such as pulmonary oedema may sometimes occur, so be alert for circulatory overload.

The concept of **targeted crystalloid fluid resuscitation** may be relevant here and requires urgent research. If this approach is adopted the initial boluses of IV crystalloids required to treat shock would only be given to keep the vital organs (especially the brain, heart and kidneys) perfused before blood becomes available and, most important of all, before specific treatments to stop the bleeding have started to take effect. Giving too much IV crystalloid fluid may theoretically increase bleeding by disrupting early clot formation and damaging the coagulation system. There is no clear evidence to indicate the precise blood pressure or clinical signs that should be achieved in a woman in shock due to PPH.

**Adequate perfusion of vital organs may be indicated by a radial pulse that can be palpated and a fully alert conscious level.**

Until bleeding has been stopped and blood is available for transfusion, our personal practice, especially in low resource settings, is therefore to start with IV boluses of 500 mL of crystalloid and reassess after each bolus.

- Keep the patient warm but do not overheat them, as this will cause peripheral vasodilatation and reduce the

**FIGURE 2.5.D.IV.9** Pressure bag over bag containing Ringer-lactate or Hartmann's solution.

blood supply to vital centres. Hypothermia will exacerbate poor peripheral perfusion, acidosis and coagulation abnormalities.

- 8 If there is evidence of a blood-clotting problem, give fresh-frozen plasma and/or other clotting factors (if available).
- 9 Further IV fluid administration should be guided by the response of the pulse rate, blood pressure and capillary refill time, and later by the hourly urine output. Aim for a pulse rate of  $\leq 100$ –110 beats/minute and a systolic blood pressure that is  $\geq 90$ –100mmHg and stable.

### Blood products

Fresh whole blood is the ideal choice if it is available. Full cross-matching of blood may take up to an hour and is often unavailable in resource poor settings. In an emergency, group-specific blood should be used. The patient's blood group should have been established during pregnancy, as this facilitates the provision of blood when it is needed. O-Rhesus-negative blood can be transfused in acute emergencies.

All large-volume infusions of blood should be warmed. A good way of warming blood is to place each bag of blood or fluid under a relative's clothes next to their skin. Do not infuse cold fluid directly through a central venous line.

### New potentially valuable treatments for PPH Tranexamic acid

If there is continuing bleeding, especially if it has been caused by genital tract trauma, this inexpensive and safe drug can be helpful. Recent evidence has shown that tranexamic acid can reduce mortality from major haemorrhage in major trauma in adults. The drug should be started as soon as possible, and within the first 3 hours after the onset of major haemorrhage, in order to be effective.

The loading dose is 1 gram over 10 minutes followed by an IV infusion of a further 1 gram over 8 hours.

The slow IV bolus dose is given by injecting 1 gram of tranexamic acid into a 100-mL bag of 0.9% saline and letting it run through over a period of about 10–20 minutes (the exact timing is not crucial).

The 8-hour infusion is given by injecting 1 gram of tranexamic acid into a 500-mL bag of 0.9% saline and giving it over a period of 8 hours (i.e. approximately 60 mL/hour). If there is a gap between the initial bolus and the subsequent infusion this probably does not matter too much, but ideally one should follow the other.

### The non-pneumatic anti-shock garment (NASG)

This compression garment is made from neoprene, a stretchable material that recoils and applies pressure through the skin. It feels like a tight diving wet-suit to wear, and consists of five segments that compress the legs (segments 1, 2 and 3), the pelvis (segment 4) and the abdomen (segment 5) (see Figures 2.5.D.iv.10 and 2.5.D.iv.11). The abdominal segment includes a foam compression ball that presses on the area of the uterus. The segments are held in place by Velcro. It is a very promising, potentially life-saving technique for low-resource settings.

Preliminary pre- and post-intervention trials have shown that the NASG significantly reduces shock, blood loss, the need for emergency hysterectomy, and maternal mortality and severe morbidity associated with PPH and other

**FIGURE 2.5.D.IV.10** NASG garment before it is placed on the patient. Reproduced with permission from Miller S, Martin HB, Morris JL. Anti-shock garment in postpartum haemorrhage. *Best Pract Res Clin Obstet Gynaecol.* 2008; **22**(6): 1057–74. © Elsevier

causes of obstetric haemorrhage. Randomised controlled trials by the World Health Organization and others are currently under way in Zambia and Zimbabwe.

The NASG is reported to reduce shock by compressing blood vessels in the lower parts of the body, thereby diverting up to 30% of total blood volume to the heart, lungs, brain and possibly the kidneys. There is evidence that, through the applied pressures of 25–50mmHg, it decreases blood flow in the pelvis and, in PPH, blood loss from the atonic uterus.

It is particularly promising in settings where there can be delays in transfer to facilities where comprehensive emergency obstetric care is available, and where blood transfusion and surgery can be undertaken. In such settings, even in hospitals, blood transfusion is frequently delayed for between 1 and 3 hours, with O-negative blood rarely available and supplies of stored blood precarious. The NASG, by stabilising the patient, gives time for blood transfusion to become established and other treatments to be given, as well as very probably reducing the amount of blood that subsequently needs to be transfused.

**FIGURE 2.5.D.IV.11** NASG garment on a patient. Reproduced with permission from Miller S, Martin HB, Morris JL. Anti-shock garment in postpartum haemorrhage. *Best Pract Res Clin Obstet Gynaecol.* 2008; **22**(6): 1057–74. © Elsevier

As reported by the International Federation of Gynecology and Obstetrics (FIGO), 'The NASG is not a definitive treatment – the woman will still need to have the source of bleeding found and definitive therapy performed.' We would qualify this statement and substitute the word

'may' for 'will', as sometimes the bleeding, particularly in PPH, may be reduced during the application of the NASG, and advanced treatments such as surgery may not then be required.

The NASG is applied in sequence from the lower legs up to the abdominal compression segment (segment 5). With experience it can be applied by one person in 2 minutes, although it takes from 5 to 10 minutes if the healthcare worker is alone and unused to applying it. Help from others present, such as porters or relatives, can be valuable. In PPH due to uterine atony, it is particularly important that someone is massaging the uterus and giving the other treatments outlined above when the NASG is being applied. After the garment is in place the legs no longer need to be elevated and the uterus can still be externally massaged by placing one hand underneath the pelvic segment of the NASG. Vaginal examinations and repair of cervical or vaginal tears can be performed while the NASG is in place. The pelvic and abdominal segments can be opened for surgery such as emergency hysterectomy or B-Lynch sutures.

The NASG can be applied in addition to all the other measures for PPH described above when signs of shock first appear (see Section 2.5.A). The only contraindication to its use is known heart disease. The aim with all treatments is for a pulse rate of  $\leq 100$ –110 beat/minute and a systolic blood pressure that is  $\geq 90$ –100 mmHg and stable in a woman who is fully alert and has a urine output of  $\geq 30$  mL/hour.

The NASG is removed segment by segment when bleeding has been reduced to safe levels and the patient's cardiovascular stability has been maintained for at least 2 hours (systolic blood pressure  $\geq 90$ –100 mmHg, heart rate  $\leq 100$ –110 beats/minute and haemoglobin concentration of  $\geq 7$  g/dL). Removal begins at the ankles with 15-minute gaps between each segment that is opened, and clinical measurements being made before each segment is removed. If the systolic blood pressure drops by  $\geq 20$  mmHg and/or the heart rate increases by  $\geq 20$  beats/minute, reapply that segment of the NASG and consider additional treatments such as further blood transfusion.

Between patients, the NASG can be laundered in the same way as for bloodstained sheets. First soak the garment in 0.5% chloride solution for 15 minutes. Then wash and scrub it with a soft brush in soapy water. Finally rinse it in clean water and leave it to air-dry. Fold and store the garment when it is completely dry.

Each NASG can be used 50–100 times, and at present costs US\$150–200.

### Stopping bleeding due to trauma to the perineum, cervix or vagina

If the bleeding continues despite all of the measures described above, examine the perineum, vagina and cervix with a sterile speculum. Postpartum bleeding with a contracted uterus is usually due to a cervical or vaginal tear. Trauma to the lower genital tract is the second most frequent cause of PPH, and may coexist with an atonic uterus.

Examine the mother carefully and repair any tears. Bleeding from trauma can be substantial and may be fatal, especially if there is pre-existing severe anaemia. Suture packs, a torch, a Sims' speculum and sutures must always be immediately available on the PPH emergency trolley.

Initially stop the bleeding with sterile packing until a surgeon is able to repair the wounds.

**It is essential to ensure that the uterus is contracted even when a traumatic cause is present.**

**FIGURE 2.5.D.IV.12** Repairing a perineal tear.

### Repairing a perineal tear

Get a good light, and start at the top of the tear. If difficult ask for help if available.

- 1 Anything except very minor tears should be repaired in the lithotomy or similar position as it provides a better view and is more comfortable for the surgeon/midwife.
- 2 Use a cutting needle on the skin and a round-bodied needle on other tissues.
- 3 Put the first stitch in above the highest point of the tear (apex). This is usually within the vagina.
- 4 When you get to the junction between the vaginal mucosa and the skin, put a needle through the loop and tie a knot.
- 5 Continue by applying stitches into the muscle and fascia to close any dead space (gaping of the vaginal skin) and again tie a knot once done.
- 6 Next close the skin by placing the needle in through the skin on one side, and then in through the sub-cutaneous tissues and out through the skin on the other side. If using interrupted sutures, the stitches are usually inserted  $\sim 1/2$  cm from the skin edges and  $\sim 1$  cm apart from each other. Tie a knot after each stitch to oppose the skin.

### Repairing a bleeding cervical tear

**Place the patient in the lithotomy position and explain the procedure to the patient.**

Get a good light and if at all possible an assistant.

Search all round the patient's cervix, if the cervix is not easily visible grasp it with a sponge holding forceps (or similar) and pull it into view. In order to visualise the entire cervix it is often necessary to follow the cervix round from anterior to posterior by pulling each segment down with the sponge holding forceps. Ideally two forceps are used and the next segment picked up with one set of forceps while traction is maintained with the other ('walking the cervix').

Once the cervical tear is identified start suturing it at its highest point (the apex).

If you cannot insert sutures, control the bleeding with a vaginal pack and transfer the patient.

## Stopping bleeding due to retained placenta or retained products of conception

**Examine the placenta and ensure that it is complete.**

### Retained placenta

A retained placenta is defined as occurring:

- 1 after active management of the third stage of labour (see Section 2.3), if the placenta is not delivered within 30 minutes of the birth
- 2 after expectant management of the third stage of labour, if the placenta is not delivered within 60 minutes of the birth.

Risk factors include a full bladder, a previous retained placenta, high parity, uterine fibroids, a history of previous uterine surgery and placenta praevia. The placenta may become trapped in the cervix or lower uterus. There may be no bleeding with a retained placenta, especially if there is abnormal adherence (placenta accreta).

A retained placenta occurs in around 2% of deliveries.

### Management of retained placenta

**If there is a clinically significant PPH, the placenta must be removed urgently.** Call for help (including an anaesthetist and an obstetrician), insert a venous cannula, take blood for haemoglobin and cross-matching as for PPH, and ensure that the operating theatre is ready.

Massage the uterus, and if there is atony it should be managed as described for PPH above. However, although oxytocin should be used as necessary, **do not give ergometrine because it causes tonic uterine contraction, which may delay expulsion.**

#### Cause 1: The placenta is separated but trapped in the lower part of the uterus or cervix

If the **placenta is undelivered after 30 minutes of oxytocin stimulation**, and the **uterus is contracted and the placenta separated** (usually indicated by the gushing of blood and rising of the uterus into the abdomen as a firm, more movable structure as with a normal placental separation and delivery), attempt controlled cord traction. During this procedure, and at all times, keep one hand on the abdomen to support the uterus and prevent its inversion.

**Avoid forceful cord traction and fundal pressure, as they may cause uterine inversion.**

This situation usually responds to firm and persistent traction on the cord with the other hand countering this on the uterus to prevent inversion. Ensure that the bladder is empty. Ask the mother to empty her bladder, otherwise catheterise the bladder if necessary. If you can see the placenta, ask the mother to push it out; an upright position may help. Undertake a sterile vaginal examination and if you can feel the placenta in the vagina or cervix, remove it.

#### Cause 2: The placenta has failed to separate from the uterus

**If controlled cord traction plus uterotonic drugs are**

**unsuccessful**, manual removal of the placenta is likely to be required (see below).

**If the cord has broken from the placenta, it is still possible for the placenta to be pushed out by contractions and by the mother.**

#### Cause 3: The placenta is morbidly attached to the uterus

Very adherent tissue may be **placenta accreta**, a situation that is more likely to occur after a previous Caesarean section. Efforts to extract a placenta that does not separate easily may result in heavy bleeding or uterine perforation, which usually requires hysterectomy.

Therefore, if there is any suspicion of a morbidly adherent placenta the patient should ideally be referred to a hospital with operating facilities and a surgical team (if available). See pages below for more details on management.

Where there is significant haemorrhage, uterine and vaginal packing with gauze or balloon tamponade/condom catheter can halt the bleeding and eventually allow residual placenta to disintegrate and resorb/expel on its own. Hysterectomy will be needed if bleeding cannot be stopped by the measures described above.

**If bleeding continues**, assess clotting status using a bedside clotting test. Failure of a clot to form after 7 minutes, or formation of a soft clot that breaks down easily, suggests coagulopathy.

If there are **signs of infection** (fever with foul-smelling vaginal discharge), give antibiotics as for endometritis.

### Manual removal of the placenta

This is a painful procedure associated with a high risk of infection unless it is undertaken using full sterile procedures. In many low-resource settings, manual removal of the placenta is undertaken without analgesia or anaesthesia, and often not even in the operating theatre.

Unless it is performed as an emergency for major PPH, we consider that manual removal of the placenta should be undertaken in an operating theatre with preceding morphine or ketamine in the presence of an anaesthetist. Elbow-length sterile gloves should be used. Provided that active PPH is not occurring, **the mother should first be adequately resuscitated with IV fluids/blood and oxygen.** The pulse rate, blood pressure, oxygen saturation and urine output should be closely monitored. Ideally, facilities for blood transfusion and, if necessary, emergency hysterectomy should be available.

After the placenta has been removed, massage the uterus to encourage tonic uterine contraction. An IV infusion of oxytocin 40 units in 500 mL or 1 litre of Ringer-lactate or

**FIGURE 2.5.D.IV.13** Introducing one hand into the vagina along the cord.

**FIGURE 2.5.D.IV.14** Supporting the fundus while detaching the placenta. Reach the placenta from the implantation site by keeping the fingers tightly together and using the edge of the hand to gradually make a space between the placenta and the uterine wall

**FIGURE 2.5.D.IV.15** Withdrawing the hand plus the placenta from the uterus.

Hartmann's solution should be administered over 4 hours to ensure continued uterine contraction.

A single dose of prophylactic antibiotics should be given just before all manual removals (2 grams of ampicillin IV or IM plus 80 mg of gentamicin IM/IV).

### Treatment of PPH that continues despite all of the above interventions

Reassess the patient and determine whether bleeding is continuing and whether there is a clotting disorder. Assess the clotting status using a bedside clotting test. Failure of a clot to form after 7 minutes, or formation of a soft clot that breaks down easily, suggests coagulopathy.

If bleeding continues, re-examine the patient and ensure that the oxytocin IV infusion is running correctly (40 units of oxytocin in 500 mL of Ringer-lactate or Hartmann's solution over 4 hours).

Exclude the following:

- inverted uterus
- retained products of conception
- damage to the genital tract: check for bleeding from the cervix, vaginal walls and perineum.

If the above measures fail to control PPH, **do not wait too long.**

The following operative interventions are available:

- B-Lynch sutures
- hysterectomy, which may be life-saving, and should be considered early in order to reduce the risk of life-threatening coagulopathy.

**Check the haemoglobin levels or haematocrit after resuscitation and when the patient is stable. Consider administering oral iron if the patient is anaemic.**

### Treatment of secondary PPH

This is particularly dangerous in low-resource settings. Severe and life-threatening anaemia can develop rapidly, and frequently the woman is admitted in shock and urgently requiring blood transfusion. Severe life-threatening septic shock can also develop.

Assess vital signs and temperature, and if the patient is shocked proceed as described above for massive PPH.

Assess the uterine size, and perform a speculum and vaginal examination and note the degree of bleeding, whether the blood is offensive, whether the cervix is still open, and whether there is cervical and uterine tenderness. Take a high vaginal swab for bacteriology (if available) before antibiotics are given.

Insert an IV line and take blood for haemoglobin, blood cultures, cross-matching and blood clotting (or clotting/bleeding time if unavailable) (as DIC may occur).

Urgently start 7 days of treatment with IV antibiotics, as the bleeding is often secondary to infection. This is especially likely if there is foul-smelling lochia, a fever, or there has been prolonged rupture of membranes prior to delivery.

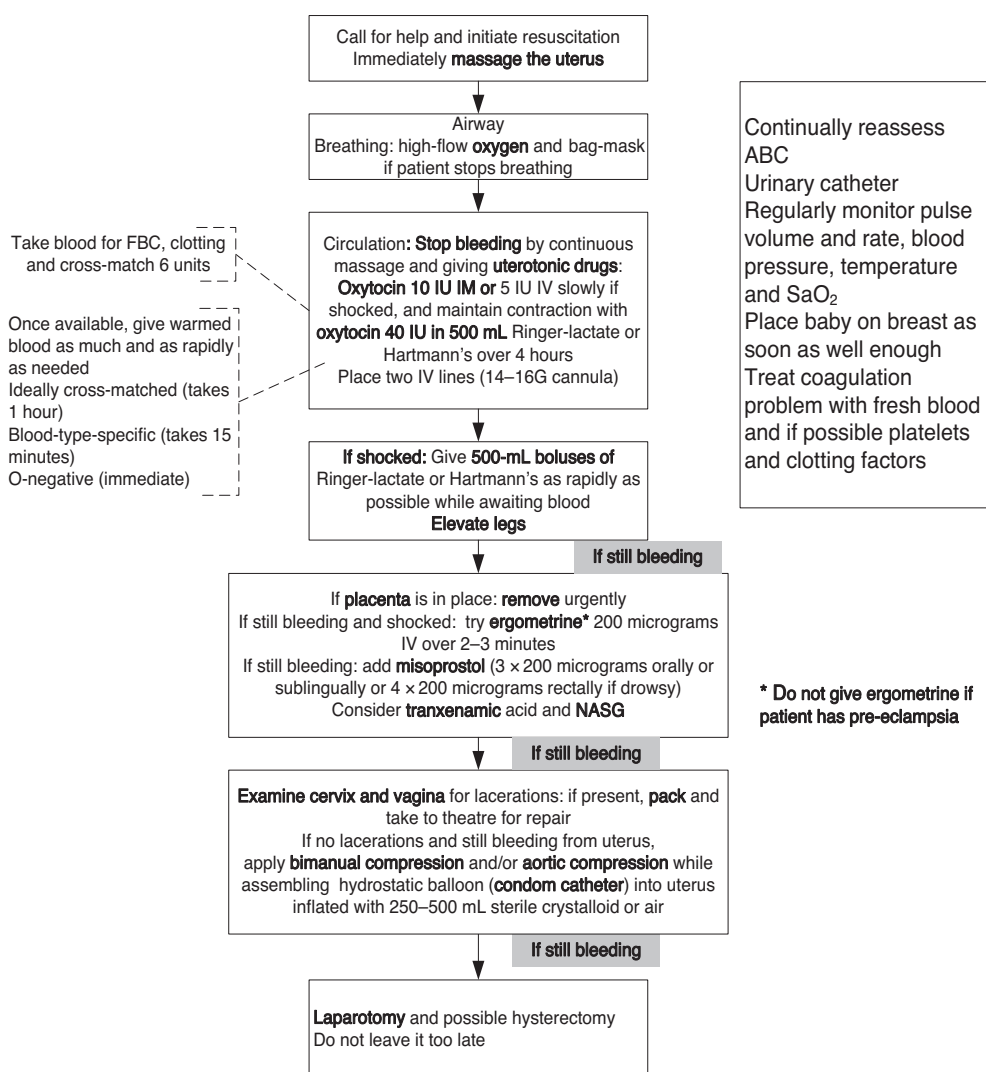

- Give IV ampicillin 2 grams IV every 6 hours
  - plus gentamicin 80 mg IV or IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours
  - plus metronidazole 500 mg IV every 8 hours.
- Alternatively, give ceftriaxone 2 grams IV or IM once daily plus metronidazole 500 mg IV every 8 hours.

Provide blood transfusion (ideally fresh blood) if the haemoglobin level is < 5 g/dL, or if it is < 7.5 g/dL with symptoms suggesting early cardiac failure or shock or if there is brisk ongoing blood loss.

Examine for suspected retained placental fragments, but beware of the high risk of uterine perforation. Feel inside the uterus using elbow-length sterile gloves, and try to remove any retained products manually or using ovum forceps. **Be very careful not to perforate the uterus.** Placental tissue that sticks to the uterus may be placenta accreta, which may result in heavy bleeding (see below for management). If the cervical os has already started to close, this approach might not be possible. If a curette is used, it should be blunt, and great care should be taken as the uterus will be soft and easy to perforate. A vacuum aspirator (as used for treating miscarriage) or digital curettage may be safer options. Laparotomy is occasionally needed to deal with the continued bleeding from an infected or ruptured uterine incision or infected placental bed.

**FIGURE 2.5.D.IV.16** Evacuating the uterus.

**FIGURE 2.5.D.IV.17** Pathway of care for massive postpartum haemorrhage (PPH). Aim for a contracted and empty uterus. FBC, full blood count; NASG, non-pneumatic anti-shock garment; ABC, airway, breathing and circulation.

### Management of placenta accreta

This serious complication is caused by the placenta being morbidly adherent to deeper layers in the uterine muscle or even external to the uterus. It is more common after a previous Caesarean section and in the presence of a placenta praevia. After Caesarean section an attempt should be made to assess the site of the placenta with ultrasound to determine whether it is likely to overlie the previous scar.

If the patient undergoes a new Caesarean section, or has a retained placenta, the procedure should be carried out by the most experienced practitioner possible and preparations made for major haemorrhage, i.e. experienced anaesthetic assistance, good intravenous access, cross matched blood and availability of the non-pneumatic anti-shock garment.

An option is to allow the placenta to be left *in situ* where it may separate and expel itself over time. This risks haemorrhage, infection and DIC and in these cases the mother must be made aware of these risks. She must be observed carefully for signs of infection, given prophylactic antibiotics (single dose of ampicillin 2g IV/IM plus gentamicin 5mg/kg body weight IV/IM) and warned about what to expect when the placenta is eventually expelled. She must have

rapid access to emergency care and be monitored as an inpatient.

Alternatively, an attempt to remove the placenta can be made. Haemorrhage, as discussed, should be anticipated and the procedure performed in theatre with adequate intravenous access, monitoring, cross-matched blood available and the most experienced anaesthetic and surgical personnel possible.

**An alternative option is an immediate hysterectomy in order to prevent later complications and the necessity for very close post-partum monitoring. The decision will need to be based on the patient's wishes, the resources available and the doctor's abilities. If there is no facility for emergency hysterectomy, the patient should be transferred to a facility where this is available.**

### Bleeding due to inverted uterus

See Section 2.6.H.

### Anaesthetic issues when managing PPH

Cardiovascular instability is a relative contraindication to regional blockade.

Rapid sequence induction agents with minimal

peripheral vasodilator action, such as ketamine, should be considered (see Section 1.24). Adrenaline and atropine should be readily available in case cardiovascular collapse occurs on induction. Ventilation with high concentrations of oxygen may be needed until the bleeding is controlled.

Volatile agents have been associated with increased blood loss due to their relaxant effects on uterine muscle. Anaesthesia should be maintained with IV agents (ketamine or etomidate) if uterine atony is contributing to haemorrhage.

### Disseminated intravascular coagulation (DIC)

Suspect and aggressively treat coagulopathy using warmed fresh blood, platelets, fresh-frozen plasma and cryoprecipitate as appropriate and available. DIC is more likely to occur if there has been a previous antepartum haemorrhage.

### Sheehan's syndrome

Very rarely, massive PPH can cause pituitary infarction (also called Sheehan's syndrome). This presents initially as failure of breastfeeding, and later as no return of menstrual bleeding, as well as fatigue, low blood pressure and loss of pubic and axillary hair. Treatment is with replacement hormones,

including oestrogen, progesterone, thyroid and adrenal hormones. Specialist endocrinological advice is necessary.

### Monitoring

Once the bleeding has been controlled, frequent observations of respiratory rate, pulse rate, blood pressure, urinary output and oxygen saturation (if available) are vital both to detect problems and to monitor the response to treatment. At least 48 hours of close observations are required.

## 2.5.E Hypertension, pre-eclampsia and eclampsia

### BOX 2.5.E.1 Minimum standards

- Blood pressure machine
- Urine protein testing sticks
- Magnesium sulphate
- Antihypertensive drugs (labetalol, hydralazine, methyldopa and nifedipine)
- Bag-valve-masks, oxygen and oropharyngeal airway
- Suction
- Patella hammer
- Pulse oximeter

### Introduction

Hypertension in pregnancy occurs when the systolic blood pressure is  $\geq 140$  mmHg and/or the diastolic blood pressure is  $\geq 90$  mmHg. If the blood pressure is elevated, confirm this by making repeated measurements (see below).

Severe hypertension (systolic pressure  $\geq 170$  mmHg and/or diastolic blood pressure  $\geq 110$  mmHg) must be treated, because a systolic or diastolic blood pressure at or above these levels is associated with a risk of cerebral haemorrhage, hypertensive encephalopathy and placental abruption.

### Measuring blood pressure and looking for hypertension

When you measure the blood pressure of a woman, she should be rested and seated at a 45-degree angle with the machine on the bed beside her. Do not prop it up on her abdomen. Also do not lie her down, as this causes compression of the central veins. Open the cuff out flat, and make sure that you place the centre of the inner bladder

FIGURE 2.5.E.1 Measuring blood pressure.

on the artery. A falsely high reading will be obtained if the cuff's bladder does not encircle at least 80% of the circumference of the arm.

If the blood pressure is consistently higher in one arm, this arm should be used for all subsequent measurements. Some automated blood pressure machines under-measure systolic blood pressure.

The systolic pressure is the onset of the first sound (Korotkov 1). The diastolic pressure is the complete disappearance of sounds (Korotkov 5). The normal systolic blood pressure in pregnancy is in the range 95–135 mmHg. The normal diastolic blood pressure is in the range 60–85 mmHg. Diastolic blood pressure measures peripheral resistance and does not vary with the woman's emotional state to the same degree that systolic pressure does. The blood pressure normally falls during the second trimester of pregnancy, reaching its lowest value by the end of the

second trimester, and returning to pre-pregnancy levels at term.

If the systolic pressure is  $\geq 140$  mmHg and/or the diastolic blood pressure is  $\geq 90$  mmHg on two consecutive readings taken  $\geq 4$  hours apart, hypertension should be diagnosed.

In addition to a blood pressure of  $\geq 140/90$  mmHg, any increase in systolic pressure of  $\geq 30$  mmHg or in diastolic pressure of  $\geq 15$  mmHg over recent previous measurements requires close monitoring, even if the pressures do not reach 140 mmHg systolic or 90 mmHg diastolic.

### The categories of hypertension in pregnancy

These can be classified as follows.

#### Pre-eclampsia

This is hypertension (blood pressure of  $\geq 140/90$  mmHg) that develops after 20 weeks' gestation, always in association with proteinuria ( $\geq 0.3$  grams in a 24-hour specimen). This level correlates with  $\geq 1+$  on dipstick testing.

Pre-eclampsia is a multi-system disorder.

Other conditions cause proteinuria, and false-positive results are possible (e.g. due to contamination with normal vaginal discharge or amniotic fluid). Urinary infection may also produce proteinuria, but rarely  $\geq 2+$  on dipstick testing. Blood in the urine due to catheter trauma, schistosomiasis or contamination with vaginal blood may also give false-positive results.

Random urine sampling, such as the dipstick test for protein, is a useful screening tool. A change from negative to positive during pregnancy is a warning sign. If **dipsticks are not available**, a sample of urine can be heated to boiling point in a clean test tube. Add a drop of 2% acetic acid to check for persistent precipitates that can be quantified as a percentage of protein in the sample. Only clean-catch midstream specimens should be used. Catheterisation for this purpose is not justified, due to the risk of urinary tract infection.

FIGURE 2.5.E.2 Testing for proteinuria without reagents/sticks.

Eclampsia is fitting associated with the syndrome of pre-eclampsia. Seizures can occur without any previous signs or symptoms.

The diagnosis of pre-eclampsia is made when there is hypertension after 20 weeks' gestation associated with significant proteinuria ( $\geq 0.3$  grams/24 hours) (see above).

It is associated with a risk of developing one or more of the following:

- significant proteinuria ( $\geq 0.3$  grams/24 hours) (see above)

- renal involvement (serum/plasma creatinine  $> 90$  micromol/litre with or without oliguria)
- haematological involvement (low platelet count, haemolysis, DIC)
- liver involvement (raised transaminases, epigastric or right upper quadrant abdominal pain)
- neurological involvement (headache, persistent visual disturbances including photophobia, scotomata, blindness and retinal vasospasm, hyper-reflexia with sustained clonus, stroke)
- pulmonary oedema
- intrauterine growth retardation
- placental abruption.

HELLP is a syndrome that consists of **H**aemolysis, **E**levated Liver enzymes and **L**ow **P**latelets. It may complicate pre-eclampsia, sometimes with only mild or borderline hypertension and marginally abnormal proteinuria.

Pre-eclampsia and eclampsia are still one of the main causes of maternal mortality and morbidity in low-resource countries. In one study it was reported that 38% of eclamptic fits occur antenatally, 18% occur in the intrapartum period, and the remaining 44% occur postpartum, usually in the first 48 hours after delivery. Sometimes the first fit occurs postnatally.

**Oedema** occurs with the same frequency in women with and without pre-eclampsia. However, if oedema develops suddenly and is widespread, always screen for pre-eclampsia. Test for oedema by pressing with your finger for 1 minute over the bony part of the mother's tibia. If there is a dent when you take your finger away, oedema is present. If the mother has been lying down, look for oedema over the sacrum. Oedema can also make a finger ring tight. Oedema of the face is more likely to represent a sign accompanying pre-eclampsia.

FIGURE 2.5.E.3 Testing for oedema of the ankles and lower back.

#### Gestational hypertension

This is hypertension that develops only after 20 weeks' gestation but with no other features of pre-eclampsia, and which resolves within 3 months after birth. Patients who present early in pregnancy (after 20 weeks) and with severe hypertension are more likely to develop pre-eclampsia.

#### Chronic hypertension

- 1 Essential hypertension (also called primary hypertension) occurs before 20 weeks' gestation, without cause (see below).
- 2 Hypertension may also be secondary to other medical conditions such as chronic renal disease, endocrine disorders or diabetes mellitus.

It is important to control the hypertension in these cases, keeping the blood pressure below 150/100 mmHg, but not permitting the diastolic pressure to go below 80 mmHg.

### **Pre-eclampsia in a woman with with chronic hypertension and gestational hypertension**

Women with hypertension in pregnancy are at increased risk of developing superimposed pre-eclampsia and should be monitored more frequently for the presence of proteinuria and systemic features of pre-eclampsia from 20 weeks' gestation onwards but especially in the third trimester.

## **Pre-eclampsia**

### **Risk factors**

These include the following:

- first pregnancy
- multiple pregnancy
- family history of pre-eclampsia
- chronic hypertension (see above)
- renal disease
- hypertension/pre-eclampsia during a previous pregnancy
- diabetes mellitus
- molar pregnancy.

For those at high risk of recurrence, a systematic review of 59 trials involving 37 560 women found that low doses of aspirin reduced the risk of pre-eclampsia by about a sixth (17%), with a similar lowering of the risk of the baby dying (14%), and a small lowering of the risk of the baby being born too early (8%). Doses up to 75 mg appear to be safe and high risk women are advised to start taking it from 12 weeks' gestation and to continue until delivery of the baby.

### **Investigations**

These include the following:

- urine dipstick test for protein and microscopy to exclude infection
- haemoglobin levels and platelet count
- urea and electrolytes, and creatinine
- liver function tests
- lactate dehydrogenase (LDH) and uric acid
- fetal growth assessment by ultrasound scan.

If there are signs of DIC, clotting studies should be undertaken (whole blood clotting time in low-resource settings; see below).

If there is severe hypertension in early pregnancy, investigations (if available) for the rarer causes such as molar pregnancy, autoimmune disorders, pheochromocytoma, etc. may be indicated.

### **Management of pre-eclampsia and gestational hypertension**

Pre-eclampsia progresses during pregnancy, and the only definitive treatment is delivery. If the patient is at term (i.e. after 36 weeks) then, after stabilisation of the mother, the baby should be delivered as soon as possible.

There is no evidence that bed rest improves the outcome for the mother or the fetus. Heavy physical labour is clearly inappropriate. However, women in low-income settings are commonly seen working in this way despite being in advanced pregnancy.

Mild cases can be cared for without hospital admission, but there need to be regular (at least weekly) checks on blood pressure and urine, and the family must be made aware of the warning signs of severe pre-eclampsia or eclampsia (see below).

If there is severe pre-eclampsia or eclampsia, if the blood pressure cannot be adequately controlled, or if there is pulmonary oedema, deteriorating renal or liver function, placental abruption or evidence of falling platelet counts or DIC, delivery is urgent but must always take place after stabilisation. In cases before 36 weeks' gestation, an injection of dexamethasone or betamethasone 12 mg IM, two doses 12 hours apart or 6 mg IM, four doses 12 hours apart, improves the likelihood of avoiding neonatal respiratory failure (see Section 3.1).

Stabilisation involves correction of severe hypertension, control of fluid intake and output, correction of blood-clotting disorders (in low-resource settings with fresh blood transfusion) and prevention or control of eclampsia (see below).

### **Antihypertensive drugs for pre-eclampsia**

Mild pre-eclampsia does not require antihypertensive drugs.

If the systolic blood pressure is 150–160 mmHg and/or the diastolic blood pressure is 95–105 mmHg, treatment with oral antihypertensive drugs should be started.

Systolic pressure of  $\geq 170$  mmHg and/or diastolic pressure of  $\geq 110$  mmHg must be urgently treated with antihypertensive drugs. **However, it is essential that the blood pressure is not lowered too rapidly, as this can seriously affect the woman's cerebral circulation and the circulation to the placenta and fetus.** Aim for a systolic blood pressure of 150 mmHg.

### **Oral antihypertensive drug treatment**

#### **Methyldopa**

This drug acts directly on the central nervous system and takes 24 hours to work. The dose is 250 mg three times a day initially, increasing every 2 days up to 750 mg three times a day. Side effects include dry mouth, postural hypotension, sedation and depression. Methyldopa is contraindicated in patients with depression or liver disease.

**The simultaneous administration of oral iron and oral methyldopa can lead to a drug interaction that can result in clinically significant increases in blood pressure (> 15 mmHg increase in systolic pressure and > 10 mmHg increase in diastolic pressure).**

#### **Labetalol**

This is a beta-blocker with mild alpha-blocking effects. The dose is 100–400 mg three times a day. Side effects include bradycardia, bronchospasm, weakness, scalp tingling (only for 24–48 hours), nausea and headache. Labetalol is contraindicated in patients with asthma.

#### **Hydralazine**

This is a vasodilator. The dose is initially 25 mg twice a day, increasing gradually to 50 mg three times a day. Side effects include uncontrolled hypotension, flushing, tachycardia, palpitations, headache and (uncommonly) a lupus syndrome.

### Treatment of severe hypertension

It is vital that severe hypertension is controlled at any gestation, both before and after delivery.

Antihypertensive drugs should be given urgently to all patients with a systolic blood pressure of  $\geq 170$  mmHg and/or a diastolic blood pressure of  $\geq 110$  mmHg.

Without urgent treatment there is a risk of cerebral haemorrhage, eclampsia and pulmonary oedema.

The aim should be a gradual and sustained reduction in blood pressure with one or more of the drugs described below.

Blood pressure should not be allowed to fall below 140/80 mmHg before delivery.

#### Hydralazine

This is the most widely available antihypertensive drug in low-resource settings. Give 5 mg IV slowly over a period of 5 minutes (it acts within 5 minutes). Repeat the BP after every 15 minutes and treat with further doses of 5 mg until the **diastolic** blood pressure is 90–100 mmHg and the systolic BP is 140–160. Repeat the hydralazine hourly as needed, or give hydralazine 12.5 mg IM every 2 hours as needed.

Alternatively, give hydralazine IV infusion, 20 mg in 200 mL of 5% dextrose at 0.5 mL (10 drops) per minute (20 drops = 1 mL for a standard giving set), and stop the drip when the diastolic blood pressure is  $\leq 90$  mmHg. Hydralazine may cause an increase in the maternal heart rate.

Side effects include uncontrolled hypotension, flushing, tachycardia, palpitations, headache and (uncommonly) a lupus syndrome.

#### Labetalol

Intravenous labetalol is preferable to hydralazine if the maternal pulse rate exceeds 120 beats/minute.

The labetalol dosage is 10 mg IV. If the response is inadequate (i.e. if diastolic blood pressure remains above 110 mmHg) after 10 minutes, give a further dose of labetalol 20 mg IV. Increase the dose to 40 mg and then 80 mg if a satisfactory response is not obtained after 10 minutes of each dose.

Alternatively, use an IV infusion of 200 mg in 200 mL of Ringer-lactate solution at 40 mg/hour, increasing the dose at 30-minute intervals as required to a maximum of 160 mg/hour.

Side effects include bradycardia, bronchospasm, weakness, scalp tingling (only for 24–48 hours), nausea and headache. **Labetalol is contraindicated in patients with asthma, as it may cause severe bronchospasm.**

#### Nifedipine

The slow release/modified action version of the tablets must always be used in this situation. Nifedipine is a calcium antagonist that can be administered as an initial 10 mg oral dose (onset of action within 10–20 minutes), with a repeat dose of 10 mg if there is an inadequate response after 30 minutes. Subsequent oral doses are 20 mg twice a day. Side effects include severe headaches associated with flushing and tachycardia. Oedema, weakness and constipation may also occur. Nifedipine is contraindicated in patients with aortic stenosis. It may inhibit labour.

Give prophylactic magnesium sulphate if hypertension is accompanied by proteinuria and/or if protein testing is

not available by symptoms which suggest that eclampsia may occur (see below).

### Eclampsia or severe pre-eclampsia

Although pre-eclampsia and eclampsia are most common in the primigravida, they can occur in multiparous patients.

#### Symptoms and signs of impending eclampsia

These include the following:

- headache, visual disturbances, epigastric pain and vomiting
- rapidly developing generalised (especially facial) oedema
- pulmonary oedema
- right upper quadrant tenderness
- recently developed hypertension  $\geq 170/110$  mmHg with proteinuria  $> 1$  gram/24 hours or a rapid rise in blood pressure
- clonus and increased tendon reflexes
- HELLP syndrome.

Any headache or epigastric pain occurring in the second half of pregnancy should be investigated for pre-eclampsia (measure the blood pressure and test the urine for protein).

#### Differential diagnosis (see Table 2.5.E.1)

- A seizure:
  - in a patient with known epilepsy (see Section 5.16.E)
  - in severe malaria (see Section 2.8.D)
  - in head injury (see Section 2.7.E)
  - in meningitis/encephalitis (see Section 2.7.E)
- Intoxication (local anaesthetic overdose).
- Amniotic fluid embolus (see Section 2.5.I).

**Maintain a high index of suspicion of pre-eclampsia or eclampsia even in those with malaria, migraine or epilepsy, as the conditions may coexist.**

**A small proportion of mothers with eclampsia have a normal blood pressure. Treat all convulsions as eclampsia until another diagnosis is confirmed.**

#### Convulsions with signs of pre-eclampsia indicate eclampsia.

Convulsions due to eclampsia:

- can occur regardless of the severity of hypertension
- are difficult to predict, but rarely occur without increased tendon reflexes, headache or visual changes
- are tonic-clonic and resemble grand mal convulsions of epilepsy
- may recur frequently, as in status epilepticus, and may be fatal
- will not be observed if the woman is alone
- may be followed by coma that lasts for minutes or hours depending on the frequency of convulsions
- occur after childbirth in about 44% of cases, usually but not always within the first 24 hours after birth. The longer the gap between delivery and a fit, the more likely the diagnosis is to be **a condition other than eclampsia** (e.g. cerebral venous thrombosis).

**The first eclamptic fit is usually self-limiting.**

**Control of blood pressure is essential in the management of severe pre-eclampsia or eclampsia where high blood pressure may cause a cerebrovascular accident (stroke). Magnesium sulphate is essential for preventing eclampsia and, if eclampsia occurs, for preventing further fits.**

**TABLE 2.5.E.1 Differential diagnosis of hypertension and convulsions in pregnancy**

Symptoms	Signs	Results of investigations	Diagnosis	Treatment
None unless very severe	Blood pressure $\geq$ 140/90 mmHg before 20 weeks' gestation	Urine for protein negative Renal function tests normal	Essential hypertension	Consider antihypertensive drugs
None unless very severe	Blood pressure $\geq$ 140/90 mmHg before 20 weeks' gestation	Proteinuria $\leq$ 2+	Hypertension secondary to other disease such as renal impairment, or autoimmune disease	Treat hypertension with drugs if severe, and treat the underlying condition
None unless very severe	Blood pressure $\geq$ 140/90 mmHg after 20 weeks' gestation	No proteinuria	Pregnancy-induced hypertension	Treat hypertension with drugs if severe
None unless very severe	Blood pressure $\geq$ 140/90 mmHg before 20 weeks' gestation	Proteinuria $\leq$ 2+	Mild to moderate pre-eclampsia	Avoid work involving heavy labour
Headaches increasing in frequency and unrelieved by paracetamol Visual disturbance Upper abdominal pain Shortness of breath Passing small amounts of urine Oedema	Blood pressure $\geq$ 140/90 mmHg after 20 weeks' gestation Hyper-reflexia Passing less than 400 mL of urine in 24 hours Pulmonary oedema Facial and rapidly developing oedema	Proteinuria $\geq$ 2+	Severe pre-eclampsia	Urgent admission to hospital Magnesium sulphate
May be history of the above Generalised convulsions Unconscious	Generalised fitting Coma Blood pressure $\geq$ 140/90 mmHg after 20 weeks' gestation Facial and rapidly developing oedema	Proteinuria $\geq$ 2+	Eclampsia	ABC Magnesium sulphate
Difficulty opening mouth and swallowing	Spasms of the face, neck and trunk Arched back Board-like abdomen		Tetanus	ABC, Penicillin, anti-tetanus immunoglobulin Muscle relaxants (magnesium and/or diazepam) Nasogastric feeding
Past history of convulsions	Convulsions Coma Normal blood pressure	EEG abnormal	Epilepsy	ABC, blood glucose Anticonvulsant drugs
Chills/rigors Headache Muscle/joint pain	Fever Convulsions Coma Severe anaemia Jaundice	Blood smear for malarial parasites	Severe malaria	ABC, blood glucose Antimalarial drugs
Headache Stiff neck Photophobia Vomiting	Fever Stiff neck Reduced conscious level or coma Convulsions	Full blood count Blood culture Lumbar puncture (unless there is evidence of raised intracranial pressure)	Meningitis or encephalitis	ABC Antibacterial or antiviral drugs
Headache Blurred vision Photophobia History of migraine	Normal blood pressure	No proteinuria	Migraine	Paracetamol Bed rest in dark room
			Cerebral venous thrombosis	

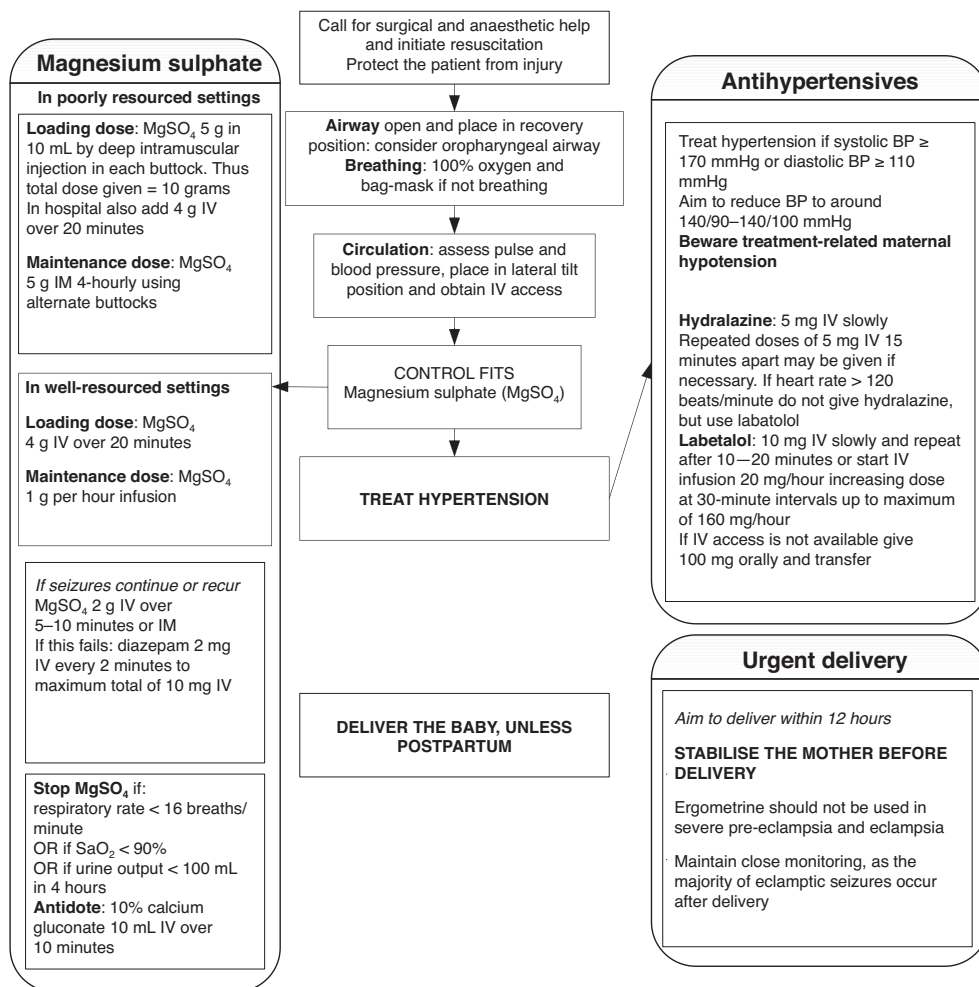

FIGURE 2.5.E.4 Pathway of care for eclampsia when the mother is having convulsions.

### Maternal complications of severe pre-eclampsia

These include the following:

- eclampsia
- cerebrovascular accident (stroke)
- renal failure
- HELLP syndrome, possible leading to rupture of the liver capsule
- pulmonary oedema
- placental abruption, possibly leading to DIC
- intrauterine growth restriction, fetal death.

### Primary assessment, resuscitation and emergency treatment of convulsions in eclampsia

#### Call for help

- Never leave the patient alone.
- Prevent maternal injury during the convulsion.

#### Airway

- If the airway is not open, use an airway-opening manoeuvre and keep it open. Consider an airway adjunct such as an oropharyngeal airway or intubation. Do not attempt to insert an oropharyngeal airway while the patient is convulsing.

- The oropharynx may need gentle suctioning under direct vision, being careful to avoid inducing laryngospasm.
- The recovery position should be adopted to minimise the risk of aspiration of vomit.

#### Breathing

- If there is spontaneous breathing, give a high concentration of oxygen via a face mask plus reservoir. Give 100% oxygen (mask with reservoir and a flow rate of at least 5 litres/minute) regardless of the mother's oxygen saturation (this increases fetal oxygen delivery as well as improving maternal tissue oxygenation).

FIGURE 2.5.E.5 The recovery position.

- If there is apnoea or hypoventilation, provide ventilation with bag-valve-mask-reservoir ventilation and 100% oxygen.

### Circulation

- Look for signs of life (breathing, movement, gagging/coughing) or for a pulse at the carotid. If these are absent or you are not sure, initiate CPR (see Sections 1.12 and 1.13).
- If the mother is over 20 weeks' gestation, put her in the left lateral tilt position and/or manually displace the uterus to reduce vena caval compression, or put her in the recovery position.
- Secure IV or intra-osseous access.
- Monitor the blood pressure.
- Attach a pulse oximeter.
- Insert a urinary catheter with strict fluid input/output chart.

Insert a 14G or 16G IV cannula and take 20 mL of blood for full blood count, blood group, cross-matching (4 units = 2 litres) and clotting. Do a 20-minute whole blood clotting time (WBCT20) test if laboratory analyses are not available (see Section 7.5).

A central venous pressure (CVP) line may be a helpful monitor to avoid fluid overload, but the benefits must be weighed against the risks. If disseminated intravascular coagulation (DIC) is established, CVP insertion is more hazardous (you must avoid subclavian vein access).

## Emergency drug treatment of eclampsia

### Stopping the convulsion and preventing further convulsions

The majority of seizures are self-limiting.

Commence **magnesium sulphate** to prevent further fits.

### Magnesium sulphate (MgSO<sub>4</sub>) treatment

**Magnesium sulphate is the anticonvulsant of choice.**

**If the mother is conscious, warn her that there will be a feeling of warmth passing through her body when magnesium sulphate is infused, and that this is not harmful. Failure to do so may result in the mother pulling out her IV cannula, and other potentially dangerous reactions.**

### Loading dose in well-resourced settings

Give 4 grams of MgSO<sub>4</sub> as 20 mL of a 20% solution of magnesium sulphate IV added to 80 mL of 5% dextrose solution given slowly over 20 minutes (total volume 100 mL). (To make 20 mL of a 20% solution, add 8 mL of 50% MgSO<sub>4</sub> solution to 12 mL of sterile water.)

If convulsions recur after completion of the loading regime, give 2 grams of MgSO<sub>4</sub> IV slowly over 10 minutes (10 mL of 20% solution is added to 90 mL of Ringer-lactate or Hartmann's solution).

Do not use the same IV line to inject other drugs if MgSO<sub>4</sub> is being given by IV infusion.

### Loading dose in resource-limited settings

Give 5 grams of MgSO<sub>4</sub> (10 mL of 50% solution) by deep intramuscular injection in **each** buttock. Thus the total dose given is 10 grams. **(Sometimes 0.5 mL of 2% or 1 mL of**

**1% lignocaine is given in the same syringe for each injection of 5 grams, to reduce the pain of the injections.)** An aseptic technique is essential.

### Maintenance dosage

- **Well-resourced countries:** Provided that there is close monitoring (ideally with a burette in giving set), give 1 gram of MgSO<sub>4</sub>/hour IV for 24 hours (i.e. 25 mL/hour of the loading dose solution of 4 grams in 100 mL described above).
- **Resource-limited countries:** give 5 grams of MgSO<sub>4</sub> IM 4-hourly (plus 1 mL of 1% lignocaine, or 0.5 mL of 2%, in the same syringe) using alternate buttocks.

### Alternative regime

This regime is recommended in Asia where pregnant women are smaller than those in Africa and there are more resources.

**Loading dose:** Give 4 grams of MgSO<sub>4</sub> as 20 mL of a 20% solution added to 80 mL of 5% dextrose solution slowly IV over 20 minutes (total 100 mL). (To make 20 mL of a 20% solution, add 8 mL of 50% MgSO<sub>4</sub> solution to 12 mL of sterile water).

Then immediately give 3 grams (6 mL of 50% solution) by deep intramuscular injection in **each** buttock. **(Sometimes 1 mL of 1% or 0.5 mL of 2% lignocaine is given in the same syringe, to reduce the pain of the injections.)**

### Maintenance dose

Give 2.5 grams of MgSO<sub>4</sub> IM every 4 hours using alternate buttocks.

### Treatment if seizures continue or recur

Give 2 grams of MgSO<sub>4</sub> if body weight is less than 70 kg, or 4 grams if body weight is over 70 kg, as an extra loading dose IV over 5–10 minutes or IM in low-resource settings.

### Alternative regime

This regime is undertaken in some West African countries, and was recommended by the World Health Organization in 2003.

**Loading dose:** 4 grams IV of MgSO<sub>4</sub> over 20 minutes: add 8 mL 50% to 92 mL Ringer-lactate or Hartmann's solution. This is followed by 10 grams 50% MgSO<sub>4</sub> solution IM (5 grams in each buttock: deep IM injections with lidocaine as above in the same syringe). **Ensure that the needle is not in a vein.**

**Maintenance dose:** This is 5 grams MgSO<sub>4</sub> 50% solution with lidocaine every 4 hours into alternate buttocks.

If eclampsia recurs, and only after 15 minutes, give 2 grams of MgSO<sub>4</sub> over 5 minutes IV: add 4 mL of 50% to 16 mL of Ringer-lactate or Hartmann's solution.

### Continued treatment with magnesium sulphate

Continue MgSO<sub>4</sub> for 24 hours after delivery or the last convulsion, provided that:

- respiratory rate is > 12–16 breaths/minute
- urine output is > 30 mL/hour (WHO figure is > 100 mL over 4 hours)
- tendon reflexes are present.

Discontinue magnesium sulphate when:

- blood pressure is stable and consistently below 150/100 mmHg
- diuresis has started
- there are no neurological symptoms.

Monitor the fetus by regular heart rate assessments.

A fluid balance chart must be kept (see below).

Remember to subtract the volume containing  $\text{MgSO}_4$  infused from total maintenance infusion volume to avoid fluid overload.

**When using magnesium sulphate, monitor hourly urine output, respiratory rate,  $\text{SaO}_2$  and tendon reflexes every 15 minutes for the first 2 hours, and then every 30 minutes.**

### **Progressive symptoms of magnesium toxicity**

These include the following:

- double vision, confusion, slurred speech, nausea and weakness
- loss of tendon reflexes
- respiratory depression ( $< 12\text{--}15$  breaths/minute) and/or  $\text{SaO}_2 < 94\%$
- respiratory arrest
- cardiac arrest.

**If magnesium toxicity is suspected, stop the infusion and if severe signs such as very slow respiration, respiratory or cardiac arrest, administer antidote of 10 mL 10% calcium gluconate IV slowly over at least 1–2 minutes.**

**Stop** the infusion of magnesium sulphate if:

- patellar reflexes are absent
- there is respiratory depression (respiratory rate  $< 12\text{--}15$  breaths/minute) or a fall in oxygen saturation to  $\leq 92\%$  on a pulse oximeter. Give oxygen to keep oxygen saturation at 94–98%
- urine output is less than 30 mL/hour over the last 4 hours.

**If respiratory depression develops**, give 100% oxygen by face mask with reservoir, and give calcium gluconate 1 gram (= 10 mL of 10% solution) IV slowly over 1–2 minutes. Too rapid administration can result in loss of consciousness, cardiac arrhythmias and cardiac arrest.

**If respiratory arrest occurs:**

- give chest inflations with bag-valve-mask ventilation with 100% oxygen
- inject calcium gluconate 1 gram (10 mL of 10%) IV slowly over 5 minutes.

The magnesium sulphate infusion may be recommenced at a reduced dose, if this is considered necessary, once normal respiration and reflexes have returned.

**Note for anaesthetists:** there is an increased sensitivity to muscle relaxants (particularly non-depolarising agents) in patients on magnesium.

In patients with known renal disease or myasthenia gravis, magnesium sulphate is contraindicated and, if available, phenytoin should be used. The loading dose is 15 mg/kg (maximum dose 2 grams) over 20 minutes by slow IV injection. Subsequently a dose of 100 mg orally twice a day can be given. IV injection if given too rapidly can cause severe hypotension, cardiac arrhythmias or respiratory arrest.

### **Other anticonvulsant drugs**

If repeated fits occur despite magnesium sulphate, give either rectal paraldehyde (10–20 mL as an enema mixed with 10 parts of Ringer-lactate solution; do not give if it is a brownish colour or smells of acetic acid; note that it crosses the placenta) or rectal diazepam (500 micrograms/kg or 10–20 mg; may cause neonatal hypothermia, hypotonia and respiratory depression).

Other causes of fitting should be considered if fits persist or recur despite magnesium sulphate. These include a cerebrovascular accident (stroke), malaria and meningitis.

**If magnesium sulphate is not available, use diazepam** (see below).

### **Diazepam**

**A bag-valve-mask must be immediately available in case the patient stops breathing.**

**Loading dose:** diazepam 2 mg increments IV every 2 minutes up to 10 mg.

If convulsions recur, repeat the loading dose.

**Maintenance dose:** diazepam 40 mg in 500 mL of Ringer-lactate or Hartmann's solution, titrated to keep the mother sedated but able to be woken and without hypoventilation.

Maternal respiratory depression may occur when the dose exceeds 30 mg in 1 hour. Assist ventilation (e.g. bag-valve-mask, anaesthesia apparatus, intubation) if necessary, and do not give more than 100 mg in 24 hours.

**Rectal administration:** give diazepam rectally when IV access is not possible. The loading dose is 20 mg in a 10-mL syringe. Remove the needle, lubricate the barrel and insert the syringe into the rectum to half its length. Discharge the contents and leave the syringe in place, holding the buttocks together for 10 minutes to prevent expulsion of the drug. Alternatively, the drug may be instilled in the rectum through a catheter.

**If convulsions are not controlled within 10 minutes**, administer an additional 10 mg per hour or more, depending on the size of the woman and her clinical response.

**Be prepared for neonatal resuscitation when diazepam has been administered, especially if it was used in large doses.**

### **Severe pre-eclampsia**

#### **Stage 1: Prevention of fitting**

If there are significantly increased tendon reflexes, often also with ankle clonus, before delivery or afterwards, and the patient shows other signs of impending eclampsia (e.g. confusion, jitteriness, severe headache), prophylactic 'anti-convulsant' therapy (magnesium sulphate where possible) should be commenced.

Other indications for magnesium sulphate treatment where eclampsia has not yet occurred include the following:

- persistent hypertension despite adequate antihypertensive drugs and good fluid management
- evidence of thrombocytopenia or liver dysfunction (if these can be measured).

The same regimen of magnesium sulphate (or diazepam if magnesium sulphate is not available) is used for prophylaxis as described above for the treatment of eclampsia. A loading dose alone may be sufficient.

## Stage 2: Reduction of blood pressure and expansion of intravascular volume

Hypertension should be treated if the blood pressure is  $\geq 170/110$  mmHg as described above. Careful fetal monitoring during the commencement of treatment is vital, as a rapid fall in maternal blood pressure may cause fetal heart rate abnormalities, especially in a growth-restricted or compromised fetus.

If the gestation is less than 36 weeks, dexamethasone or betamethasone 12 mg IM in two doses 24 hours apart should be given to improve fetal lung maturity and decrease the risk of neonatal respiratory failure, if time allows.

### Antihypertensive drugs

See pp. 202–3.

### Volume expansion during antihypertensive treatment

Antihypertensive agents such as nifedipine and hydralazine act as vasodilators. In pre-eclampsia where intravascular volume is reduced, a small volume load should be given immediately prior to IV antihypertensive treatment (300 mL or Ringer-lactate or Hartmann's solution IV over 20 minutes). Colloid or starch, such as Haemaccel (500 mL), which remains for longer in the intravascular compartment, may be helpful. Clinical examination for signs of cardiac failure (see Section 2.7.A) should be sought before and after such treatment.

## Stage 3: Anticipate and/or manage complications

### Airway and breathing

- Keep the airway clear.
- The respiratory rate should be recorded regularly (ideally it should be 15–40 breaths/minute).
- **Beware of over-sedation, aspiration, pulmonary oedema and laryngeal oedema (which presents with stridor).**
- If the respiratory rate is less than 12–15 breaths/minute, particularly if the mother is receiving magnesium sulphate or opiates for pain control, action should be taken and other signs of toxicity sought (see above).
  - If an opiate is being used, naloxone may be required.
  - If magnesium sulphate is being given, stop this and give calcium gluconate (see above).
- Oxygen can be given using nasal cannulae (ideally with  $\text{SaO}_2$  monitoring) if  $\text{SaO}_2$  is less than 94%. Keep  $\text{SaO}_2$  in the range 94–98%.
- Arrange for a chest X-ray if aspiration is suspected.
- An increased respiratory rate is an early sign of pulmonary oedema.

### Circulation

#### Consider fluid balance/fluid overload (urinary catheterisation is important).

Usually there is net fluid overload in pre-eclampsia, but the fluid has leaked out of the intravascular compartment due to low oncotic pressure (partly due to hypoalbuminaemia) and increased capillary permeability.

Complications of excessive fluid in the wrong compartment include cerebral oedema, pulmonary oedema and laryngeal oedema (stridor).

Renal failure may develop secondary to the hypertension

or to intravascular hypovolaemia (or as a primary injury in severe pre-eclampsia).

**Keep IV fluids at a rate of less than 100 mL/hour or less than 1 mL/kg per hour (the World Health Organization suggests a rate of less than 1 litre in 6–8 hours). Fluid restriction should be maintained until there is postpartum diuresis, which is easy to recognise as there is usually oliguria in severe pre-eclampsia. If there is APH or PPH, fluid restriction will probably not be appropriate.**

- Insert an indwelling urinary catheter, and keep a strict intake–output chart with hourly running totals. The total maintenance fluid intake should not exceed 1.5–2 litres over 24 hours. If the average urine output is less than 30 mL/hour over a period of 4 hours this is usually due to the decreased intravascular volume, and will respond to a bolus of 200 mL of IV Ringer-lactate or Hartmann's solution, which can be repeated if necessary.
- In the presence of over-hydration, particularly with heart failure or renal impairment, furosemide 20–40 mg IV should be given. **Mannitol is not advisable because of the fluid load that results from its administration, and because of its rebound effects.**
- Beware of cardiac arrhythmias. Ideally monitor potassium levels regularly and ECG continuously.
- Magnesium sulphate is renally excreted, so careful observation for magnesium toxicity is required if there is oliguria.
- Fluid infusion equal to the same quantity as the urinary output in the preceding hour plus 30 mL is a useful guide to IV fluid administration.
- Central venous pressure (CVP) monitoring may be useful to guide management, especially if urine output is low. (Keep the CVP at up to + 6 cmH<sub>2</sub>O in a spontaneously breathing patient.)

### Additional organ involvement

#### Neurological complications

These include cerebrovascular accidents and cerebral oedema.

Undertake regular (2-hourly) neurological examination (including pupillary and tendon reflexes) and record the AVPU and/or Glasgow Coma Scale (GCS) scores. All patients should be able to open their eyes to stimulus, obey commands and respond to questions about their name and age. If not, they are over-sedated or may be developing cerebral complications.

The GCS Scale has three components, with a maximum possible score of 15:

E	Eye-opening response (E)	Spontaneous	4
		To speech	3
		To pain	2
M	Best motor response (M)	None	1
		Obeys command	6
		Localises to pain stimulus	5
		Withdraws	4
		Abnormal flexion/decorticate posture	3

A GCS score of  $\leq 8$  indicates coma and an airway that is not protected by pharyngeal and/or laryngeal reflexes.

Cerebral oedema is usually localised to the occipital and parietal cortical areas, and is a result of cerebral vasospasm. Magnesium sulphate can help to prevent this. Mannitol is not indicated. Recurrent convulsions despite magnesium sulphate with or without other anticonvulsants may require intubation and controlled ventilation (if available).

### Haematological complications

These include disseminated intravascular coagulation (DIC).

- Group and save and cross-match fresh blood.
- Check the full blood count, including a platelet count if possible.
- Do a whole blood clotting test as well as APTT (if available) (see Section 7.5). Failure of a clot to form after 7 minutes, or formation of a soft clot that breaks down easily, suggests coagulopathy.
- If the platelet count is  $> 100\,000 \times 10^9$ , a major coagulation problem is unlikely. Spontaneous haemorrhage may occur with counts below  $10\,000 \times 10^9$ .
- In frank DIC, give whole fresh blood if there is bleeding.

### Hepatic complications

These include jaundice, bleeding tendency, hepatic failure, hepatic sub-capsular oedema or hepatic rupture (the last two cause right upper quadrant or epigastric pain).

Delivery of the baby is urgent.

### Fetal problems

These include intrauterine growth retardation, fetal distress in labour, preterm delivery as a result of obstetric intervention, fetal death due to placental abruption or fetal asphyxia in labour.

### General nursing care

- Airway and breathing management should be undertaken as appropriate. This includes ensuring that  $\text{SaO}_2$  remains normal at  $\geq 94\%$ .
- Maintain the patient in the lateral tilt or recovery position at all times before delivery.
- Indwelling aseptically placed urinary catheter and hourly urine output measurement.
- Care of eyes and oral hygiene.

**The HELLP syndrome (Haemolysis, Elevated Liver enzymes, Low Platelet counts) syndrome is a dangerous form of severe pre-eclampsia.**

- If the platelet count is  $< 50\,000 \times 10^9$  there is a high risk of bleeding, and if bleeding occurs in the absence of platelet transfusions, fresh blood may be helpful.
- Liver dysfunction may cause upper abdominal pain, and lowering of the blood pressure may be helpful.
- Delivery is urgent.

### Stage 4: Delivery of the baby

The need for *in-utero* transfer should be considered,

particularly if there are maternal complications that are likely to require a Caesarean section or high-dependency care. The need for delivery is dependent on the maternal and fetal conditions. Either Caesarean section or induction of labour may be appropriate, depending on the clinical findings. Although delivery will resolve the disease, it is inappropriate to deliver an unstable mother, even if there is fetal distress. Once eclamptic seizures have been controlled, severe hypertension has been treated and any hypoxaemia corrected, delivery can be expedited.

In severe pre-eclampsia, aim to deliver within 24 hours of the onset of symptoms. In eclampsia, aim to deliver within 12 hours of the onset of convulsions.

It is important to stabilise the mother's condition first. Then decide about the mode of delivery.

In selected patients, **labour may be induced** if the following conditions apply:

- the cervix is favourable
- the maternal condition is stable (i.e. eclampsia and blood pressure are controlled), there is no fetal distress and there is a cephalic presentation.

### Assessment of the cervix

- If **the cervix is favourable** (i.e. soft, thin and partly dilated), rupture the membranes with an amniotic hook or a Kocher's forceps, and induce labour using an oxytocin infusion (see Section 2.3) or oral misoprostol (see Section 2.3 and below).
- If **vaginal delivery is not anticipated** within 12 hours (for eclampsia) or within 24 hours (for severe pre-eclampsia), deliver by Caesarean section.
- If there are **fetal heart rate abnormalities** ( $< 110$  beats/minute or  $> 160$  beats/minute), consider Caesarean section if this is safe for the mother.
- If **the cervix is unfavourable** (i.e. firm, thick and closed) and **the fetus is alive**, deliver by Caesarean section if the mother is adequately resuscitated.
- If **there are no facilities for Caesarean section** or if **the fetus is dead or too premature for survival**, deliver vaginally.

### Aiming for vaginal delivery

If **the cervix is unfavourable** (i.e. firm, thick and closed) and the fetus is alive, Caesarean section should be performed. If the fetus is dead, consideration should be given to induction of labour using misoprostol (unless there has been a previous Caesarean section, in which case misoprostol is contraindicated).

There are many possible misoprostol regimens for induction of labour (vaginal misoprostol tablet, oral misoprostol solution or oral misoprostol tablet). Each has been widely used. The latest evidence is that oral misoprostol solution is the most appropriate treatment (Cochrane reviews).

**Oral misoprostol solution:** A single misoprostol tablet is dissolved in drinking water (a 200-microgram tablet in 200mL of water or a 100-microgram tablet in 100mL of water), and 20–25 mL of misoprostol solution (20–25 micrograms) are then given every 2 hours. The solution is stable for up to 24 hours at room temperature, but should then be discarded.

**Oral misoprostol tablets:** 100-microgram misoprostol tablets are cut to 25 micrograms size and administered orally every 2 hours up to a maximum of six doses. However,

this may not be very accurate, so there is a danger of giving an incorrect dosage. The solution described above is much safer.

### Caesarean section

If Caesarean section is performed, ensure that coagulopathy has been treated. Ensure that fresh blood for transfusion is available.

Spinal anaesthesia is usually safer than general anaesthesia for Caesarean section, unless there is a contraindication (e.g. maternal refusal, coagulopathy, thrombocytopenia, decreased conscious level, ongoing seizures). There does not appear to be an exaggerated decrease in blood pressure after spinal anaesthesia, and vasopressors (e.g. ephedrine) should be used cautiously in order to avoid a hypertensive response. An IV bolus of 500 mL of Ringer-lactate or Hartmann's solution may occasionally be required if the blood pressure does fall.

The use of general anaesthesia in severe pre-eclampsia or eclampsia is very hazardous. There may be laryngeal oedema, which makes airway management difficult, and increases in blood pressure during intubation and extubation, with an increased risk of intracranial haemorrhage. Drugs to weaken the vasopressor response to intubation should be used.

**Local anaesthesia or ketamine in women with pre-eclampsia or eclampsia are contraindicated unless facilities and/or expertise dictate that these are the safest options in a given situation.**

### Stage 5: Management after delivery

- If the patient is post-eclampsia or at high risk of convulsions, continue to administer parenteral anticonvulsants (i.e. magnesium sulphate, or diazepam if magnesium sulphate is not available) for 24 hours after the birth. Continue for as long as the patient has increased tendon reflexes.
- **Do not give ergometrine to women with pre-eclampsia, eclampsia or high blood pressure, because it increases the risk of convulsions and cerebrovascular accidents.**
- Monitor the mother closely.
- Use antihypertensive agents if the diastolic blood pressure is > 105–110 mmHg or the systolic blood pressure is > 160 mmHg.
- Continue oxytocin infusion to keep the uterus contracted.
- **Syntometrine (which contains ergometrine, and can cause or worsen hypertension) is contraindicated.** Give oxytocin alone or with misoprostol, and avoid the possible hypertensive effects of ergometrine. If postpartum haemorrhage occurs, this should be managed as described in Section 2.5.D.iv.
- Keep the mother in the delivery unit or close observation area for at least 24 hours after the last fit.
- Review the need for further anticonvulsants and antihypertensive drugs.
- Regular monitoring is essential.
- It is not uncommon for the blood pressure to drop transiently following delivery only to rise again after 24 to 48 hours. Patients with severe pre-eclampsia and eclampsia should be monitored as in-patients for 72 hours after delivery so that dangerous post-partum rises in BP can be detected and treated.
- Plans for care should be communicated to the patient

### BOX 2.5.E.2 Emergency box for eclampsia

Equipment	Quantity
Drugs	Magnesium sulphate 50%, 5 g in 10-mL ampoule × 10 ampoules Calcium gluconate 10%, 10-mL ampoule × 2 ampoules Hydralazine, 20 mg in 1-mL ampoule × 2 ampoules Labetalol, 200 mg in 20-mL ampoule × 1 ampoule 0.9% Sodium chloride, 10-mL ampoule × 10 ampoules Diazepam, 5 mg/mL ampoules × 20
Intravenous fluids	500-mL bag of Ringer-lactate or Hartmann's solution × 1 Giving set × 1 IV blood giving set × 1
Venous access	20-gauge cannula (pink) × 2 18-gauge cannula (green) × 2 16-gauge cannula (grey) × 2 Tourniquet × 1 Fixation tape × 1 roll
Airway equipment	Guedel airways: sizes 4, 3 and 2 <b>Self-inflating bag-mask-valve</b> Green oxygen tubing (2 metres) and high and medium concentration (MC) facemasks for oxygen delivery Yankauer sucker
Other equipment	50-mL syringe × 2 20-mL syringe × 2 10-mL syringe × 2 Green needles × 2 Patella hammer × 1 Urinary catheter Charts for vital signs and fluid balance

and her attendants. The attendants should be educated about the use of the left lateral tilt position prior to delivery, the use of the recovery position after convulsions, the risk of aspiration of food, and care of the IV site.

- Before the mother goes home, the family and attendants should be warned about the risk of postnatal depression, especially if the outcome has been poor. The woman or girl should be followed up closely in the community.
- In women with severe pre-eclampsia/eclampsia a plan should be made to monitor the BP in the post-partum period, even in women who are not discharged on antihypertensive medication. This is because the BP is commonly labile during this period. One or ideally two checks (or more if the BP is poorly controlled) should be advised over the first 2 weeks following delivery. This may be done at a clinic local to the patient's residence, but may require that the patient stay in or near the hospital if no facilities exist close to her home.
- Women and their families should also be warned about

the symptoms of severe pre-eclampsia and advised that although delivery does usually resolve the disease, it can still worsen suddenly in the first 2 weeks following delivery (rarely up to 6 weeks).

- Antenatal care provided by the hospital during a future pregnancy is important. There is an increased risk of pre-eclampsia and hypertension if these problems have been present before.
- All patients are at risk of deep vein thrombosis (DVT), so close observation and appropriate treatment if DVT is identified are important (see Section 2.5.H). Anti-embolism stockings and low-molecular-weight heparin (or unfractionated heparin if the former is not available) prophylaxis should be considered early on.

Hypertension may take from many days to up to 3 months to resolve. Resolution will occur if the diagnosis is pre-eclampsia, unless there is an underlying medical cause.

### Monitoring and preparation for emergencies

- Measure pulse rate and volume, blood pressure, respiratory rate and oxygen saturation regularly. A minimum of hourly if receiving  $MgSO_4$  and more often if unstable.
- Monitor fluid intake and urinary output hourly.
- Monitor AVPU and GCS scores, reflexes and pupil responses hourly.
- Monitor the mother for confusion and visual disturbance.
- Monitor the fetus regularly.
- Record all drugs used.

**Each maternity unit should have an emergency box to ensure that appropriate equipment and drugs are readily available.**

## 2.5.F Prolonged and obstructed labour, uterine rupture and shoulder dystocia

### Prolonged and obstructed labour

It helps to reduce prolongation of labour if mothers in labour are allowed to sit upright, or in a lateral or semi-upright position, **never flat on their backs**. They should be encouraged to stand, and be mobile in the first stage of labour for as long as is comfortably possible. The benefits of this include the assistance of gravity in the descent of the baby, the avoidance of pressure on the inferior vena cava (IVC), with all of the effects of compression on the circulatory dynamics, and possibly a reduction in the pain of contractions.

### Recognition of prolonged or obstructed labour and early referral

**Remember the three P's: Power (too little), Passenger (too big) and Passage (too small).**

### Prevention of prolonged labour

- Good antenatal care is essential, so that the presentation of the fetus is known (and ideally confirmed by ultrasound examination) before the onset of labour. **If the presentation is abnormal, the mother must be transferred to hospital as soon as she goes into labour.**
- Use of the modified WHO partograph.
- Optimal nutritional state in the mother.
- Absence of anaemia in the mother.
- Adequate fluids and glucose during labour.
- Ensuring adequate bladder emptying.
- Emotional support.

FIGURE 2.5.F.1 Cervical dilatation over time.

### Risks associated with slow progress in labour

#### For the mother these include the following:

- infection
- uterine rupture
- fistulae
- death.

#### For the baby they include the following:

- infection
- insufficient oxygen supply to the brain and traumatic injury
- stillbirth
- neonatal death
- permanent brain damage.

FIGURE 2.5.F.2 Obstruction of the fetal head's descent.

**FIGURE 2.5.F.3** Development of increasing moulding of skull bones of fetus in labour. Increasing moulding is a sign of cephalo-pelvic disproportion.

**Main causes of slow progress in labour**

These include the following:

- 1 poor-quality uterine contractions
- 2 malpresentations and malpositions
- 3 disproportion between the size of the baby and the size of the pelvis; **it is important to exclude causes (1) and (2) before diagnosing this.**

**All three of these causes require urgent transfer to hospital.**

**Bandl's ring**

The presence of a Bandl's ring may be one sign that is seen in obstructed labour. It is often a late sign.

A Bandl's ring is a depression between the thickened upper segment and the thinned lower segment. A distended bladder sometimes forms a third swelling.

**Moulding of the fetal head**

Moulding refers to the overriding of the fetal skull bones that may occur during labour. Moulding should be assessed at the sagittal suture (not the lambdoid). During descent of the fetal head, the fetal skull bones move closer together. Moulding is described in three stages. The first stage (+) occurs when the bones touch, the second stage (2+) occurs when the bones overlap but are reducible, and the third stage (3+) is irreversible overlapping of the bones. Moulding, especially 3+, may suggest cephalo-pelvic disproportion, and should be looked at in conjunction with other clinical signs of obstructed labour.

**Partogram in obstructed labour**

Figure 2.5.F.4 shows the partogram for Mrs H, a mother who was admitted in active labour at 10 am.

**FIGURE 2.5.F.4** Partogram of obstructed labour.

- The fetal head is 3/5 palpable.
- The cervix is dilated to 4 cm.
- Three contractions occur in 10 minutes, each lasting for 20–40 seconds.
- Clear amniotic fluid is draining.
- There is fetal head moulding.

At 2 pm:

- The fetal head is still 3/5 palpable.
- The cervix is dilated to 6 cm and to the right of the alert line.
- There is a slight improvement in contractions (three in 10 minutes, each lasting for 40 seconds).
- There is second-degree moulding.

At 5 pm:

- The fetal head is still 3/5 palpable.
- The cervix is still dilated to 6 cm.
- There is third-degree moulding.
- The fetal heart rate 92 beats/minute.

Caesarean section was performed at 5.30 pm.

**Note:** The partogram for Mrs H is characteristic of obstructed labour. There is arrest of cervical dilatation in the active phase of labour, with no descent of the fetal head.

The presence of meconium and a falling fetal heart rate suggest fetal distress. All of these features, plus moulding of the fetal skull bones, point to cephalo-pelvic disproportion.

Oxytocin was rightly withheld, as Mrs H was multiparous, and this drug would therefore have increased the risk of uterine rupture in this patient.

### Diagnostic issues in obstructed labour

#### The mother

- The patient may be dehydrated, tachycardic, ketotic (urine positive for ketone bodies, breath smells of ketones), febrile and exhausted, and there may be infected vaginal secretions.
- The bladder may be distended with retained urine, or it may be oedematous.
- Abdominal examination may reveal haemoperitoneum from a ruptured uterus. Blood may not appear vaginally, due to the impacted fetal head, which should be

dislodged upwards to allow full assessment. If a ruptured uterus is suspected, a laparotomy should be performed (see below).

- Abdominal examination may reveal distended bowel from sepsis and ileus.

#### The fetus

- The lie and relationship of the fetus to the pelvis must be assessed.
- Despite visible caput at the introitus, 60% of the fetal head may still be palpable abdominally.

TABLE 2.5.F1 Diagnosis of unsatisfactory progress of labour

Cervix not dilated	False labour
No palpable contractions/infrequent contractions	
Cervix not dilated beyond 4 cm after 8 hours of regular contractions	Prolonged latent phase
Cervical dilatation to the right of the alert line on the partogram	Prolonged active phase
Secondary arrest of cervical dilatation and descent of the presenting part in the presence of good contractions	Cephalo-pelvic disproportion
Secondary arrest of cervical dilatation and descent of the presenting part with large caput, third-degree moulding, cervix poorly applied to the presenting part, oedematous cervix, ballooning of the lower uterine segment, formation of a retraction band, and maternal and fetal distress	Obstruction
Less than 3–4 contractions in 10 minutes, each lasting from less than 40 seconds to 1 minute, with 1 minute of relaxation between contractions	Inadequate uterine activity
Presentation other than vertex with occipito-anterior	Malpresentation
Cervix fully dilated and the woman has the urge to push, but there is no descent	Prolonged expulsive (second stage) phase

FIGURE 2.5.F5 Partogram showing prolonged active phase of labour.

FIGURE 2.5.F6 Partogram showing inadequate uterine contractions corrected with oxytocin.

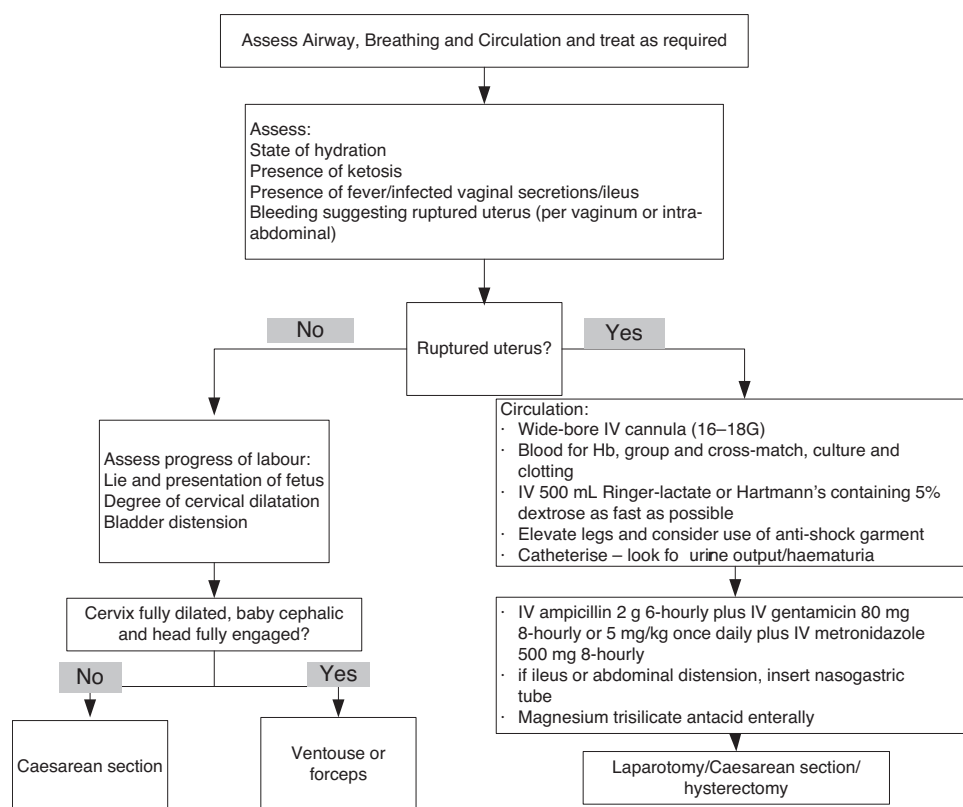

FIGURE 2.5.F.7 Pathway of care in obstructed labour.

The cervix in the primigravida whose partogram is shown in Figure 2.5.F.5 was 4 cm dilated on admission. Her contractions were ineffective at two in 10 minutes, decreasing to one contraction in 10 minutes. Her membranes ruptured 3.5 hours later, but her cervix dilated only a further 2 cm in 4 hours, with no further dilatation in the subsequent 3 hours. Fetal distress developed, with meconium and a falling fetal heart rate. Caesarean section was performed. It would have been advisable to start an oxytocin infusion at 13.30 hours, or at least by 15.30 hours.

The primigravida whose partogram is shown in Figure 2.5.F.6 started an oxytocin infusion at the time of membrane rupture, which increased the efficacy of contractions. She progressed to a spontaneous vaginal delivery. The fetal heart rate was satisfactory throughout.

## Emergency treatment for obstructed labour

Assess ABC and resuscitate if required.

- Place a wide-bore IV cannula (14- to 16G).
- Place the mother in the left lateral tilt or recovery position.
- Send blood for haemoglobin, grouping and cross-matching, and electrolytes if possible.
- Give 1 litre IV of Ringer-lactate or Hartmann's solution containing 5% or 10% glucose over 1 hour as an infusion, or as rapidly as possible if the patient is shocked. Then reassess.
- Catheterise the patient to decompress the bladder, measure urine output and look for haematuria.
  - The presence of haematuria may suggest uterine rupture.
  - If there is concern about the viability of the vaginal

and bladder wall, the catheter may be kept *in situ* for up to 6 weeks to prevent or minimise the formation of a vesico-vaginal fistula.

- Give IV ampicillin (2 grams 6-hourly), gentamicin (80 mg IV/IM 8-hourly or 5 mg/kg body weight IV/IM once every 24 hours) and metronidazole (500 mg 8-hourly). Cefuroxime (1.5 grams 8-hourly, if available) can be given instead of ampicillin plus gentamicin.
- Measure the pulse rate, capillary refill time (CRT), blood pressure, temperature and urine output frequently.
- If uterine rupture has been excluded, shock may be due to hypovolaemia, sepsis or both.

If there has been recent food intake, or abdominal distension is present, the stomach should be emptied using a nasogastric tube, and then 10 mL of magnesium trisilicate oral suspension should be given to reduce the acidity of the gastric contents.

## Overcoming slow progress in labour

- If the cervix is fully dilated and there is cephalic presentation and no signs of obstruction, instrumental delivery (ventouse or forceps) can avoid the need for Caesarean section. However, if the cervix is fully dilated and there is obstruction, instrumental delivery can make Caesarean section very difficult by causing further impaction of the fetal head.
- If the cervix is not fully dilated, in the primigravida with cephalic presentation, give an oxytocin infusion.
- If the cervix is not fully dilated, with abnormal presentation, perform a Caesarean section.
- If there is a ruptured uterus, a laparotomy and Caesarean hysterectomy must be performed.

Urgent referral is required if the above measures are not possible. Stabilise the mother's ABC before transfer if necessary.

### Reasons for fetal death in obstructed labour

- Strong contractions with inadequate relaxation between contractions (sometimes made worse by inappropriate use of oxytocin) interfere with placental exchange.
- Excessive moulding of the head, in cephalic presentation, leads to intracranial haemorrhage. In breech presentation, the head may be trapped by an incompletely dilated cervix, or may not enter the pelvis because of disproportion.
- Ascending infection, amnionitis and severe intrauterine infection caused by prolonged ruptured membranes and labour, and/or unsterile vaginal examinations.
- Ruptured uterus.

### Risks of Caesarean section in obstructed labour

These include the following:

- intra-operative haemorrhage
- post-operative shock
- generalised peritonitis
- the hazards of general or regional anaesthesia
- rupture of the uterine scar in subsequent pregnancies

**FIGURE 2.5.F.8** Mechanism and anatomy of vaginal fistulae. The arrows show where this mother's cervix, rectum and bladder are being pinched between the baby's head and the mother's spine and pubis. (a) The baby's head can press the mother's vagina and bladder against the symphysis pubis or the sacrum. This can make the tissues necrose (die) and cause a fistula. (b) The fistula can be in various places: 1, between the bladder and the vagina; 2, between the urethra and the vagina; 3, between the bladder and the cervix; 4, between the rectum and the vagina (recto-vaginal fistula); 5, between the vagina and the small gut. (c) A vesico-vaginal fistula. (d) A catheter has been placed in a recto-vaginal fistula.

- wound complications
- pelvic abscess
- visceral damage, especially to the bladder; it may be difficult to pass a catheter with a very impacted fetal head, and the bladder is often oedematous.

The management of uterine rupture in this setting depends on its site and extent. With a straightforward anterior rupture without extension, uterine repair (plus bilateral tubal ligation) may be most appropriate and safe.

If infection is present before a Caesarean section is performed, dangerous complications can follow. In one series of 107 Caesarean sections, performed in 156 patients with intrapartum infection, the following complications occurred:

- post-operative shock: 18 patients (17%)
- generalised peritonitis: 70 patients (65%)
- mortality: 13 patients (12%).

### Rupture of the uterus

**Complete rupture of the uterus is life-threatening to both mother and baby.**

#### Causes

A previous Caesarean section scar may rupture during labour. However, obstructed labour, even without a uterine scar, particularly in a woman of high parity, may cause uterine rupture. It may be caused by inappropriate use of oxytocic drugs, especially in multiparous women, or in the presence of cephalo-pelvic disproportion. No woman who is receiving an oxytocin infusion should be left alone.

Ideally, always use a burette giving set to administer IV oxytocin to avoid dangerous over-dosage. **In the absence of a burette, refer to the progressive oxytocin dosage, and use as described in Section 2.3, making sure to slow or stop once labour is well established.**

Uterine rupture may be caused by violence or trauma during pregnancy, sometimes as a result of domestic violence (see Section 2.11).

#### Risk factors for uterine rupture

These include the following:

- malpresentation and malposition
- previous Caesarean section, especially if oxytocic agents

**FIGURE 2.5.F.9** Bandl's ring in obstructed labour. Uterine rupture may be imminent.

are used, or if a classical Caesarean section scar is present

- previous uterine surgery (e.g. myomectomy), or uterine perforation at the time of dilatation and curettage (D&C) or manual removal of the placenta; this is often unrecognised
- the multiparous woman who has delivered normally before and has a significantly larger baby or a malposition in the current pregnancy, and is allowed a prolonged second stage.

### Symptoms and signs

Uterine rupture usually presents with hypovolaemic shock, but vaginal bleeding can be concealed. The baby is usually dead.

Around 50% of ruptures occur at or near full dilatation.

- There is a change in the nature of the pain, from severe intermittent pain to a constant dull ache.
- Vaginal bleeding may or may not be present.
- There is maternal shock due to blood loss with or without vagal stimulation, as well as dehydration, exhaustion, and ketoacidosis in cases of prolonged obstructed labour.
- Abdominal distension occurs that is tender to palpation, the fetal parts may be very easily palpated, and there is absence of a fetal heart rate.
- On vaginal examination, the presenting part may be high or impacted.
- Uterine rupture may be preceded by the appearance of Bandl's ring (see Figure 2.5.F.9).

Suspect rupture in a patient with any of these risk factors.

### Primary assessment and resuscitation

**Call for help, especially for a surgeon and an anaesthetist, as urgent laparotomy will be required.**

#### Airway

- If the airway is not open, use an airway-opening manoeuvre and keep it open. Consider an airway adjunct such as an oropharyngeal airway or intubation.
- The oropharynx may need gentle suctioning under direct vision, but be careful to avoid inducing laryngospasm.
- The recovery position should be adopted to minimise the risk of aspiration of vomit (see Figure 2.5.F.10).

**FIGURE 2.5.F.10** The semi-prone or recovery position.

#### Breathing

- If there is spontaneous breathing, give a high concentration of oxygen via a face mask with reservoir. Give

100% oxygen (mask with reservoir and flow rate of at least 6 litres/minute) regardless of the mother's oxygen saturation. This increases fetal oxygen delivery as well as improving maternal tissue oxygenation.

- If the patient is apnoeic or hypoventilating, provide chest inflations with bag-valve-mask-reservoir ventilation and high-flow oxygen.

### Circulation

**Evaluate the pulse rate and volume, peripheral circulation (capillary refill time) and blood pressure.**

- **If signs of life are absent, initiate CPR.**
- **Perform the left lateral tilt or manual displacement of the uterus.**
- **If the patient shows signs of shock, support the circulation as described below.**
  - Insert a 14- to 16G IV cannula and take 20mL of blood for a full blood count, cross-matching (4 units = 2 litres) and clotting. Do a whole blood clotting time (WBCT) test if laboratory analyses are not available.
- Give 500mL to 1 litre of Ringer-lactate or Hartmann's solution by rapid IV bolus.
- Reassess, and if shock is still present, give blood (if available) (500mL as rapidly as possible after warming) or another 500mL to 1 litre of Ringer-lactate or Hartmann's solution.
- If the patient is ketotic from prolonged obstructed labour, add 50mL of 50% glucose to the second litre of Ringer-lactate or Hartmann's solution.
- Central venous access may be needed for volume replacement if peripheral access is not possible.

### Emergency treatment

- 1 Obtain consent for laparotomy and hysterectomy.
- 2 Try to place a second IV cannula.
- 3 Perform urgent laparotomy under general anaesthesia.
- 4 The type of operation will depend upon the size and site of rupture, and the degree of haemorrhage.
- 5 Give IV prophylactic antibiotics (ampicillin 2 grams or cefuroxime 1.5 grams plus metronidazole 500mg).

The rupture may extend anteriorly towards the back of the bladder, laterally towards the uterine arteries, or into the broad ligament plexus of veins, leading to massive haemorrhage.

Posterior rupture may occur, and is usually associated with intrauterine malformations, but has occurred in patients who have had a previous Caesarean section or uterine trauma, or after rotational forceps. Fundal rupture has been documented, and a detailed history usually elicits previous dilatation and curettage (D&C) or manual removal of the placenta.

Continuing haemorrhage is an indication for performing a total or subtotal hysterectomy. Subtotal hysterectomy is a simpler procedure than total hysterectomy, and has a reduced risk of ureteric or bladder damage.

The choice of uterine repair depends on the site of the injury. In one series of 23 cases of ruptured uterus, hysterectomy was undertaken in 15 cases (65%) and repair in the other 8 cases. Five successful further pregnancies were reported without repeat rupture (all delivered by Caesarean section). In another Middle Eastern series of 11 cases of uterine rupture, 8 cases had uterine repair, and all became pregnant again and were delivered by Caesarean section.

**Shoulder dystocia** (see video for download on [www.mcai.org.uk](http://www.mcai.org.uk))

Shoulder dystocia is caused by impaction of the shoulders against the bony pelvis. Special manoeuvres are required to deliver the shoulders. The reported incidence is between 0.15% and 2% of all vaginal deliveries. Shoulder dystocia carries a significant risk to the baby due to hypoxia, fractures of the clavicle and humerus, and injuries to the brachial plexus.

The problem lies at the **pelvic brim** where the anterior shoulder gets caught, while the posterior shoulder has usually entered the pelvis. Treatment therefore aims to encourage the anterior shoulder into the pelvis, or if this fails, either rotating the posterior shoulder round into the anterior position or delivering the posterior arm first. Traction on the head when the anterior shoulder is caught above the pelvic brim will not work and is dangerous.

Delivery should occur within 5 minutes of the delivery of the head. The longer the delay, the greater the risk of hypoxic injury to the baby.

Postpartum haemorrhage is common after shoulder dystocia, and there is a risk of serious vaginal and perineal lacerations.

### Risk factors for shoulder dystocia

**Antepartum** risk factors include the following:

- fetal macrosomia
- maternal obesity
- diabetes
- prolonged pregnancy
- advanced maternal age
- male gender
- excessive weight gain
- previous shoulder dystocia
- previous big baby.

**Intrapartum** risk factors include the following:

- prolonged first stage
- prolonged second stage
- oxytocin augmentation of labour
- assisted delivery.

**These risk factors often do not help in the prediction of individual cases of shoulder dystocia. Therefore the practice of emergency drills is essential for good management of the unexpected case.**

Slow progress in labour, particularly in the multiparous patient or in the woman with a past history of a big baby or difficulty delivering the shoulders, should alert one to the possibility of shoulder dystocia.

During delivery, signs include the following:

- difficulty delivering the face and chin
- head retractions between contractions
- head bobbing
- the delivered head becomes tightly pulled back against the perineum (turtle sign).

As soon as the situation is suspected, a plan of action should be initiated.

### Management of shoulder dystocia

If risk factors are present, try if possible to have an experienced obstetrician present in the second stage of labour. However, 50% of cases are unexpected.

Be prepared for the problem, including postpartum haemorrhage, which may follow.

Try each manoeuvre for 30–60 seconds only: if it does not work, move on. Try to recognise it early on and before applying any traction to the head, which can delay helpful procedures and cause Erb's paralysis.

**The following acronym suggested by Advanced Life Support in Obstetrics (ALSO) is helpful (see [www.also.org.uk](http://www.also.org.uk)):**

**HELPERR:** H = Help

E = Evaluate/Episiotomy

L = Legs (McRoberts)

P = Pressure (suprapubic)

E = Enter (posterior arm and Wood's screw)

R = Rotate (on to all fours)

R = Repeat

1 **Call for help. This condition needs the most experienced team and extra helpers.**

2 **McRoberts manoeuvre (legs)** (see Figures 2.5.F.11 and 2.5.F.12). Both thighs are sharply flexed, abducted and rotated outwards, ideally by two assistants. Each assistant holds the leg in the region of the thigh and flexes the leg until the thigh lies parallel to the anterior abdominal wall. This will reduce the angle between the sacrum and the lumbar vertebrae to help to free the impacted shoulder. If two assistants are not available, the mother may be placed in the all fours position (see below).

**FIGURE 2.5.F.11** McRoberts manoeuvre, showing how important it is to fully flex both legs on to the mother's abdomen so that the thighs lie parallel to the anterior abdominal wall.

**FIGURE 2.5.F.12** In McRoberts manoeuvre, with only one assistant the left leg is held flexed against the abdomen by a nurse, and the mother holds her right leg in this position.

- 3 **Suprapubic pressure with moderate traction (not fundal pressure).** Suprapubic pressure is applied to reduce the diameter between the shoulders and push the anterior shoulder underneath the symphysis pubis. It is important to know where the fetal back lies, so that pressure is applied in the right direction (i.e. from the fetal back forwards towards the fetal chest). If you are unsure of the position of the back, confirm it by vaginal examination. Pressure should be applied to the back of the shoulder with the heel of the hand, and sometimes a rocking movement may be helpful. Strong traction and fundal pressure should be avoided.

FIGURE 2.5.F.13 Suprapubic pressure.

- 4 **Apply moderate traction (harder pulling can make impaction worse and cause Erb's paralysis).** Once both McRoberts manoeuvre and suprapubic pressure are in place, moderate traction can be applied while discouraging maternal efforts (which can increase the impaction of the shoulders).
- 5 **Consider an episiotomy.** A medio-lateral episiotomy is recommended to allow more room for manoeuvres such as delivering the posterior shoulder, allowing the operator to use the sacral hollow, and reducing vaginal trauma.
- 6 **Deliver the posterior arm and shoulder.** Insert a hand up to the fetal axilla and hook the posterior shoulder down. Traction on the posterior axilla then brings the posterior arm within reach. Run your index finger or middle finger, or both, along the back of the fetal humerus, then flex the elbow at the antecubital fossa, which will disengage the arm, which can then be brought down (hold the hand and sweep it across the chest). Sometimes it comes out directly lying alongside the head, and sometimes it comes out with an element of rotation anteriorly.
- 7 **Internal rotational manoeuvres (Rubin's and Wood's screw manoeuvres).** These measures are rarely required.

**Rubin's manoeuvre.** The operator inserts the fingers of one hand vaginally, positioning the fingertips behind the anterior shoulder. The shoulder is then pushed towards the fetal chest.

**Wood's screw manoeuvre.** If Rubin's manoeuvre is unsuccessful, the fingers of the opposite hand may be inserted vaginally to approach the posterior shoulder from the front of the fetus. The combination of these two movements may allow rotation of the shoulders and aid delivery. If delivery of the posterior shoulder or arm is not successful, try to rotate the posterior shoulder 180-degrees in a corkscrew fashion (clockwise or anticlockwise) to bring it to an anterior position, from which the delivery can continue as normal (this rotation

FIGURE 2.5.F.14 Delivery of the posterior arm. Reproduced with permission from Macdonald S, Magill-Cuerden J (ed.) *Mayer's Midwifery: a textbook for midwives*. Elsevier Health Sciences; 2010. © Elsevier

FIGURE 2.5.F.15 Rubin's manoeuvre.

releases the impacted anterior shoulder that ends up in the posterior pelvis). It is important not to twist the fetal head or neck during this manoeuvre.

- 8 **All fours position.** This is another procedure that can be useful if no help is available. The mother quickly positions herself evenly on hands and knees (Gaskin's manoeuvre). In many cases this alone relieves the dystocia. In addition, it can assist with the delivery of the posterior arm. The other manoeuvres described above can also be performed with the mother in this position. Early on try to deliver the posterior shoulder from this position. Sometimes pushing one leg forward into the

FIGURE 2.5.F.16 Wood's screw manoeuvre.

FIGURE 2.5.F.17 Reverse Wood's screw manoeuvre.

FIGURE 2.5.F.18 The all-fours position for shoulder dystocia (the method to use if you have no one to assist you). Guide the head downwards so that the posterior shoulder which has now become upwards with the adoption of the all-fours position is delivered.

'starting of a race' position can open up the pelvis from this position.

- 9 **Symphiotomy.** If the baby is still undelivered, symphiotomy should be considered.
- 10 Check the vagina and perineum for trauma, and repair accordingly.
- 11 Prepare for postpartum haemorrhage.

## 2.5.G Severe infection in the puerperal period

### Diagnosis of infection after childbirth

TABLE 2.5.G.1 Symptoms and signs of infection, with diagnosis and treatment

Symptoms	Signs	Investigations	Diagnosis	Treatment
Rigors/chills Lower abdominal and/or pelvic pain Foul-smelling liquor Persistent light vaginal bleeding History of incomplete placenta delivered History of prolonged rupture of membranes, frequent unsterile vaginal examinations in labour	Fever (usually > 38°C) Tender uterus Shock Delayed rate of involution of uterus	Full blood count, including white blood cell count Blood culture Lochia for microscopy, culture and sensitivity	<b>Endometritis</b>	Treat shock urgently if present IV antibiotics Ampicillin 2 grams IV/IM every 6 hours <i>plus</i> gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours <i>plus</i> metronidazole 500 mg IV every 8 hours
Breast pain Rigors	Tender over breast Red wedge-shaped area of induration of one breast Fever > 38°C		<b>Mastitis</b>	If bacterial infection is suspected, give anti-staphylococcal antibiotics: flucloxacillin or cephalexin orally for 7 days
Breast pain Rigors, chills and/or malaise	Swinging fever Fluctuant swelling in the breast, possibly with pointing and draining of pus		<b>Breast abscess</b>	Surgical drainage If the patient is systemically very unwell, give anti-staphylococcal antibiotics IV: flucloxacillin or cefotaxime or ceftriaxone

(continued)

Symptoms	Signs	Investigations	Diagnosis	Treatment
History of Caesarean section Rigors, chills and/or malaise  Severe abdominal pain Vomiting	High, swinging fever Swelling and redness around incision  High fever Abdominal distension Rigid abdomen Absent bowel sounds Shock (see above for signs)		<b>Wound abscess</b>  <b>Peritonitis</b>	Surgical drainage  Treat shock Give IV antibiotics Nasogastric tube Immediate laparotomy in operating theatre
Lower abdominal pain Diarrhoea History of Caesarean section	Swinging fever Swelling in adnexae or pouch of Douglas Tender uterus Ultrasound	Full blood count, including white blood cell count Blood culture Pus for microscopy, culture and sensitivity	<b>Pelvic abscess</b>	Give IV antibiotics: Ampicillin 2 grams IV/IM every 6 hours <i>plus</i> gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours <i>plus</i> metronidazole 500 mg IV every 8 hours Surgical drainage
Pain in the lower abdomen or loin Nausea and/or vomiting Increased frequency of passing urine	High fever Tenderness of one of the loins over the kidney Normal bowel sounds	Microscopic examination of urine Stick tests for infection (if available) Urine culture and sensitivity if possible	<b>Pyelonephritis</b>	IV antibiotics (see Section 2.8.F) If the patient is in shock, initiate immediate treatment
Difficulty in breathing Cough, sometimes with expectoration Pleuritic chest pain	Fever Respiratory distress Signs of consolidation or effusion	Chest X-ray Ultrasound if there is effusion	<b>Pneumonia</b>	IV antibiotics (see Section 2.8.A)
Rigors Headache Muscle and/or joint pains	Fever Enlarged spleen Shock Reduced consciousness Jaundice Anaemia Fitting	Full blood count Thick film for parasites Blood glucose	<b>Malaria</b>	Antimalarial drugs (see Section 2.8.D)

## Endometritis

This is the most serious and common cause of puerperal sepsis. It accounts for up to 15% of maternal deaths in resource-limited countries.

Infection of retained products of conception is the most common cause (suspect this if there is excessive vaginal bleeding or poor involution of the uterus). This can lead to long-term health problems, including infertility, chronic pelvic inflammatory disease and ectopic pregnancies.

Endometritis is defined as infection of the genital tract at any time between the onset of rupture of the membranes or labour and the 42nd day following delivery or abortion, in which two or more of the following are present:

- abdominal and/or pelvic pain
- fever of  $\geq 37.5^{\circ}\text{C}$  (can be masked by paracetamol or other antipyretic drugs)
- abnormal quantity of vaginal discharge
- foul-smelling discharge
- delay in the rate of involution of the uterus.

Puerperal sepsis can present with few symptoms (the

woman feels unwell and usually has a fever). It can also progress rapidly to become life-threatening within hours.

### Pathogens that cause sepsis

The pathogens most commonly responsible are group A beta-haemolytic streptococcus (often of community origin) and endotoxin-producing enterobacteria (e.g. *E. coli*). Less commonly involved are *Clostridium*, *Bacteroides*, *Chlamydia* and *Mycoplasma*. Bacterial infections are often mixed.

### Risk factors

These include the following:

- prolonged rupture of membranes (> 48 hours before delivery)
- contact with others, especially children, with a bacterial throat infection (*Streptococcus*)
- frequent (particularly unsterile) vaginal examinations
- prolonged and obstructed labour
- instrumentation (e.g. forceps delivery)
- Caesarean section (especially in an emergency)

- retained products of conception
- lack of sanitary towels and hygienic materials to manage lochia during the postnatal period
- sickle-cell disease.

### Pathogenesis

- Endotoxins are released from the cell wall of Gram-negative bacteria.
- Endotoxins can cause shock.
- Extensive tissue necrosis, even gangrene, may occur, especially in the uterus.

### Prevention

- Antibiotic prophylaxis for prolonged rupture of membranes, manual removal of the placenta and Caesarean section.
- Antiseptic cream for vaginal examinations (e.g. Hibitane obstetric cream).
- Provision of sanitary towels and other hygienic items to all women and girls who have given birth, and where family poverty means that these items are not available.

### Complications

These include the following:

- wound infection and wound dehiscence (burst abdomen)
- peritonitis
- ileus
- septicaemia, possibly accompanied by shock
- abscess formation in cul-de-sac and sub-diaphragmatic space
- adnexal infections
- ovarian abscess
- pelvic abscess
- breast infection or abscess
- deep vein thrombosis
- pulmonary embolus.

### Investigations

These include the following:

- high vaginal swab if bacteriology facilities are available
- midstream samples of urine (MSSU) and microscopy of urine.

### Treatment

Treat as an emergency, including IV fluid boluses if shock is present (see Section 2.5A), if there is persistent tachycardia (> 100 beats/minute), hypotension (systolic blood pressure < 90 mmHg), increased respiratory rate (> 25 breaths/minute), confusion or disorientation, oliguria (< 30 mL/hour), rash or bradycardia (< 50 beats/minute).

Give antibiotics until the patient has been fever-free for 48 hours or 7–10 days:

- ampicillin 2 grams IV every 6 hours
  - plus gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours
  - plus metronidazole 500 mg IV every 8 hours.

**If fever is still present 72 hours after initiating antibiotics, re-evaluate the patient and consider revising the diagnosis.**

Often a 1 to 2 week antibiotic course is completed orally once the patient has been fever free for 48 hours.

If retained placental fragments are suspected, perform a digital exploration of the uterus to remove clots and large

pieces. Use ovum forceps or a large curette if necessary, but be very careful not to penetrate the uterine wall, which is very soft at this stage. Where general anaesthesia is not available, agents such as ketamine may be considered for this procedure.

If there is no improvement with conservative measures, and there are symptoms and signs of general peritonitis (abdominal pain, fever, and abdominal tenderness with rebound tenderness), perform a laparotomy to drain the pus, and if the uterus is the source do not leave it too late to perform a hysterectomy.

### Wound infections

Wound infections may be superficial or deep. Superficial infections involve the skin and subcutaneous tissues, but not the rectus sheath (fascia). They may present with cellulitis or abscess formation. Cellulitis should be treated with antibiotics; this may prevent the development of a wound abscess.

Clear or purulent fluid exuding from the wound should raise concern that the infection is deep to the sheath. Where there is abscess formation, the wound should be opened by removing sutures to the skin and subcutaneous tissues, to allow drainage of pus. Antibiotics are not always required if an abscess is drained and the surrounding tissues appear healthy.

The wound may require debridement if tissue necrosis is suspected. If the sheath looks healthy and intact, the fascial sutures should be left *in situ*. The wound should be packed with a damp dressing, which must be changed every 24 hours.

If the sheath appears necrotic or infected, it should be opened and the peritoneal cavity inspected for collections of pus. If pus is present, it should be evacuated, and a broad corrugated drain left *in situ* in the peritoneal cavity to facilitate drainage post-operatively.

**Necrotising fasciitis** is a relatively uncommon but potentially life-threatening variant of wound infection, which presents with rapidly spreading cellulitis, with severe pain and tenderness. Urgent wide debridement of necrotic tissue is required, with antibiotics as for deep wound infection (see below). Secondary closure should be undertaken 2–4 weeks later, provided that the infection has resolved.

### Antibiotic regimes for wound infections

Where possible, swabs should be taken for culture and sensitivity before starting antibiotics.

### Superficial infections

Give ampicillin 500 mg by mouth, four times a day for 5 days, plus metronidazole 500 mg by mouth, three times a day for 5 days.

### Deep infections

Give benzyl penicillin, 2 million units (1200 mg) IV every 6 hours, plus gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours, plus metronidazole 500 mg IV every 8 hours.

IV antibiotics should be continued until at least 48 hours after the pyrexia has settled.

**The patient may then be switched to oral antibiotics, as described above.**

## Peritonitis

Treat shock, if present. Then:

- provide nasogastric suction
- infuse IV fluids for maintenance and replacement
- give antibiotics IV until the patient has been fever-free for 48 hours:
  - ampicillin/amoxicillin 2 grams IV/IM every 6 hours
  - *plus* gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours
  - *plus* metronidazole 500 mg IV every 8 hours.
- if necessary, perform a laparotomy to repair diseased or injured bowel.

## Pelvic abscess

Give antibiotics before draining the abscess, and continue until the patient has been fever-free for 48 hours:

- ampicillin/amoxicillin 2 grams IV every 6 hours
- *plus* gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours
- *plus* metronidazole 500 mg IV every 8 hours.

If **the abscess is fluctuant in the cul-de-sac**, drain the pus through the cul-de-sac (culdocentesis) (see below). If **the spiking fever continues**, perform a laparotomy.

Bowel may be secondarily involved in the inflammatory process, and care must be taken to avoid bowel perforation.

Peritonitis may develop in association with a pelvic abscess. Prompt nasogastric suction and administration of intravenous fluids are important, as well as IV antibiotic therapy as described above.

## Culdocentesis and colpotomy

### Culdocentesis for the detection of pus

- Apply antiseptic solution to the vagina, especially the posterior fornix.
- Infiltrate with 1% lignocaine.
- Gently grasp the posterior lip of the cervix with a tenaculum and gently pull to elevate the cervix and expose the posterior vagina.
- Place a long needle (e.g. spinal needle) on a syringe and insert it through the posterior vagina, just below the posterior lip of the cervix (see Figure 2.5.G.1).
- Pull back on the syringe to aspirate the cul-de-sac (the space behind the uterus).
- If pus is obtained, keep the needle in place and proceed to colpotomy (see below).

**FIGURE 2.5.G.1** Culdocentesis: diagnostic needle aspiration of the cul-de-sac.

### Colpotomy for a pelvic abscess

If **pus is obtained** on culdocentesis, keep the needle in place and make a stab incision at the site of the puncture.

Remove the needle and insert blunt forceps or a finger through the incision to break the loculi in the abscess cavity (see Figure 2.5.G.2).

- Allow the pus to drain.
- Insert a disinfected soft rubber corrugated drain through the incision. (If a surgical drain is not available, a makeshift drain can be prepared by cutting off the fingertips of a disinfected rubber glove.)
- If required, use a stitch through the drain to anchor it in the vagina.
- Remove the drain when there is no more drainage of pus.
- If **no pus is obtained**, the abscess may be higher than the pouch of Douglas. A laparotomy will be required for peritoneal lavage (wash-out).

**FIGURE 2.5.G.2** Colpotomy for pelvic abscess.

## Mastitis

Mastitis may be infective or non-infective, ranging in severity from mild local erythema and tenderness through to abscess and septicaemia.

- Non-infective mastitis may be due to a blocked lactiferous duct, or to difficulties with breastfeeding technique. It may lead to infective mastitis.
- Infective mastitis is common in lactating women. It is usually caused by the bacterium *Staphylococcus*, which generally responds to a 7- to 10-day oral course of flucloxacillin or a cephalosporin, both of which are safe to take while breastfeeding.

Mastitis usually presents with a hot red swollen section of one breast. It may be associated with flu-like symptoms, namely pyrexia of 38°C or above, chills and myalgia.

### Treatment

*Continue breastfeeding.* Although the symptoms of mastitis may discourage breastfeeding, it is important to try to continue. Regular breastfeeding will help to:

- remove any blocked breast milk from the breast
- resolve the symptoms of mastitis more quickly
- prevent mastitis from becoming more serious.

The milk from the affected breast may be a little saltier than normal, but is safe for the baby to drink. Any bacteria that are present in the milk will be harmlessly absorbed by the baby's digestive system and cause no problems.

**Breastfeed frequently on the affected side, in order to empty the breast of retained milk.** The baby can empty

the breast more efficiently than a breast pump. However, if the baby is not feeding well, a **breast pump or hand expression** will be needed to get the milk out. It may be less painful if the affected breast is given to the baby second, after the let-down reflex has occurred.

Mastitis can usually be successfully treated by resting, drinking plenty of fluids and varying the baby's position at the breast. It is important to ensure that the baby is properly attached to the nipple, and that the breast is empty after the feed. It may be necessary to feed more frequently, and to express the remaining milk after a feed. Paracetamol is useful for pain control. Massaging the areas of tenderness may be beneficial.

### Prevention of mastitis

The following advice should be given to any mother who has experienced mastitis:

- Relieve engorgement promptly. Milk that does not flow gets thicker and clogs the ducts.
- Breastfeed frequently. Do not restrict the length of feedings.
- If the mother feels her breasts getting full, she should encourage the baby to feed without waiting for the baby to initiate this.

### Repeated mastitis

This is usually the result of irregular breastfeeding patterns, such as missing feeds and giving bottles in place of breastfeeding. Recurrent mastitis may also result from tiredness and stress.

With regard to antibiotic treatment, the bacterium involved in mastitis is usually *Staphylococcus*, and the two most effective antibiotics are cloxacillins and cephalosporins, which are safe to take while breastfeeding. A 10-day oral course is recommended.

## 2.5.H Pulmonary embolism

### BOX 2.5.H.1 Minimum standards

- Oxygen.
- IV unfractionated heparin.
- Low molecular weight heparin.
- Subcutaneous heparin.
- Blood clotting measurements.
- Anti-embolism stockings.

### Introduction

If left untreated, as many as 24% of patients with deep vein thrombosis (DVT) will have a pulmonary embolism. However, when DVT is treated with anticoagulants (if that is possible), pulmonary embolism occurs in only 4.5% of cases, and the mortality rate is less than 1%.

Deaths are equally common antenatally and postnatally. Pregnancy is a thrombogenic state associated with a five- or sixfold increase in the risk of pulmonary embolism. The majority of DVTs in pregnancy are ileo-femoral, and these are more likely to embolise.

**Anti-embolism stockings and early mobility after Caesarean section and after childbirth are the main ways of preventing this.**

### Additional risk factors

- **Operative delivery:** Caesarean section increases the risk of pulmonary embolism by two- to eightfold; the risk is greater after an emergency procedure than after an elective one.
- **Age:** The mortality from pulmonary embolism is 100 times higher in pregnant women over 40 years of age than in those aged 20–25 years.
- **Obesity.**
- **Congenital and acquired thrombophilia:** Patients with antithrombin III deficiency, protein C and S deficiency, activated protein C resistance, and lupus anticoagulant and antiphospholipid antibody are at increased risk of pulmonary embolism.

- **Surgical procedures during pregnancy or the puerperium (especially Caesarean section).**
- **Other risk factors:** Restricted activity, pre-eclampsia, dehydration, excessive blood loss and homocystinuria.

### Clinical presentation

- Dyspnoea, tachypnoea, pleuritic chest pain, cough, haemoptysis and leg pain.
- Massive pulmonary embolism may be associated with cyanosis, circulatory collapse with hypotension, syncope or convulsions and central chest pain.
- Occasionally, patients present with unexplained tachycardia.

TABLE 2.5.H.1 Signs and symptoms of pulmonary embolism

Findings	Patients with proven pulmonary embolism (%)
Tachypnoea	89
Dyspnoea	81
Pleuritic pain	72
Apprehension	59
Cough	54
Tachycardia	43
Haemoptysis	34
Temperature > 37°C	34

Tachycardia and a few localised crepitations may be the only findings on physical examination.

Massive pulmonary embolism may produce right-sided heart failure with jugular venous distension, an enlarged liver, a left parasternal heave, and fixed splitting of the second heart sound.

Clinical evidence of DVT may not be found in patients with pulmonary embolism. Symptoms and physical findings must be interpreted with caution during pregnancy, because

dyspnoea, tachypnoea and leg discomfort are common findings as pregnancy progresses.

### Investigations

Request a full blood count, urine and electrolytes, oxygen saturation, and (when available) clotting studies and arterial blood gases.

Request an ECG and chest X-ray (if available). These investigations do not confirm or refute the diagnosis of pulmonary embolism.

- **ECG** is non-specific for the diagnosis of pulmonary embolism. The changes in electrical axis that occur in normal pregnancy make the ECG findings in pulmonary embolism even less specific. Sinus tachycardia is the most common abnormality. Right axis deviation and right ventricular strain pattern may be present with a large pulmonary embolism. The S1Q3T3 pattern is very rare.
- **Chest X-ray** helps to exclude pneumothorax and pneumonia. The non-specific radiological changes in pulmonary embolism include segmental collapse, a raised hemidiaphragm, consolidation and unilateral pleural effusion. A wedge-shaped infarction is a rare finding.

### Primary assessment and resuscitation for possible pulmonary embolism (ABC approach)

Call for help.

#### Airway

- Use an opening manoeuvre if the airway is not open or is partially obstructed. If there is an improvement, use airway adjuncts to maintain the airway.
  - An oropharyngeal airway is usually appropriate only if the patient is unconscious.
- Suction if necessary.
- The airway may need to be maintained and protected by intubation using experienced senior help (if available).

#### Breathing

- Provide a high concentration of **oxygen** through a face mask with reservoir bag, if there is adequate spontaneous respiration.
- For patients with inadequate ventilation or depressed conscious level, respiration should be supported with oxygen via a bag-valve-mask and experienced senior help summoned (if available).

Give 100% oxygen (mask with reservoir and flow rate of at least 6 litres/minute) regardless of SaO<sub>2</sub>, as it increases fetal oxygen delivery as well as improving maternal tissue oxygenation.

#### Circulation

- Place a wide-bore IV cannula (16- to 18G).
- Place the woman in a lateral tilt or recovery position if undelivered and more than 20 weeks' gestation.
- If possible, locally treat clinically suspected pulmonary embolism while awaiting confirmation from objective tests (if available) to prevent further thromboembolic complications and extension of the existing thrombus.
  - IV unfractionated heparin is the mainstay of treatment.
  - Initiate treatment with an IV bolus of 5000 IU of heparin given over 5 minutes.

- **Note:** there are serious potential risks of anticoagulation, in particular the risk of life-threatening haemorrhage in the 24 hours after delivery, especially after Caesarean section.
- Empirical anticoagulation should be undertaken only when the diagnosis is clear clinically.
- **Additional treatment options for shocked patients** (if available) include thrombolytic therapy using streptokinase, pulmonary embolectomy and transvenous catheter fragmentation of the clot (available only in well-resourced units). Expert advice should be sought (if available).

### Secondary assessment and emergency treatment

Involve the senior obstetrician, the anaesthetist and the medical team (if available).

Transfer the patient to the **high-dependency area** (if available) and commence close monitoring of heart rate, blood pressure, central oxygenation (SaO<sub>2</sub> if possible), ECG (if available) and urine output.

#### Anticoagulation

**Heparin** is the anticoagulant of choice in pregnancy, as it does not cross the placenta. Rapid and prolonged anticoagulation prevents extension of the thrombus and its recurrence.

When available, acute therapy is with an IV bolus of unfractionated heparin, 5000 IU over 5 minutes, followed by an IV infusion of 1000–2000 IU/hour for 5–10 days. The dose is adjusted to maintain the activated partial thromboplastin time (APTT) at 1.5–2.5 times the control. Repeat the APTT every 6 hours during the first 24 hours of therapy, and thereafter monitor it daily.

Treatment may then be continued with subcutaneous heparin at a dose of 10000 IU twice daily. Maintaining the APTT in the therapeutic range (1.5–2.5 times the control) following subcutaneous heparin may be problematic, and can lead to under- or over-anticoagulation. Low-molecular-weight heparin (LMWH) is ideal if available.

Before giving heparin, measure the platelet count (if available).

Rare complications of heparin treatment are allergy and thrombocytopenia. The platelet count should be monitored at the onset of treatment and monthly thereafter.

**Warfarin** crosses the placenta and is associated with characteristic damage to the fetus in the first trimester. Major fetal CNS abnormalities such as microcephaly and optic atrophy are also seen with warfarin use in the second and third trimesters. In addition, there is a higher risk of intracerebral bleeds from the trauma of delivery, and a higher risk of bleeding complications during labour and delivery.

**For all these reasons, warfarin is not recommended in the antenatal period.** However, warfarin can be initiated in the postpartum period and overlapped with heparin until the INR is maintained at 2.0–3.0.

#### Can a patient be anticoagulated with heparin if APTT is not available?

This is difficult. You will need to weigh the risks of not treating against the risks of treating. The only good thing about this situation is that the half-life of heparin is short (a few hours).

- If the diagnosis is uncertain and/or the risk to the patient is low, do not give heparin.

- If the diagnosis is likely and the patient is unwell, give 5000 units IV as a bolus and then subcutaneous heparin in small doses of 5000 units 12-hourly. Increase to 10000 units twice daily over a few days.
- If the diagnosis is certain and the patient is severely ill, give 5000 units IV as a bolus and start an infusion at 500 units/hour. Use your clinical judgement and increase slowly over 6 hours to 1000–2000 units/hour. Switch to subcutaneous heparin as soon as possible and be aware of bleeding complications.

LMWH as described above is a good alternative.

### Anticoagulant treatment of deep vein thrombosis and/or pulmonary embolism

Following IV unfractionated heparin given as resuscitation (as described above), provide a heparin infusion of 1000–2000 IU/hour, and adjust the dose to maintain the APTT at 1.5–2.5 times the patient's control. Repeat the APTT every 6 hours during the first 24 hours of therapy. Thereafter monitor the APTT daily unless it falls outside the therapeutic range.

Another option is to treat with an LMWH such as enoxaparin given subcutaneously. The drug is available in syringes of 40, 60, 80 and 100 mg. The dose should be based on the patient's pre-pregnancy weight and should be given 12-hourly. The dose will vary depending on the drug used, but for enoxaparin is 1 mg/kg 12 hourly (note this is a greater total dose than the non-pregnancy dose of 1.5 mg/kg/24 hours). If coagulation tests are available, the aim is to achieve an APTT of 1.5–2.5 times the pre-treatment level. If these tests are not available, careful monitoring for signs of overdose, which can cause haemorrhage, should be

undertaken and the mother should be warned of the symptoms to be alert for.

The mother can then be discharged home when she has been taught how to administer the injections and dispose safely of the needles.

Anticoagulation following pulmonary embolism or DVT should be continued throughout pregnancy and for at least 3 months postpartum.

LMWH should be continued for the duration of the pregnancy, and for at least 3 months after delivery. An expert should be consulted about the use of prophylactic heparin during any further pregnancy.

On entering labour, the mother should not be given any further doses of LMWH. If an elective Caesarean section is planned, the mother should have the usual dose of LMWH on the night before surgery, but the morning dose should be omitted. After delivery, as long as there are no concerns about bleeding, enoxaparin should be restarted 4 hours after a vaginal delivery and 8 hours after a Caesarean section. A once daily regimen may be used, especially after 3 days when concerns about haemorrhage are much reduced.

Shocked patients with a pulmonary embolus should ideally be managed on an intensive-care or high-dependency unit (if available). These patients will ideally have arterial blood pressure and central venous pressure (CVP) monitoring. They will also receive haemodynamic support with adequate fluid management and inotropes, in order to ensure maximal right heart filling.

All women at high risk of DVT or pulmonary embolism (e.g. those who have suffered these conditions before, in this or a previous pregnancy) should use anti-embolism stockings and receive subcutaneous heparin until they are fully mobile.

## 2.5.1 Amniotic fluid embolism

### Introduction

Amniotic fluid embolism occurs when a bolus of amniotic fluid is released into the maternal circulation during uterine contractions. It becomes trapped in the maternal pulmonary circulation and causes cardiorespiratory collapse and clotting problems with disseminated intravascular coagulation (DIC). It is very rare, and extremely difficult if not impossible to treat without high-level resources.

### Clinical presentation

Amniotic fluid embolism usually presents late in the first stage of labour. It has also been reported during first-trimester surgical termination of pregnancy, second-trimester termination, after abdominal trauma and after amniocentesis.

The diagnosis is essentially clinical and by exclusion and treatment of other possible causes. Amniotic fluid embolism may occur during labour (70%), during Caesarean section (19%) or immediately postpartum (11%).

The major signs include the following:

- acute hypotension or cardiac arrest

- acute hypoxaemia (dyspnoea, cyanosis or respiratory arrest)
- coagulopathy (laboratory evidence of DIC or fibrinolysis or severe clinical haemorrhage) if the patient survives long enough for DIC to become established (more than 30 minutes)
- the absence of other causes or symptoms.

### Diagnosis

- This is based on the clinical presentation.
- Chest X-ray may show pulmonary oedema, adult respiratory distress syndrome (ARDS), or right atrial enlargement and prominent pulmonary arteries.
- The ECG may show a tachycardia and right ventricular strain pattern.
- Clotting studies may show thrombocytopenia and elevated fibrin degradation products or D-dimers. The clotting and bleeding times are very prolonged.

### Differential diagnosis

- **Pulmonary embolus:** infrequent during labour, often

accompanied by chest pain, without development of coagulopathy.

- **Air embolism:** may follow ruptured uterus, pressurised IV infusion or Caesarean section. The distinguishing feature in air embolism is pre-cordial water-wheel murmur. There is no coagulopathy.
- **Septic shock:** unlikely in the absence of evidence of preceding infection and pyrexia.
- **Anaphylactic shock:** there is no coagulopathy.
- **Eclampsia:** usually preceded or accompanied by hypertension and proteinuria.
- **Toxic reaction to anaesthetic or local anaesthetic agents:** there is no coagulopathy.
- **Acute left heart failure:** usually more insidious onset. There is no coagulopathy.
- **Cerebral haemorrhage:** no cyanosis or hypotension. There is no coagulopathy.
- **Massive obstetric haemorrhage:** the history may help. Beware concealed abruption. Uterine atony may be a feature of both. Hypoxaemia in massive obstetric haemorrhage is less pronounced than in amniotic fluid embolism.
- **Aspiration of gastric contents:** usually occurs in an unconscious patient, or during induction of or emergence from general anaesthesia. There is no coagulopathy.

## Management

Management is supportive, and aims to correct hypoxaemia, shock and coagulopathy and its consequences.

- Give 100% inspired oxygen by face mask and reservoir.
- If the patient is unconscious (P or U on the AVPU scale), intubation and assisted ventilation (if available) are needed.
- High positive end-expiratory pressure (PEEP) should be avoided.
- Two large-bore cannulae (16G) IV should be sited.
- Urgently cross-match blood, ideally at least 6 units of group-specific blood with retrospective cross-matching (if available) should be ordered. Check clotting factors (or clotting time) and platelets. Blood needs to be sent for a full blood count, clotting, fibrinogen and fibrinogen degradation product (FDP) levels (if available) immediately, and frequent repeated estimations of haematological parameters are required (if available).

- Cardiac arrest is managed according to protocols (see Section 1.13).
- If the woman is in labour, immediate delivery is required, by Caesarean section (under general anaesthetic) if vaginal delivery is not imminent. In cardiac arrest, if a cardiac output cannot be restored immediately, cardiac massage and ventilation should continue and Caesarean section should be performed.
- Circulatory support depends on the causes of decreased cardiac output. The available haemodynamic data indicate that high left heart filling pressures, reflecting a failing left ventricle, are a feature of the condition. In patients who survive the initial haemodynamic collapse, there is a high risk of secondary pulmonary oedema (70%). Inotropic support, ideally guided by monitoring of the central venous pressure (CVP), may be life-saving.
- If massive obstetric haemorrhage occurs, large volumes of fresh blood and blood products may be required.
- Monitoring of cardiac filling pressures may help to prevent fluid overload and pulmonary oedema.
- Place an arterial line if possible.
- Correct coagulopathy with fresh blood, platelets, fresh-frozen plasma and cryoprecipitate (rich in fibrinogen) if available.
- Massive haemorrhage may be due not only to coagulopathy, but also to coexisting uterine atony. Oxytocic drugs will be needed. Uterine tamponade may reduce blood loss while the coagulopathy is corrected.
- Patients who survive are at high risk for heart failure, ARDS and DIC. If the patient is sustaining a cardiac arrest, there is a high risk of neurological injury. As in other cardiac arrests associated with pregnancy, delivery may improve the success of resuscitation.

## Outcome

The outcome is poor, even when optimum treatment and monitoring is available, so it is important to exclude other possible and treatable causes of collapse, including anaphylaxis, pulmonary embolism, haemorrhage, sepsis, myocardial infarction, eclampsia, intracranial haemorrhage, hypoglycaemia and drug toxicity (e.g. magnesium, local anaesthetics).

The outcome depends on the facilities for cardiorespiratory support and the ability to manage the DIC with blood and blood products.

## 2.6

## Complications that require hospital care

### 2.6.A Ovarian cysts in pregnancy

Ovarian cysts in pregnancy may cause abdominal pain due to torsion or rupture. Laparotomy is required if torsion of an ovarian cyst is suspected. If the findings at laparotomy

are suggestive of malignancy (i.e. solid areas in the tumour, growth extending outside the cyst wall), the specimen should be sent for immediate histological examination if

available and the woman should be referred to a tertiary care centre for evaluation and management.

Corpus luteum cysts are common and normal in the first trimester. They should **not** be removed surgically, as the corpus luteum will disappear as pregnancy progresses.

### Asymptomatic ovarian cysts

If, on ultrasound, the cyst is found to be more than 10 cm in diameter, observe by regular ultrasound examinations for growth or complications. If there is torsion this will produce pain and the cyst will need to be surgically removed.

Surgery will pose a significant risk of miscarriage and premature delivery. In the case of a torqued cyst, the resulting

necrosis and infection will themselves place the women and fetus at risk of acute complications and therefore prompt intervention is unavoidable.

Malignancy is difficult to diagnose even where access to advanced imaging such as MRI is available, and therefore a decision to operate on the basis of suspected malignancy is not advised in low resource settings, unless the index of suspicion is very high. If this is considered then it should take in to account the gestation of the pregnancy, the risk of pregnancy loss/prematurity, and the treatment available to the mother following delivery.

If the cyst is less than 10 cm in diameter and remains so on ultrasound examination, it will usually regress on its own and does not require treatment.

## 2.6.B Reduced fetal movements, intrauterine death and stillbirth

### BOX 2.6.B.1 Minimum standards

- Pinard's stethoscope.
- Doppler device for fetal heart rate monitoring.
- Ultrasound scan.
- Misoprostol and oxytocin or ergometrine.
- Fresh blood for transfusion.

### General management

Check for fetal heart sounds, and if they are present, measure the fetal heart rate.

If the fetal heart cannot be detected with a Pinard's stethoscope, Doppler device or ultrasound scan, refer to Table 2.6.B.1 below.

### Diagnosis

TABLE 2.6.B.1 Diagnosis of reduced fetal movements

Symptoms	Signs	Investigation	Diagnosis	Treatment
Decreased or absent fetal movements Bleeding (but may not be external) Collapse Severe constant abdominal pain	Shock in the mother Tense and/or tender uterus Fetal distress or absent fetal heart sounds	Pinard's stethoscope, Doppler device or ultrasound scan	Placental abruption	Deliver the baby as soon as possible (see below) by Caesarean section if there are signs of fetal life
Decreased or absent fetal movements Bleeding (but may not be external) Collapse Severe constant abdominal pain	Shock in the mother Diffuse uterine tenderness with easily felt fetal parts Fetal distress or absent fetal heart sounds	Pinard's stethoscope, Doppler device or ultrasound scan	Ruptured uterus Major risk factors are prolonged labour, previous Caesarean section and use of oxytocin	Treat shock When the mother is stable perform laparotomy
Decreased or absent fetal movements If membranes are ruptured, meconium staining of liquor	Abnormal fetal heart rate (< 100 beats/minute or > 180 beats/minute)	Pinard's stethoscope, Doppler device or ultrasound scan Partogram should show alerts	Fetal asphyxia	Deliver the baby as soon as possible (see below) by Caesarean section if there are signs of fetal life
Absent fetal movements	Symphysis-fundal height decreases Absent fetal heart rate If membranes are ruptured, meconium staining may be present	Pinard's stethoscope, Doppler device or ultrasound scan Full blood count in mother Clotting screen, including measurement of platelet count in mother	Fetal death	Deliver baby as soon as possible (see below)

## Fetal death in the absence of an abruption

Fetal death *in utero* (IUFD) may be the result of fetal asphyxia from placental failure, fetal infection, cord accident or congenital anomalies. Where syphilis is prevalent, a large proportion of fetal deaths are due to this disease.

Fetal death can be confirmed by abdominal ultrasound with confidence if there is a lack of fetal heart activity.

If fetal death *in utero* is diagnosed, inform the woman or girl and her family and discuss the options for management with them.

Common causes are infection (especially malaria and chorioamnionitis), abruption, and placental insufficiency. In the case of intrapartum IUFD, fetal hypoxemia, often, but not always, associated with a prolonged obstructed labour or malposition, may be to blame. In the laboring patient uterine rupture must also be considered.

The following investigations should be performed as a minimum: blood group and cross match, Hb, malaria RDT +/- malaria smear and urine analysis to assess for urinary infection and pre-eclampsia. Syphilis is also common in some settings and may cause IUFD and premature labour.

If a clotting test shows failure of a clot to form after 7 minutes, or a soft clot that breaks down easily, suspect coagulopathy. Obtain fresh blood for transfusion and give broad-spectrum IV antibiotics, including metronidazole.

### Expectant management

Explain to the mother that in 90% of cases the fetus is spontaneously expelled within 1 month of diagnosis. However, most mothers and their families will request delivery as soon as possible.

In addition, expectant management carries with it the risk of infection and DIC both of which complicate management and risk the mother's life. If this approach is used, it should be possible to monitor the patient for complications and there should be access to prompt and comprehensive treatment if they occur.

If IUFD is diagnosed in a laboring woman, then once she has been assessed and treated for potential causes as above the labour can be allowed to continue with the usual monitoring. It is important to actively assess for life-threatening causes such as abruption and rupture.

### Active management

If there is no evidence of active labour and no indication for urgent delivery by Caesarean section, induction of labour with misoprostol is an effective way of inducing labour. As is the case for mid-trimester miscarriage, mifepristone, where available, can be helpful in shortening the length of time it takes for misoprostol to work. This is especially the case where there is no evidence of labour, the cervix is unfavourable and the patient is primiparous.

The following drug regime is recommended for women with an IUFD of 26 weeks' gestation or more (see below for women with a previous Caesarean section and Section 2.5.D.ii for management of miscarriage before 26 weeks' gestation):

- Mifepristone 200 mg orally stat (omit if not available). Wait for 36 to 48 hours after giving this drug – shorten if any clinical concerns arise during this interval
- misoprostol 50 micrograms orally or vaginally every 4 hours to a total of 5 doses
- if delivery has not occurred by the fifth dose of

misoprostol, the patient should be reviewed by a doctor. Subsequent options for management include continued use of misoprostol (usually after a period of 'rest' for 12 to 24 hours), or use of oxytocin.

For women with an IUFD at term (37 weeks and over) an alternative is to use the same induction of labour protocol as described previously (Section 2.3 'Managing labour and delivery'), for women with a live fetus, i.e. 25 micrograms of misoprostol every 2 hours.

Note: The evidence base for the optimum dose of misoprostol to be used in this scenario is poor, and it is recognised that higher doses of 100 micrograms or more every 4 to 6 hours, have historically been used. Recent evidence *suggests* that lower doses *may* be as efficacious, and it is with this in mind, as well as concerns about optimising safety, that the above dose has been recommended. Further research is needed into the optimal regimen, especially in resource poor settings.

### Women who have undergone a previous caesarean section

In women with a previous Caesarean section, previous uterine surgery, or in grandmultiparae, there is a risk of dehiscence/rupture in labour that is likely to be increased with the use of misoprostol, and therefore its use should be avoided. Vaginal delivery is still the preferred mode of delivery if the fetus is dead, but care must be taken to minimise the risk as much as possible.

If the cervix is favourable (Bishop score 6 or more) and ARM possible, then especially in women who have delivered previously, ARM alone will often result in delivery over the following 24 hours. If labour does not become established following ARM, then oxytocin can be titrated, using the usual protocol to augment/induce the labour.

If the cervix is unfavourable, then the oxytocin infusion may be started with intact membranes, and continued until the cervix becomes favourable for ARM (usually < 8 hours). Oxytocin use is associated with a lower risk of dehiscence/rupture than induction with misoprostol, but still increases the risk as compared with spontaneous labour. Close monitoring of the infusion, to prevent hyperstimulation, and of the patient for signs of any complication, is therefore essential.

Alternatively, the cervix can be 'ripened' with a Foley balloon catheter as previously described. ARM may then be performed, and oxytocin used as above if necessary.

Whichever method is used, all women with risk factors for rupture/dehiscence must be identified and monitored carefully with this complication in mind. Early recognition is the key to preventing maternal morbidity and mortality.

The membranes should be kept intact for as long as possible to prevent infection. However, they may be ruptured if it is necessary to achieve delivery. Vaginal assessments should be performed in a sterile manner and as infrequently as possible. If the membranes have been ruptured for more than 18 hours, treat the patient with prophylactic antibiotics (ampicillin 2 grams IV stat followed by 1 gram every 6 hours). If there are **signs of infection** (fever and/or foul-smelling vaginal discharge), give antibiotics as described for endometritis (see Section 2.5.G).

### Oxytocin

Although misoprostol is recommended as the first-line induction agent in the case of IUFD where there are no risk factors

for dehiscence/rupture, Oxytocin may be used if misoprostol is not available or proves ineffective. It may also be used where the risk of rupture is high (as discussed above), and a titratable and short-acting agent is therefore preferred.

In practice oxytocin is more effective following rupture of the membranes, although of course it is preferable to keep these intact as long as possible to avoid infection. As a minimum, rupturing the membranes before the cervix becomes favourable (Bishop score > 6), should be avoided.

Try not to use oxytocin within 8 hours of using misoprostol.

Avoid Caesarean section if possible, except for unavoidable obstetric reasons such as transverse lie, suspected uterine rupture or major abruption.

### Fetal death in the presence of an abruption

Adopt the active management approach described above.

## Stillbirth

### Introduction

Between 2.08 and 3.79 million stillbirths occur each year worldwide. Of these, 98% occur in low- and middle-income countries and 55% occur in rural families in sub-Saharan Africa or South Asia where facilities for giving birth are much poorer than in urban areas (less skilled birth attendants and comprehensive emergency obstetric care). Around 45% of stillbirths occur during birth (intra-partum). The global average rate is 19 in 1000 births, the rate in low-resource settings is  $\geq 25$  in 1000 births, and the rate in well-resourced settings is  $< 5$  in 1000 births.

Most stillbirths are not registered and the body is disposed of without any recognition or rituals such as naming, funeral services, or even the mother holding or dressing her baby. In some cultural settings there is a belief that sinning by the mother or evil spirits are responsible for the stillbirth, and the dead baby may be seen as a taboo object. Families affected may be subjected to stigma and marginalisation. Some healthcare workers believe that few stillbirths are preventable, and that these babies were just 'not meant to live'. There is considerable suffering involved for the family, and mothers frequently become depressed or anxious after a stillbirth, with similar emotions to those experienced after the death of a child.

### Definitions of stillbirth

An early stillbirth is defined by the International Classification of Diseases as a birth weight of  $\geq 500$  grams or, if this measurement is missing,  $\geq 22$  completed weeks of gestation or, if this is missing, a body length of  $\geq 25$  cm.

The World Health Organization defines stillbirth as a birth weight of  $\geq 1000$  grams or, if this measurement is missing,  $\geq 28$  completed weeks of gestation or, if this is missing, a body length of  $\geq 35$  cm.

### Causes of stillbirth

The major causes, which are the same as the causes of maternal and neonatal mortality, are as follows:

- complications of childbirth
- maternal infections in pregnancy (e.g. syphilis)
- medical disorders of pregnancy (especially pre-eclampsia or hypertension)
- maternal under-nutrition and fetal intrauterine growth retardation
- congenital abnormalities.

### Prevention

The most important issues in low-resource situations are to increase the number of skilled birth attendants who can manage antenatal and intra-partum care, to increase the number of healthcare facility-based births, and to prevent or treat syphilis and malaria during pregnancy.

Specifically, the following ten interventions have been subjected to systematic review and reported to reduce stillbirth rates:

- 1 taking folic acid before and soon after conception
- 2 insecticide-treated bed nets or intermittent drug treatment to prevent malaria
- 3 detection and treatment of syphilis
- 4 detection and management of hypertensive disorders in pregnancy
- 5 detection and management of diabetes
- 6 detection and management of fetal growth restriction
- 7 routine induction to prevent post-term pregnancy
- 8 skilled care at birth
- 9 basic emergency obstetric care
- 10 comprehensive emergency obstetric care.

The main aim is to strengthen the healthcare systems involved in antepartum and intra-partum care, which include in addition to the ten items listed above:

- prevention of malaria (see Section 2.8.D) and syphilis (see Section 2.8.H) in endemic areas
- the availability of emergency obstetric surgery, in particular Caesarean section, without delay and with attention to 'task shifting' to improve access, especially in rural areas
- improved antenatal care
- advocacy to address poverty and its consequences (stillbirth rates are inversely correlated with wealth and development)
- systems to manage and prevent domestic violence
- efforts to achieve sexual equality, improve reproductive health and improve the secondary education of boys and girls.

Ideally, bereaved families should form groups that advocate for change at all of the levels identified above.

*The Lancet* Stillbirths series, launched in London, New York, Hobart, Geneva, New Delhi, Florence, and Cape Town on 14 April 2011. [www.thelancet.com/series/stillbirth](http://www.thelancet.com/series/stillbirth)

## 2.6.C Fetal distress during labour

### BOX 2.6.C.1 Minimum standards

Pinard's stethoscope  
Hand-held battery-operated ultrasonic fetal heart rate monitor

### Introduction

In all clinical circumstances, the well-being of the pregnant woman takes precedence over that of the unborn baby, and there are often situations where resuscitation of the mother will automatically bring about benefits for the fetus.

Careful thought has to be given to the assessment and management of the fetal condition in labour. This is especially so in resource-limited countries, where severe shortages of both equipment and suitably trained personnel often mean that women do not receive the life-saving care which they require in labour.

**In such situations, strict prioritisation of needs is required, and fetal well-being has to take second place to maternal survival.**

When considering taking steps to monitor fetal well-being, the following factors must be taken into account:

- 1 the cost of monitoring equipment, including maintenance, and replacement of disposable items
- 2 the cost of training staff in the use of such equipment
- 3 the proportion of caregivers' time required to be allocated to assessment of fetal well-being
- 4 the availability of suitable interventions, should fetal distress be diagnosed
- 5 the potential risks to the mother of an intervention for the sake of fetal well-being
- 6 the availability of neonatal care facilities and expertise, following on from an intervention to deliver a distressed and possibly premature baby.

Methods of monitoring fetal well-being in labour range from the low-cost low-technology Pinard's stethoscope to the relatively expensive high-technology cardiotocograph.

### Pinard's stethoscope

The Pinard's stethoscope is cheap, portable and resilient, and requires no electricity or battery. It is used to listen to the fetal heart through the maternal abdomen for 60 seconds immediately following a contraction. It should be recorded every 60 minutes in the latent phase of labour, every 15–30 minutes in the active phase of the first stage of labour, every 5 minutes in the second stage, and after every contraction when the woman is pushing in the second stage.

A healthy fetus will withstand the relative hypoxia brought about by the compression of the blood vessels in the placenta during a uterine contraction.

A simple ultrasound Doppler monitor (e.g. a Sonicaid) can be used instead of a Pinard's stethoscope, but it does require batteries.

### Fetal heart rate monitoring by Pinard's/Sonicaid: normal ranges and abnormalities

It should be noted that evidence and guidance is lacking

on the use of intermittent fetal monitoring in settings without access to continuous electronic fetal monitoring (CEFM).

Where CEFM is available any abnormality detected by intermittent monitoring results in the mother being transferred on to CEFM. Where this is not possible, it is even more difficult to determine whether fetal distress is present.

In addition, without the ability to perform fetal blood sampling (below), it is not possible to confirm whether the fetus is distressed before delivery, or to determine the degree of distress likely. It should be noted that approximately 50% of babies with pathological electronic fetal heart rate tracings are not in fact distressed.

The impact of intermittent fetal monitoring on Caesarean section rates and neonatal morbidity and mortality, in this context, is therefore unknown. Decisions on whether to pursue Caesarean section with its inherent risks for the current and future pregnancies, is extremely difficult in this context, where information on the fetal condition is so incomplete.

### The normal fetal heart rate

**Baseline:** The baseline is the rate that is returned to after any episodes of variation such as an acceleration or a deceleration. In simple terms it is the most common heart rate for that baby.

When listening with a Pinard's this may be the rate over the first minute of listening. However, if part of the minute includes a period of more rapid heartbeat (an acceleration), or slower heart beat (deceleration) then it may be higher or lower than the baseline.

Therefore, if when listening, the fetal heart can be heard to be very slow or very fast for part or all of the period, auscultating this may not be the baseline and it will be necessary to continue listening over a longer period to gain more information.

The normal range for the baseline is between 120 and 160bpm. A rate of 110 to 120bpm is often also a normal finding, especially in babies at term or post term. A rate of 160 to 170 can also be a normal finding in a premature baby. A rate below 110 and above 170 is always considered to be abnormal.

**Variability:** It is normal for the fetal heart rate to vary with every beat. This variation occurs continually above and below the baseline and is usually by approximately 5 to 15bpm from the lowest to the highest reading (although normal variation is up to 25bpm). Variation is not easily detected by the Pinard's stethoscope as monitoring involves counting for 1 minute and it is therefore the average heart rate over that time that is obtained. With a Sonicaid, however, the fetal heart rate is often displayed and it can be seen to vary around a certain level (the baseline).

Variability is a positive sign, and generally suggests that the fetus is coping well with labour.

**Accelerations:** These are episodes where the fetal heart rate increases by 15 beats or more above the baseline and for more than 15 seconds. They can be heard on a Pinard's with practice, although they are easier to hear the higher and longer they are. They are easier to see on a Sonicaid,

where the number displayed can be seen to increase over a period before falling back to its more usual level.

Accelerations are a positive sign as they represent fetal movement. If the fetus is distressed it will not move and the accelerations will stop. Although it is reassuring when they are present, accelerations are often not present during labour.

### **Abnormalities of the fetal heart rate**

**Tachycardia:** This is a fetal heart rate above 160–170 bpm.

A tachycardia is often caused by a maternal pyrexia or tachycardia and in these instances it will often resolve once the maternal observations have normalised.

**Decelerations:** A deceleration is a reduction in the fetal heart rate 15 bpm or more below the base line for 15 seconds or more.

An early deceleration occurs at the onset of the contraction and recovers by the end of the contraction. It is a common feature during labour (especially the second stage) and is not usually associated with fetal distress, and therefore it is not routine to listen to the fetal heart rate during a contraction.

A late deceleration starts during or at the end of a contraction and persists beyond the end of the contraction. This is more commonly associated with fetal distress and if it occurs the fetal heart should be monitored following the next 2 contractions to see if it recurs. If it does, there is a significant chance that the fetus is distressed.

**Bradycardia:** A bradycardia is a deceleration that continues for over 3 minutes. It may occur during pregnancy or labour and may be associated with inferior vena-caval compression if the patient is lying supine, sudden drops in blood pressure from any cause or cord compression.

It may also represent the end stage of a prolonged period of fetal distress. If the cause of the bradycardia is self-limiting, then the fetal heart should recover, whereas if it has occurred due to period of prolonged distress or the insult is ongoing, it will not recover and will end in fetal death. Even if it resolves, a bradycardia of over 10 minutes may cause brain damage to the fetus and have implications for the neonate.

### **Cardiotocograph**

The cardiotocograph is a relatively expensive, sophisticated but non-invasive item of equipment that requires expertise in its use and in its interpretation, as well as regular maintenance, and ongoing provision of disposables, such as print-out paper. It also requires a power supply (either mains electricity or batteries).

It has a high sensitivity for detecting possible evidence of fetal distress, but a relatively low specificity, such that an additional method of assessment of fetal well-being, usually scalp pH assessment, is required in order to avoid excessive intervention.

If a cardiotocograph is used in the absence of fetal blood sampling, there are certain fetal heart rate patterns which are very likely to be associated with serious fetal distress and that warrant urgent actions to protect the fetus, usually immediate delivery.

### **Fetal scalp pH assessment**

This is achieved by fetal scalp blood sampling, which is

carried out with the woman in the lithotomy position with a wedge to prevent aorto-caval compression or in the left lateral position.

A speculum is inserted in the vagina, the fetal scalp is visualised with the aid of a light source, and a blood sample is obtained using a lancet and a capillary tube.

A blood gas analyser (an extremely expensive item of equipment) is required for assessment of the sample.

### **Fetal blood gas analysis**

This is used to detect fetal acidosis, which is a consequence of hypoxia.

A capillary sample is assessed for pH and base excess. Generally, a pH of  $\geq 7.25$  is considered to be normal, but it has to be borne in mind that acidosis may develop rapidly, and the sample therefore needs to be repeated if the CTG abnormality persists. A full guide to the interpretation and use of fetal blood gas analysis is not included here as it is not a technique available in the majority of resource poor settings.

Fetal blood sampling is contraindicated if the mother is infected with HIV or in high prevalence areas in the untested patient.

### **Clinical assessment of fetal well-being**

A large amount of information may be gained by clinical assessment as follows.

#### **History**

- Gestational age is important, as an immature fetus withstands the stresses of labour less well than if it had reached term. Similarly, those with intrauterine growth retardation are at risk.
- A reduction in fetal movements should always give rise to concern, as it may reflect fetal distress (see Section 2.6.B).
- Pre-eclampsia, antepartum haemorrhage (APH), preterm pre-labour rupture of membranes (PPROM) or other obstetric or medical problems, prolonged pregnancy, multiple pregnancy, diabetes and previous Caesarean section all increase the risk of fetal distress.
- The use of oxytocin, a maternal fever, meconium- or bloodstained liquor, and prolonged first and second stage of labour also increase the risk.
- The duration of labour at the time of admission is crucial, as obstructed labour is a potent cause of severe maternal and fetal morbidity and mortality.

#### **Examination of the maternal abdomen**

- **Fetal size:** small or large for dates.
- **Amniotic fluid volume:** oligohydramnios (too little) or polyhydramnios (too much).
  - Oligohydramnios is often associated with poor fetal growth. Growth-restricted fetuses are more likely to become distressed in labour than are well-grown fetuses.
  - Polyhydramnios may be associated with fetal abnormalities or fetal infection *in utero*.
- **Abdominal tenderness with or without hardness feeling like wood:** consider placental abruption.
- **Colour of amniotic fluid after rupture of membranes:**
  - bloodstained: consider placental abruption

- meconium-stained: consider the possibility of a hypoxic episode causing fetal distress.
    - (a) Passage of meconium is often a physiological (normal) phenomenon in a mature fetus.
    - (b) In the presence of plentiful amniotic fluid, the meconium will be dilute. Where there is little fluid, it will be thick.
    - (c) Meconium may signal fetal distress. It may also trigger neonatal respiratory problems through meconium aspiration, which occurs when a distressed fetus gasps *in utero* or during delivery.
    - (d) During the final stages of a breech delivery, meconium may be passed because of the compression of the fetal abdomen. In this case, passage of meconium is not necessarily a sign of fetal distress.
  - **Frank blood loss vaginally:** consider placental abruption, uterine rupture, placenta praevia and vasa praevia.
  - **Haematuria in labour:** this may signal uterine rupture, usually in association with severe abdominal pain and tenderness, commonly in a woman with a previous Caesarean section scar or in a woman of high parity, particularly where labour is induced or augmented.
- Management of fetal distress**
- If fetal distress is suspected, attention should first be paid to detecting and treating maternal factors, including hypovolaemia, sepsis, obstructed labour and uterine rupture.
  - The woman should be turned (tilted) on her left side or placed in the recovery position, to prevent aorto-caval compression.
  - Facial oxygen should be administered at a high flow rate.
  - Oxytocin should be discontinued if ongoing, and if still detected *in situ*, misoprostol tablets may be removed from the vagina.
  - Antibiotic therapy will be indicated if infection (including chorio-amnionitis) is suspected.
  - Vaginal examination should be performed to assess the feasibility of vaginal delivery, either spontaneously or by using forceps or ventouse.
  - If suspected fetal distress continues despite the above measures and vaginal delivery is not rapidly achievable then a decision about whether to proceed to Caesarean section needs to be made. This is a difficult decision, which ideally takes into consideration a number of factors including: the obstetric history and wishes of the patient, the availability of neonatal care, the degree of fetal compromise suspected and the speed with which Caesarean section can be performed, the availability of hospital care and Caesarean section in subsequent deliveries, and the presence/absence of other relative indications for Caesarean section.
  - If a decision is made to deliver by Caesarean section and a delay is anticipated (> 30 minutes), then a tocolytic such as terbutaline 250 microgram s/c may be beneficial if the contractions are felt to be contributing to the fetal distress.

## 2.6.D Multiple births

### Introduction

Twins occur in around 1 in 80 pregnancies. Non-identical twin rates vary depending on age, parity and racial background; in Africa, rates are higher than the world average. The incidence of monozygous (identical) twins is relatively constant worldwide, at 3.5 in 1000 births.

Multiple pregnancies are associated with higher risks for both the mother and the fetus. Ultrasound scanning should be undertaken if the uterine size is larger than expected, or if abdominal examination of fetal parts leads to suspicion of multiple fetuses.

If ultrasound scanning facilities are not available, abdominal examination after delivery of any first baby should be performed to **exclude a second twin before oxytocin or Syntometrine is given to aid delivery of the placenta.**

### Maternal risks associated with multiple pregnancy

These include the following:

- miscarriage
- anaemia
- preterm labour
- hypertension
- polyhydramnios
- operative delivery
- postpartum haemorrhage.

### Fetal risks associated with multiple pregnancy

These include the following:

- stillbirth or neonatal death
- preterm delivery
- intrauterine growth restriction
- congenital abnormalities
- cord accident
- specific complications of twin pregnancies (e.g. twin-to-twin transfusion syndrome)
- difficulties with delivery.

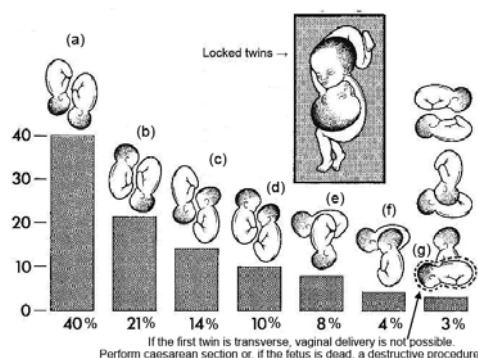

FIGURE 2.6.D.1 Twin pregnancy.

If a twin pregnancy is diagnosed, additional care should be provided. Iron and folate treatment must be ensured, due to the increased risk of anaemia. Preterm labour and delivery present the greatest risk of fetal illness and death. If the mother develops premature labour, a course of antenatal steroid injections should be given, betamethasone 12 mg IM, two doses 24 hours apart, or dexamethasone 6 mg IM four doses 12 hours apart.

### Presentation of twins

- In 40% of cases both twins are cephalic.
- In 21% the second twin is a breech.
- In 14% the first twin is a breech.
- In 10% of cases both twins are breeches.
- In all remaining cases, one twin or the other, or occasionally both, are transverse.

In Figure 2.6.D.2, the first twin is the lower one.

**FIGURE 2.6.D.2** The range of different twin positions *in utero* at birth.

### Antenatal monitoring in multiple pregnancy

- A 2-weekly check-up (urine for protein if blood pressure is elevated, ultrasound if possible) is recommended from 28 to 36 weeks; warn the woman about the risk of preterm delivery.
- Iron and folate treatment must be ensured as increased risk of anaemia is present.
- A weekly check-up is recommended from 37 weeks.
- Be alert for signs of pre-eclampsia and premature labour.

### Twin delivery

Vaginal delivery is usually safe, but must be undertaken in a healthcare facility where comprehensive emergency obstetric care is available. If labour has not started by 39–40 weeks' gestation based on an accurate LMP or first trimester ultrasound, consider induction.

## Summary of management during labour

### Delivery of first twin

- 1 Insert an IV cannula. Maternal blood should be obtained for a full blood count and blood grouping. A blood sample should be kept for cross-matching.
- 2 Ensure that the lie of the first baby is longitudinal.
- 3 Augment contractions only when indicated.
- 4 Prepare two delivery packs with extra clamps. Remember that there are almost always two membranes to rupture with twins, so have an amniotome ready.

- 5 Make sure that the cervix is fully dilated.
- 6 Empty the mother's bladder.
- 7 Deliver the first baby as normal.
- 8 **Always clamp the maternal end of the cord of the first twin to prevent the second twin bleeding from it.**
- 9 As the first baby is delivered, stabilise the lie of the second twin to a longitudinal position by asking an assistant to place their palms firmly on either side of the uterus in a longitudinal direction. The baby's position should be stabilised in this way until the head or buttocks are fixed in the maternal pelvis. If the second twin is not longitudinal on assessment, undertake version (see below).
- 10 Tie a marker (e.g. gauze) to the clamp on the cord of the first baby to identify it.

### Delivery of second twin

- 1 The second baby should preferably be born within 30 minutes.
- 2 Check the fetal heart rate of the second baby.
- 3 Stabilise the lie of the second twin, by external version if necessary (see above).
- 4 Provided the lie is longitudinal and contractions do not restart 5–10 minutes after delivery of the first baby, start an oxytocin infusion, increasing carefully to achieve adequate contractions. Note that contractions may not be felt by the mother, so it is important to keep your hand on the uterus to identify them.
- 5 When the presenting part is well into the pelvis, rupture of the membranes can be performed during a uterine contraction.
- 6 Delivery of the second baby should not be rushed, but assisted delivery should be considered if the second baby has not been delivered by 30 minutes after delivery of the first.
- 7 If the lie of the second twin is transverse, attempt external version.
- 8 If external version is successful, or the second twin is longitudinal, wait for the presenting part to enter the pelvis, then perform artificial rupture of membranes (ARM) and allow normal cephalic or breech delivery if there is no fetal distress.
- 9 If external cephalic version is unsuccessful, either carry out internal version with breech extraction or perform a Caesarean section.

**Internal podalic version: It is essential that as the baby descends, rotation of the fetus is encouraged to obtain a back-up (back anterior) position (as in breech delivery).** Grasp a fetal foot. **Make sure that it is a foot, not a hand.** Pull gently down into the birth canal so that the fetal back is encouraged to turn anteriorly. An attempt is made to pull the fetal foot as gently as possible in an attempt to pull it as low as the vulva before the membranes rupture. It may be that maternal effort will be sufficient once the baby's leg has been brought down into the vagina and the remainder of the delivery can then be managed as for an assisted breech delivery. Continued traction (avoiding soft tissues as for all breech deliveries) is permissible in this scenario, to facilitate descent of the buttocks, arm and head (breech extraction, see Figure 2.6.D.3).

- 10 If there is fetal distress or delay, perform an assisted vaginal delivery if cephalic. Note that cephalo-pelvic

disproportion is very uncommon in the case of the second twin.

FIGURE 2.6.D.3 Internal version for transverse lie in a second twin.

**Postpartum management of a twin birth**

- 1 After the birth of the second baby, give 10IU oxytocin IM after ensuring that there is no third baby in the uterus. Then give oxytocin 40 units IV in 500mL of Ringer-lactate or Hartmann's solution over 4 hours, to reduce the risks of postpartum haemorrhage due to atonic uterus.
- 2 Deliver the placenta by controlled cord traction after giving oxytocin IM.
- 3 After the placenta and membranes have been delivered, examine and record on the chart the number of placentas, amnions, chorions and cord vessels. Check the placenta and membranes for completeness.
- 4 Check and repair any vaginal and perineal damage.
- 5 Monitor the mother carefully for postpartum bleeding over the next few hours.
- 6 Provide extra support to assist with the care of the babies.
- 7 At least a 24-hour stay in hospital is required.
- 8 Observe vaginal bleeding closely, because of the risk of postpartum haemorrhage.

**Hooking or locking of heads**

This is a rare complication during vaginal delivery.

Women may present with locked twins with the first trunk partially delivered. The head of the second twin will have entered the maternal pelvis, and needs to be pushed upwards to allow descent of the head of the first twin. If the first baby is already dead, it can be delivered by decapitation. After delivery of the body, the head is dis-impacted and the second twin is delivered. Finally, the first head is delivered with a vulsellum.

If the first baby is still alive (e.g. if the delivery is taking place in hospital), or if despite decapitation of the first baby the second one cannot be delivered, proceed immediately to Caesarean section if this is safe for the mother.

## 2.6.E Malpresentations and malpositions including breech delivery

### Introduction

Malpresentations and malpositions can be due to maternal pathology (e.g. contracted pelvis, uterine fibroids) or fetal pathology (e.g. hydrocephalus), which ideally should be diagnosed antenatally. Most often there is no apparent cause.

**Malpresentations** are all presentations of the fetus other than a vertex presentation (e.g. face presentation, breech presentation).

**Malpositions** are abnormal positions of the vertex of the fetal head (with the occiput as the reference point) relative to the maternal pelvis.

**A fetus in an abnormal position or presentation may result in prolonged or obstructed labour.**

### Management

Review the progress of labour using a partograph (see Section 2.2).

**Note:** Observe the mother closely. Malpresentations increase the risk of uterine rupture because of the potential for obstructed labour.

### Assessment of the fetal position

#### Determining the presenting part

The most common presentation is the vertex of the fetal head.

If the **vertex is the presenting part**, use landmarks of the fetal skull to determine the position of the fetal head (see Figure 2.6.E.1). However, although the anterior fontanelle is larger than the posterior one and has four sutures leading from it, one of these is small and may be difficult to feel.

#### Determining the position of the fetal head

FIGURE 2.6.E.1 The fetal skull.

The fetal head normally engages in the maternal pelvis in an occiput transverse position.

With descent, the fetal head rotates so that the fetal occiput is anterior in the maternal pelvis (see Table 2.6.E.1). Failure of an occiput to rotate to an occiput anterior position results in a persistent transverse presentation. Rotation may also occur to an occiput posterior position.

An additional feature of a normal presentation is a well-flexed vertex (see Figure 2.6.E.2), with the fetal occiput lower in the vagina than the sinciput.

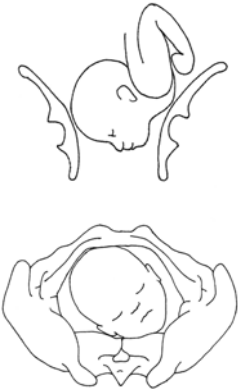

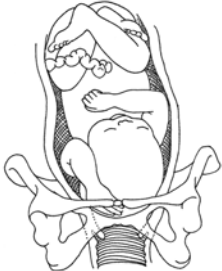

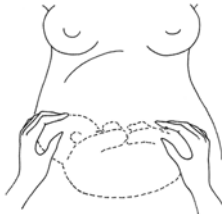

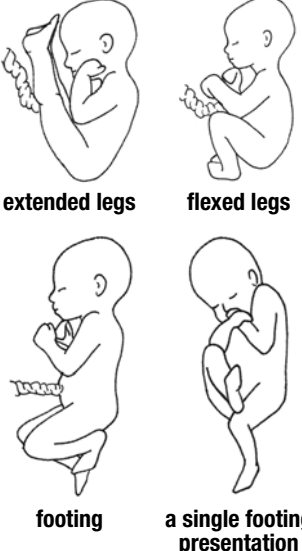

FIGURE 2.6.E.2 Well-flexed vertex presentation.

TABLE 2.6.E.1 Diagnostic features of malpositions and malpresentations

Position	Observations	Picture from introitus
<i>Malpositions</i>		
<b>Occiput anterior</b>	<b>On vaginal examination provided that the head is flexed</b> only the posterior fontanelle with three sutures entering it is felt	 <b>Occiput anterior</b>
		 <b>Left occiput anterior</b>
		 <b>Right occiput anterior</b>
<b>Occiput posterior</b>	On <b>vaginal examination</b> , the posterior fontanelle is towards the sacrum and the anterior fontanelle may be easily felt if the head is deflexed On abdominal examination the lower part of the abdomen is flattened, and the fetal limbs are palpable anteriorly	 <b>Occiput posterior</b>
		 <b>Left occiput posterior</b>
<i>Malpresentations</i>		
<b>Brow presentation</b> is caused by partial extension of the fetal head so that the occiput is higher than the sinciput	On <b>abdominal examination</b> , more than half of the fetal head is above the symphysis pubis, and the occiput is palpable at a higher level than the sinciput On <b>vaginal examination</b> , the anterior fontanelle and the orbits are felt	

Position	Observations	Picture from introitus
<p><b>Face presentation</b> is caused by hyper-extension of the fetal head so that neither the occiput nor the sinciput are palpable on vaginal examination</p>	<p>On <b>abdominal examination</b>, a large amount of head is palpable on the same side as the back, without a cephalic prominence on the same side as the limbs</p> <p>On <b>vaginal examination</b>, the face is palpated, the examiner's finger enters the mouth easily and the bony jaws are felt</p>	
<p><b>Compound presentation</b> occurs when an arm prolapses alongside the presenting part</p>	<p>Both the prolapsed arm and the fetal head present in the pelvis simultaneously</p>	
<p><b>Transverse lie and shoulder presentation</b></p>	<p>The fetus lies in the transverse position with usually the shoulder presenting</p> <p>On <b>abdominal examination</b>, neither the head nor the buttocks can be felt at the symphysis, and the head is usually in the flank</p> <p>On <b>vaginal examination</b>, a shoulder may sometimes be felt. An arm may prolapse and the elbow, arm or hand may be felt in the vagina</p>	
<p><b>Breech presentation</b> occurs when the buttocks and/or the feet are the presenting parts</p>	<p>On <b>abdominal examination</b>, the head is felt in the upper abdomen and the breech in the pelvic brim. Auscultation locates the fetal heart higher than expected with a vertex presentation</p> <p>On <b>vaginal examination during labour</b>, the buttocks and/or feet are felt; thick, dark meconium is normal</p>	 <p style="text-align: center;"> <b>extended legs</b>      <b>flexed legs</b>  <b>footing</b>      <b>a single footing presentation</b> </p>

### Malpositions of the fetal head

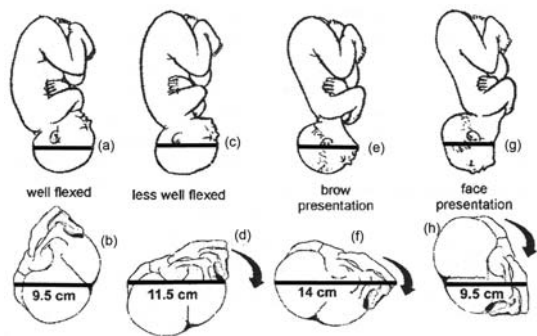

As the baby's head extends (deflexes), the diameter that has to pass through the mother's birth canal gets larger, until the baby becomes a brow presentation (14 cm). Then it gets smaller as the baby becomes a face presentation (see Figure 2.6.E.3).

Labour gets more difficult as the head extends, with brow and mento-posterior face presentations being

impossible to deliver vaginally unless the baby is particularly small in relation to the mother's pelvis.

A face presentation is easier to deliver than a brow presentation. This is because the head has now become fully deflexed.

The vertex presentations in Figure 2.6.E.3 show the diameters of the skull. When the head is well flexed (a), the shortest diameter of the skull is entering the mother's pelvis.

**FIGURE 2.6.E.3** (a), (c), (e) and (g) are all vertex presentations. The only normal one is the well-flexed head (a). As (a) turns through to become (g), the baby’s head becomes more and more extended (deflexed).

In a brow presentation (e), which is the most difficult type, the longest diameter is trying to enter it.

### Management of malpositions

#### Occiput-posterior positions

Around 15–20% of term cephalic fetuses are in an occiput-posterior (OP) position before labour, and approximately 5% are OP at delivery. Most fetuses (around 90%) rotate to the occiput-anterior (OA) position, some maintain a persistent OP position, and others rotate from an OA to an OP position during labour and delivery.

Arrested labour may occur when the head does not rotate and/or descend. Delivery may be complicated by perineal tears or extension of an episiotomy because an instrumental delivery is performed or because a persistent OP presentation requires passage of a greater diameter. The newborn infant is more likely to need resuscitation.

Diagnosis of an OP position in the second stage is generally made by digital examination, but if there is uncertainty, ultrasound examination is both useful and accurate in the right hands.

#### Management

There is no effective method of facilitating rotation from OP to OA before labour begins.

#### First stage of labour

Manual rotation (see below) must not be attempted in the first stage of labour, as it can lead to a prolapsed cord or complex presentations (e.g. hand). It is also technically more difficult and may introduce infection.

- 1 If there are signs of obstruction or the fetal heart rate or pattern is abnormal (< 110 beats/minute or > 160 beats/minute, or abnormal dips) at any stage, deliver by Caesarean section if this can be safely undertaken.
- 2 If the membranes are intact, rupture them.
- 3 If there are no signs of obstruction, augment labour with oxytocin.

#### Second stage of labour

If the cervix is fully dilated:

- If the fetal head is more than 3/5 palpable above the symphysis pubis, or the leading bony edge of the head is above –2 station and there is fetal distress and/failure to descend, perform a Caesarean section.

- If the fetal head is less than 3/5 above the symphysis pubis, or the leading bony edge of the head is between 0 station and –2 station, try manual rotation (see below) if there is no clear progress in the second stage with an OP position after 30 minutes of pushing.

However, expectant management of the OP position is appropriate in the presence of a reassuring fetal heart rate, adequate space on clinical examination of the pelvis, and continued progress in the second stage. More than 50% of multiparous women and more than 25% of nulliparous women with persistently OP fetuses achieve spontaneous vaginal delivery.

Therefore it is not appropriate to routinely perform prophylactic rotation at the beginning of the second stage of labour.

Delivery from an OP position rather than rotation (see below) is more appropriate in women who, on clinical examination, are found to have ample room between the fetal occiput and the maternal sacrum/coccyx, and when the pelvis is too narrow to permit anterior rotation (women with an anthropoid pelvis with a narrow transverse diameter, and women with an android pelvis with a narrow arch).

**FIGURE 2.6.E.4** Finger rotation of occiput posterior to occiput anterior position. Reproduced with permission from Argani CH, Satin A. Management of the fetus in occiput posterior position. In: UpToDate, Post TW (ed.), UpToDate, Waltham, MA (accessed 5/8/14). © 2014 UpToDate, Inc. For more information visit [www.uptodate.com](http://www.uptodate.com).

### Manual rotation

Successful rotation after the onset of the second stage of labour is more likely to be successful if it is performed before arrest occurs. Manual rotation can convert 90% of OP or transverse arrest situations to OA.

Manual rotation is more successful in multiparous women and young women.

Rotation is important if there is a need for a fast delivery and/or if there is minimal or slow descent after a trial of pushing.

First empty the bladder.

There are two methods for rotating the fetus.

- 1 A hand is inserted into the vagina with the palm upward. Digital rotation is performed by placing the tips of the index and middle fingers in the anterior segment of the lambdoid suture near the posterior fontanelle (see Figure 2.6.E.4).

The fingers are used to flex and slightly dislodge the vertex, rotating the fetal head to the OA position by rotation of the operator's hand and forearm. The thumb may also be used with gentle downward pressure more anteriorly on the parietal bone to aid this rotation. The fetal head should be held in place for a few contractions to prevent rotation back towards the posterior position.

- 2 The operator's four fingers are placed behind the posterior parietal bone with the palm up and the thumb over the anterior parietal bone. The right hand is used for the left OP position, and the left hand is used for the right

**FIGURE 2.6.E.5** Manual rotation of occiput posterior to occiput anterior position. **Manual rotation of occiput posterior to occiput anterior position.** Reproduced with permission from Argani CH, Satin A. Management of the fetus in occiput posterior position. In: UpToDate, Post TW (ed.), UpToDate, Waltham, MA (accessed 5/8/14). © 2014 UpToDate, Inc. For more information visit [www.uptodate.com](http://www.uptodate.com).

OP position. The head is grasped with the tips of the fingers and thumb. During a contraction, the patient is encouraged to push and the operator attempts to flex and rotate the fetal head anteriorly. Occasional mild upward pressure may help to slightly displace the head and facilitate rotation (see Figure 2.6.E.5).

If rapid delivery is indicated, failed manual rotation may be followed by vacuum delivery from the OP position. Manual rotation performed prior to instrumental birth is associated with little or no increase in risk to the pregnant woman or to the fetus.

Ventouse or forceps delivery should never be attempted above 0 station or if the head is more than 1/5 above the symphysis pubis.

### Delivery of a brow presentation (see Table 2.6.E.1)

In brow presentation, engagement is usually impossible, and arrested labour is common. Spontaneous conversion to either vertex presentation or face presentation can rarely occur, particularly when the fetus is small or when there is fetal death with maceration. It is unusual for spontaneous conversion to occur with an average-sized live fetus once the membranes have ruptured.

If the fetus is alive, deliver by Caesarean section if this can safely be undertaken.

If the fetus is dead and:

- the cervix is not fully dilated, deliver by Caesarean section
- the cervix is fully dilated, deliver after craniotomy.

If the operator is not proficient in craniotomy, deliver by Caesarean section.

Only if the fetus is small or very low in the vagina, a brow presentation might be delivered by vacuum extraction, forceps delivery or symphysiotomy.

### Delivery of a face presentation (see Table 2.6.E.1)

#### Background

This presentation occurs in 1 in 500–1000 pregnancies. It is due to extension of the fetal neck, caused by either a fetal abnormality or progression from a deflexed occipito-posterior position in labour. Diagnosis is important, as a face presentation may be mistaken for breech presentation.

#### Diagnosis

Face presentation may be detected on ultrasound scan before labour, but the majority of cases are unpredictable because they arise in labour.

On abdominal examination, a large amount of head is palpable on the same side as the back, without a cephalic prominence on the same side as the limbs.

On vaginal examination, in early labour the presenting part is high. Landmarks are the mouth, jaws, nose, and malar and orbital ridges. The presence of bony gums (alveolar margins) distinguishes the mouth from the anus. The mouth and the zygoma ridges of the maxillae (upper jawbone) form the corners of a triangle, whereas the anus is on a straight line between the ischial tuberosities.

Avoid damaging the eyes with trauma or use of antiseptics.

**Ventouse must not be used.**

In early labour, particularly with the occipito-posterior position and a multiparous patient, deflexion is common. In such cases, uterine contractions often cause increased flexion, and delivery will proceed as normal. However, if extension occurs, a brow presentation and finally the fully extended face will result. Most face presentations therefore only become obvious late in labour.

Descent is usually followed by internal rotation with the chin passing anteriorly. If the chin is towards the pubis (mento-anterior), the baby can often be delivered normally, although an episiotomy is usually necessary. If the chin lies towards the back, delivery will not occur and a Caesarean section will be required.

The widest biparietal diameter is 7 cm behind the advancing face, so even when the face is distending the vulva, the biparietal diameter has only just entered the pelvis. Descent is less advanced than vaginal examination suggests, even allowing for gross oedema. The head is always higher than you think.

**Abdominal examination is vital.**

The head is born by flexion, causing considerable perineal distension in the process and risking considerable perineal trauma, so **consider an episiotomy**. Anterior rotation having occurred, the neck comes to lie behind the symphysis pubis and the head is born by flexion. The shoulders and body are born in the usual way.

With satisfactory uterine action and the mento-anterior (MA) position, spontaneous delivery or easy 'lift-out' (forceps-only) assisted delivery will ensue in 60–90% of cases (see Figure 2.6.E.6).

**FIGURE 2.6.E.6** Mento-anterior position.

If spontaneous delivery of an MA face does not occur, a 'lift-out' forceps delivery can be performed (see Section 2.13 on forceps delivery).

In mento-posterior (MP) positions (see Figure 2.6.E.7), the neck is too short to span the 12 cm of the anterior aspect of the sacrum. In addition, the neck would have to be extended to pass under the symphysis, but it is already maximally extended. Delivery is impossible unless a very small fetus or one that is macerated allows the shoulders to enter the pelvis at the same time as the head.

Even with MP positions, anterior rotation will occur in the second stage in 45–65% of cases, so a persistent MP

**FIGURE 2.6.E.7** Mento-posterior position. Reproduced with permission from Macdonald S, Magill-Cuerden J (ed.) *Mayer's Midwifery: a textbook for midwives*. Elsevier Health Sciences; 2010. © Elsevier

position or mento-transverse arrest is encountered in only 10% of face presentations.

Persistent MP positions are usually delivered by Caesarean section (if this is possible and safe), in order to reduce fetal and maternal morbidity.

After birth, the oedema and bruising of the child's face may persist for some days, and may make feeding difficult.

Vaginal manipulation of persistent MP position has been successfully achieved with ultrasound guidance.

**Management**

- Make a diagnosis.
- Check for cord presentation or prolapse.
- Continuously monitor the fetal heart rate.
- Examine regularly to check that progress is adequate.
- Give oxytocin if progress is not satisfactory. (Caesarean section may be preferred to augmentation if facilities are available.)
- **Do not use scalp electrodes or perform fetal blood sampling.**
- If the position is MA, vaginal delivery should be possible.
- Perform an episiotomy.
- If the fetus is persistently presenting in an MP position, deliver by Caesarean section (if appropriate resources are available and it is safe to do so).

**Delivery of compound presentations (see Table 2.6.E.1)**

Here more than one part of the fetus is facing the cervix (e.g. an arm prolapsing alongside the presenting part). It is more common in prematurity.

Compound presentations, especially minor degrees involving just a hand can be managed expectantly in the early stages of labour, especially in the multiparous patient, and can sometimes be digitally encouraged back into the uterus. If they progress or persist and cause delay in the first or second stages of labour, then Caesarean section should be undertaken.

## Transverse and oblique lies (see Table 2.6.E.1)

### Background

These are associated with prematurity, uterine fibroids and placenta praevia, and consequently are associated with high maternal and fetal morbidity. Always try to identify the underlying pathology, if any.

If the membranes are intact in early labour, it is worth attempting external cephalic version (see below under breech).

The presentation of shoulder, limb or cord in the presence of ruptured membranes means that Caesarean section is the only option for delivering a viable infant. If the fetus is dead, unless it is very small and macerated, it is safer to perform a destructive procedure if an operator experienced in the procedure is available, and it is acceptable to the patient.

### Practical points to remember

- Using ultrasound, try to identify the cause of the abnormal lie, if any.
- **Positively exclude placenta praevia with ultrasound before performing digital vaginal examinations. If there has been no vaginal bleeding, placenta praevia is still possible.**
- Caesarean section can be extremely difficult:
  - The lower segment will be poorly formed.
  - Fibroids, when present, can distort the anatomy and inhibit access.
  - Placenta praevia is associated with severe haemorrhage.
- A vertical uterine incision may sometimes be most appropriate for the above reasons.
- Keep the membranes intact while making and extending the uterine incision, as this aids manipulation of the fetus into a longitudinal plane for delivery.
- Delivery is usually best achieved by finding, grasping and bringing down a foot (recognisable by the heel) into the incision. If the foot is difficult to find, the back and buttocks should be identified and the legs followed until a foot is found.
- If delivery is still impossible, the uterine incision can be extended upwards in the midline, making an 'inverted T'. **If an extended uterine incision has been used, it is essential to undertake an elective Caesarean section in subsequent pregnancies, because of the risk of uterine rupture during labour.**

## Breech delivery (see Table 2.6.E.1)

### Background

At 28 weeks, 20% of babies are breech, but most fetuses will turn spontaneously so that only 3–4% will remain breech at term. There is a higher rate with prematurity. Vaginal delivery (although safer for the mother than Caesarean section) carries a higher risk of perinatal and neonatal mortality and morbidity due to birth asphyxia and trauma.

### Hazards of vaginal breech delivery

Compared with the cephalic presentation at term, there is a greater risk of perinatal and neonatal mortality and morbidity, due principally to fetal congenital anomalies and birth trauma and asphyxia. In terms of maternal outcomes, vaginal birth is generally better for the mother than Caesarean

section, as the operative complications associated with major abdominal surgery and the resulting uterine scar are avoided. All of these factors are especially relevant in resource-limited countries.

### Minimising problems

#### Options

- If there are no associated complications of pregnancy (e.g. previous Caesarean section, pre-eclampsia), explain the three options to the woman and her family:
  - external cephalic version (ECV)
  - trial of vaginal breech
  - elective Caesarean section (only if this is safe).
- On the basis of current evidence, all women with uncomplicated breech presentation at term should be offered ECV.
- If it is decided that an elective Caesarean section is the best option, wait until at least 39 weeks (babies may still turn spontaneously until then).
- A trial of vaginal breech delivery is appropriate if **both mother and baby** are of normal proportions.
  - The presentation should be either frank (hips flexed, knees extended) or complete (hips flexed, knees flexed, but feet not below the fetal buttocks).
  - There should be no evidence of fetopelvic disproportion – that is, adequate pelvis (using clinical judgement) and estimated fetal weight < 4000 grams (clinical measurement).
  - In some smaller women it may be appropriate to exclude a vaginal breech option where the estimated fetal weight is < 4000 grams, provided that Caesarean section is safe.
  - There should be no evidence (on ultrasound) of hyperextension of the fetal head.

### Fetal complications of breech presentation

These include the following:

- cord prolapse
- birth trauma as a result of extended arm or head, incomplete dilatation of the cervix, or cephalopelvic disproportion
- asphyxia due to cord prolapse, cord compression, placental detachment or arrested head
- damage to abdominal organs
- broken neck.

### External cephalic version (ECV)

#### Background

Current recommendations in well-resourced countries are that ECV should be performed with the mother wide awake, but 'starved', having made her informed choice and having given consent for Caesarean section if necessary, close to theatre, after fetal monitoring has been carried out, and using ultrasound guidance, and tocolysis where necessary. These safety guidelines minimise the risks of maternal injury and fetal distress, allowing early detection and treatment if necessary. However, in resource-limited settings, the avoidance of breech delivery by ECV is highly beneficial, and the method described below is a reasonable compromise.

ECV may be performed between 37 and 42 weeks' gestation if there is a single uncomplicated breech pregnancy. There should be no previous uterine scars, previous antepartum bleeding, fibroids or a placenta praevia. On admission, the fetal heart should be listened to regularly. If

available, ultrasound should be performed to demonstrate the fetal presentation, an adequate amount of liquor, a flexed fetal head and the position of the fetal legs. The mother should be awake and have given consent to the procedure.

The membranes must be intact, with adequate amniotic fluid and no complications of pregnancy.

### Procedure

If possible, use ultrasound to demonstrate the fetal position, an adequate amount of liquor, a flexed fetal head, a free loop of cord, and the position of the fetal legs (extended or flexed).

- The mother lies on her side (usually her right), which will allow a forward somersault (from 'left sacro-anterior' position, which is the commonest breech position).
- The bed is tilted head down to allow gravity to assist in disengaging the breech.
- If the uterus is relaxed, an attempt is made to turn the baby, by disengaging the breech with one hand and flexing the head further with the other.
  - This should not hurt the mother, but it will be uncomfortable; the movement on her abdomen is made easier by using lubricant (e.g. sweet almond oil, talc, ultrasound gel).
  - The manoeuvres are illustrated in Figure 2.6.E.8.
- Ensure that the fetal heart rate is normal (110–160 beats/minute).
- In well-resourced settings only, and with relatively only slightly more success, and if the uterus is not relaxed, tocolysis may be helpful. Consider giving a dose of 250 micrograms terbutaline subcutaneously.
- The fetal heart rate should be listened to regularly during the procedure.
- Whether the ECV is successful or not, after the procedure listen carefully to the fetal heart every 5 minutes for 30–60 minutes. If this is normal, the mother is allowed home.
- If the first attempt is unsuccessful, consider bringing the mother back the next day for a repeat trial.
- If the fetal heart rate becomes abnormal, turn the woman on to her left side, and reassess every 5 minutes. If the

FIGURE 2.6.E.8 External cephalic version.

fetal heart rate does not become normal within 30 minutes, deliver by Caesarean section (if the facilities are available and it is safe to do so).

- In well-resourced settings where blood group including rhesus factor is universally collected, and where the mother is rhesus negative, 500IU of anti-D immunoglobulin should be given after ECV. Unfortunately, anti-D immunoglobulin is expensive.

Figure 2.6.E.8 shows the steps involved in ECV. It illustrates how a right-handed person would turn a baby. If you are left-handed, turn the baby the other way.

(a) Place one hand below the breech, and your other hand above the head. Lift the breech out of the pelvis. Bring the head and breech closer together so as to flex the baby.

(b) and (c) Turn the baby by guiding the head forwards as you lift the buttocks up. In this way you make the baby do a forward somersault (i.e. turn head over heels).

(d) If you fail to turn the baby, try turning them with a backward somersault.

All mothers should be warned about the possible subsequent risks of reduced fetal movements, vaginal bleeding, rupture of the membranes and onset of labour. If ECV is successful, the pregnancy can be managed as a cephalic presentation. If it is unsuccessful, future management should be discussed and a decision made regarding whether to opt for elective Caesarean section or trial of vaginal breech delivery.

### Trial of vaginal breech delivery

This is a difficult issue where there is limited availability of safe surgery, or surgery without delay. A trial may not be appropriate if:

- the mother is very small and/or the baby is large
- there is evidence of fetal–pelvic disproportion – that is, an inadequate pelvis (using clinical judgement) and an estimated fetal weight exceeding 4000 grams
- evidence (on ultrasound) of hyper-extension of the fetal head.

If there has been a previous Caesarean section or other scar in the uterus, a repeat Caesarean section may be preferable, although this will depend on the availability of safe surgery. Moving the woman to a waiting home next to a unit that provides comprehensive emergency obstetric care from 37 weeks' gestation (if available) may be a good option.

### Procedure

- The mother should confirm her informed choice of vaginal delivery.
- If the mother is in hospital, an obstetrician, anaesthetist and operating theatre should be ready.
- Careful fetal monitoring and documentation of the partograph should be undertaken.
- The bladder must be emptied either naturally or with an in–out catheter.
- If spontaneous rupture of the membranes occurs, do a vaginal examination to check for cord prolapse. Meconium is common and not a sign of fetal distress.
- Amniotomy may be used to accelerate labour, where indicated, and careful use of oxytocin may be used to correct poor uterine activity if the mother is having her first baby. However, oxytocin should only be used in a well-resourced hospital. It should not be used for poor

progress due to poor uterine contractions in a mother who has previously given birth. Where available and safe, it is reasonable to perform a Caesarean section, rather than commencing oxytocin, even in primiparous women who are making inadequate spontaneous progress in labour.

- Caesarean section should be considered if there is poor progress or fetal distress.
- Ensure that a healthcare worker with adequate experience in delivering breech babies vaginally is present during the second stage.

**The basic principle of delivering a breech is to avoid interfering.**

- Active pushing should not be encouraged until the breech has descended to the pelvic floor and the cervix is fully dilated as confirmed by vaginal examination.
- Sitting the patient up at this stage may help to encourage descent of the breech. An **episiotomy** may well be required, but should not be performed until the anus is visible or until the baby's buttocks are distending the perineum.
- The breech will usually rotate spontaneously to lie with the sacrum anteriorly. **Rarely it will try to turn posteriorly, and this must be prevented by holding the baby by the bony pelvis and rotating the baby to the back-anterior position as it descends with maternal effort.**
- Extended legs are delivered by flexing the knee joint of the baby and then extending at the hips.
- The baby is **supported** only when the arms are delivered and the nape of the neck becomes visible. Avoid holding the baby's abdomen, as internal organs may be traumatised; the pelvis should be held gently to support the weight of the baby and prevent hyperextension of the fetal neck.
- As the mother pushes, the anterior shoulder tip will become visible. A finger is run over the shoulder and down to the elbow to deliver the arm, if this does not occur spontaneously. The other shoulder will rotate anteriorly spontaneously to allow similar delivery of the other arm. If the arms are not delivering spontaneously despite the shoulders being visible, the Løvset manoeuvre should be used (see Figure 2.6.E.9). Traction on

the baby combined with rotations as shown (multiple if necessary) will usually result in each arm dropping out of the cervix. Minimal assistance by the healthcare worker running a finger along the arm to disengage it may sometimes help.

- The baby lies supported as the head engages and the neck comes into view (see Figure 2.6.E.10).

**FIGURE 2.6.E.10** Breech delivery: the baby should hang until the hair line at the back of the neck is seen.

- Delivery of the head may then be performed by the Mauriceau–Smellie–Veit manoeuvre (see Figure 2.6.E.11). The right hand is placed in the vagina, the fetus is supported on the right forearm, the middle finger of the hand is passed into the baby's mouth, and the first and third fingers are placed **just below** the bony ridges of the lower part of the orbits (the maxilla). The eyes must not be compressed. Pressure is applied to flex and deliver the head. The left hand is used to press upwards and posteriorly on the back of the fetal head to encourage flexion.
- Alternatively, forceps may be used to achieve the controlled delivery of the head. An assistant should hold the baby's feet to elevate the body above the horizontal to

**FIGURE 2.6.E.9** Breech delivery using Løvset method. Reproduced with permission from Macdonald S, Magill-Cuerden J (ed.) *Mayes' Midwifery: a textbook for midwives*. Elsevier Health Sciences; 2010. © Elsevier

**FIGURE 2.6.E.11** Breech delivery: delivering the head by the Mauriceau–Smellie–Veit manoeuvre. To help to deliver the head safely, lay the body on your forearm. Put the index and middle fingers of your left hand on the bony ridges below the eyes. Place your right index finger on the occiput, flex the head, and deliver the head slowly and in a controlled way.

allow the operator access to apply forceps. The nape of the neck must be in view before the baby's body is lifted upwards, or damage to the fetal neck may be caused. It is also essential that the baby is not lifted too high, as this will damage the neck.

If the head fails to descend into the pelvis (i.e. the nape of the neck does not appear), first check that the cervix is fully dilated. If it is not, it will need to be incised. If the cervix is fully dilated, if possible forceps (ideally Piper's) may be applied to the fetal head to facilitate delivery. Firm suprapubic pressure may be applied in the midline to encourage the unengaged head to flex and facilitate delivery. If this is unsuccessful, a symphysiotomy should be considered. All of these manoeuvres are potentially dangerous for the mother. If the fetus dies, a destructive procedure should be undertaken.

### **Elective Caesarean section for breech**

This is advisable for the following:

- failed external cephalic version
- if vaginal birth is contraindicated, or the mother wishes
- double footling breech
- a very large fetus
- a small or malformed maternal pelvis
- a hyperextended or deflexed fetal head.

Before and at operation:

- Explain to the woman that she will have a scarred uterus, which may create problems in future pregnancies.
- Ensure that the presentation remains breech before anaesthetising the patient.
- Note that if the uterine incision is too small, there can be difficulty delivering the after-coming head.
- Remember to keep the fetal back upwards during delivery.

## **2.6.F Preterm pre-labour rupture of membranes (PPROM) and/or preterm labour**

### **Introduction**

PPROM is defined as spontaneous rupture of the membranes before the onset of labour and prior to 37 weeks' gestation. It occurs in 2–4% of single pregnancies and 7–20% of multiple pregnancies, and accompanies 60% or more of preterm births.

PPROM is associated with maternal mortality and morbidity with neonatal complications, which include cord prolapse, neonatal sepsis and respiratory failure, pulmonary hypoplasia and malpresentations.

Preterm labour is defined as labour that begins before 37 weeks' gestation. It has increasingly serious implications for the neonate the earlier it occurs.

Preterm labour may occur without PPRM. However, ruptured membranes are a common early consequence of premature labour. Likewise PPRM can occur before labour, but the risk of progression to labour following PPRM is high (see below).

There are multiple risk factors for preterm labour and PPRM. They include intrauterine infection, twin pregnancy, polyhydramnios, abruption, malaria, urinary tract infection/pyelonephritis and uterine anomalies (including large fibroids).

### **Clinical findings in the woman with PPRM and/or preterm labour**

In PPRM the fluid may come out quickly as a sudden large flow, or it may trickle out over 1–2 hours, after which recognition is more difficult. Around 50% of women go into labour within 24–48 hours, and 70–90% within 1 week. The gap is longer the earlier in pregnancy the rupture occurs.

There may be no history or signs to suggest that PPRM has occurred, and therefore the woman may present with preterm labour. Preterm labour may also occur without PPRM.

It is important if possible to distinguish PPRM from

urinary incontinence, bacterial/fungal vaginal infection or a 'show' of cervical mucus.

Premature labour is considered to be present if there are regular contractions (usually at least every 10 minutes) associated with cervical effacement and/or dilatation.

In its early stages it is very difficult to diagnose accurately, as the patient may present before cervical change has occurred, and it is then only with time that the cervical change becomes apparent.

Important differential diagnosis for premature labour, where cervical change has not yet occurred, include: Braxton Hicks contractions, urinary tract infection, musculoskeletal pain, constipation and diarrhoea.

Infection can itself result in premature labour and therefore patients presenting with threatened preterm labour should be assessed and treated for an underlying cause. Common examples of infections that precipitate premature labour include malaria and urinary tract infection/pyelonephritis.

### **Management of PPRM and/or preterm labour**

Avoid doing a digital vaginal examination unless active labour is under way and/or birth is imminent, as it increases the risk of infection.

A sterile speculum examination should be undertaken to look for amniotic fluid passing through the cervix or in the posterior fornix. A swab should be taken of the fluid and sent to the laboratory for microscopy and culture (if bacteriological facilities are available), looking especially for group B streptococcus.

Monitor vital signs (temperature, heart rate and blood pressure), vaginal discharge (check sanitary towels regularly; do not use tampons), uterine activity and possible tenderness, and fetal heart rate, and where possible perform an ultrasound examination to assess the amniotic fluid index, presentation, gestation and placental site.

Also check a full blood count, maternal blood group, malaria RDT +/- smear and a midstream specimen of urine (MSSU). If available a CRP along with the white blood cell count may help to indicate an underlying infection.

Although there is no evidence that bed rest is appropriate, if it is undertaken apply anti-embolism stockings (if available) and encourage leg exercises to prevent deep vein thrombosis.

Inform the paediatrician (if available).

Sexual intercourse should not occur after PPRM.

### When to consider antibiotics

1 Symptomatic ascending infection *in utero* in the mother (fever, maternal and/or fetal tachycardia, foul-smelling vaginal discharge, uterine tenderness and signs of systemic illness) needs **urgent treatment with IV antibiotics (ampicillin plus gentamicin plus metronidazole)**. If this is overlooked, the lives of both the mother and the baby will be in danger:

- ampicillin 2 grams IV/IM, then 1 gram IV 6-hourly
- *plus* gentamicin 80 mg IV/IM 8-hourly or 5 mg/kg body weight IV/IM once every 24 hours
- *plus* metronidazole (vial containing 500 mg in 100 mL) 500 mg or 100 mL IV infusion every 8 hours. Do not give metronidazole IM.

**Usually there will be uterine contractions, but whether or not they are present the baby must be delivered as soon as possible.**

2 Asymptomatic infection (no fever and no systemic signs of illness) is a more common problem which may progress to a life-threatening infection at any time. It is therefore essential that all women who have/or may have undergone rupture of membranes, are monitored regularly for the symptoms and signs of infection. These include: labour, generalised uterine pain, flushing and chills, body aches, fever (> 37.5°C), tachycardia, tachypnoea and fetal tachycardia.

3 If premature rupture of membranes is confirmed, the patient is stable, and a decision has been made to manage the patient expectantly (see below) then give prophylactic antibiotics as follows to help more safely to prolong the pregnancy:

- a. Erythromycin 250 mg TDS plus amoxicillin 500 mg TDS both orally and for 7 days.

4 **All patients with confirmed premature labour should receive prophylactic antibiotics when in active labour as follows:**

- a. IV ampicillin 2 grams IV/IM, then 1 gram IV 6-hourly. Discontinue antibiotics immediately after delivery if there are no signs of infection in the mother.

5 Maternal fever (> 38°C) or other indication of infection in labour (e.g. offensive liquor) requires that the mother be treated with IV penicillin/ampicillin, metronidazole and gentamicin as in 1. above. If this is the case, **the newborn infant should also be treated with IV antibiotics from birth without waiting for any signs of infection to appear (see Section 3.1).**

### Minimising the risk of surfactant deficiency in the newborn with antenatal steroids

High-dose corticosteroids can improve surfactant production in the newborn, but steroids must not be given if there is evidence of tuberculosis or HIV infection. A transient

increase in blood glucose levels can occur with the use of steroids in diabetes. Even one dose of steroids can be effective in improving lung maturity in the newborn.

Give betamethasone, 12 mg IM, two doses 24 hours apart or dexamethasone, 6 mg IM, four doses 12 hours apart. Maximum benefit is achieved 24 hours following the second dose and for 1 week thereafter. Although it is not evidence based, where delivery is urgent, it is common practice to accelerate the course of steroids by giving the two 12 mg doses of either betamethasone or dexamethasone 12 hours apart.

A second course of dexamethasone or betamethasone can be given if more than 2 weeks have elapsed since the first course of treatment was given, and delivery has not occurred but premature labour has restarted. No more than two courses should be given.

### Stopping premature labour

There is evidence to demonstrate that labour can sometimes be delayed by treating the mother with tocolytic drugs. There is no evidence, however, that tocolysis alone is beneficial to the baby or mother. In fact their use is potentially dangerous, as delaying delivery may result in progression of the process which caused the premature labour in the first place, e.g. infection or abruption.

However, tocolysis may be useful to allow administration of antenatal corticosteroids (as above), thereby protecting the baby from lung surfactant deficiency. They may also allow transfer of the mother to a hospital where safer therapy can be provided for a preterm baby.

Tocolysis should not be given for more than 48 hours as this is the time taken for antenatal steroids to achieve their maximum therapeutic effects.

Premature labour is considered to be present if there are regular contractions at least every 10 minutes associated with cervical effacement and/or dilatation.

**It is unsafe to try to stop labour if the membranes are ruptured.**

Although tocolysis is not recommended after 34 weeks' gestation in well-resourced settings, it may possibly be helpful between 34 and 36 weeks' gestation in low-resource settings, as well as between 28 and 34 weeks.

If labour is well advanced and the cervix is more than 5 cm dilated, tocolysis will probably not be helpful.

### Drugs used for tocolysis

There is always the option of not trying to stop uterine contractions, as the evidence of benefit is very limited. If antenatal corticosteroids are not going to be given and there is no need to transfer the patient, then tocolytics are not indicated.

#### Terbutaline

This is given in a dose of 250 micrograms subcutaneously every 6 hours.

#### Nifedipine

Nifedipine given orally is the most appropriate drug.

The side effects of nifedipine include facial flushing, headache, nausea, tachycardia, dizziness, a fall in blood pressure, heart failure and (rarely) increased liver enzymes.

Contraindications are situations where delivery is desired, such as antepartum haemorrhage, severe pre-eclampsia, infection, fetal distress and all cases of PPRM

in low-resource settings. Nifedipine should not be given if the mother has heart disease.

Before starting nifedipine, measure urea and electrolytes and liver function tests (where available).

Regular and frequent measurements of the mother's vital signs, as well as the fetal heart rate, should be undertaken. Closely observe for signs of heart failure. If the blood pressure falls, give a bolus of 250–500 mL of Ringer-lactate or Hartmann's solution.

#### Doses of nifedipine:

- Initial dose: 20 mg of oral nifedipine.
- Up to three further doses can be given at 30-minute intervals if uterine contractions persist.
- If this stops labour, and the blood pressure is stable, give a maintenance dose of 20 mg three times a day for up to a total of 48 hours. The maximum daily dose is 120 mg of nifedipine.

#### How long to wait before inducing labour when there is PPROM

The decision on timing of delivery is difficult, and it depends on the stage of pregnancy, the availability of comprehensive emergency obstetric care, the quality of neonatal care available and the obstetric history and wishes of the patient.

If expectant management is undertaken women with PPROM should be resident in a healthcare facility where comprehensive emergency obstetric care is available. Induction of labour should be undertaken by 36 weeks as prolonging the pregnancy beyond this stage is of reduced benefit to the fetus.

In a resource poor setting it is reasonable to induce the pregnancy at a much earlier gestation, even if this will result in a neonatal death, in order to reduce maternal risk.

Patients should be monitored closely for any symptoms or signs of infection, and if any develop delivery should be achieved urgently (via induction or Caesarean section, whichever is indicated) regardless of gestation.

Suggested monitoring would include:

- Regular review for symptoms of infection, e.g. uterine pain, body aches, flushing, chills. The patient should be advised to report such symptoms as they occur.
- 2 to 4 times daily vital sign assessment – tachycardia (> 100 bpm), tachypnoea (> 20), and pyrexia (> 37.5° C) should raise suspicion of infection.
- At least twice weekly inflammatory marker assessment such as CRP (where available). Note: corticosteroid administration causes a transient increase in the maternal white blood cell count but does not affect CRP.

#### Clinical problems in the neonate associated with preterm birth

These include the following:

- Surfactant deficiency leads to increasing levels of respiratory difficulty with decreasing gestational age.
- There is an increased risk of infection and hypothermia.
- Nutritional problems: maturity is more important than weight with regard to the ability to feed and digest. Babies who are born before 36 weeks' gestation nearly always need some help with feeding. Breast milk is ideal, and everything possible should be done to help the mother to sustain her lactation until the baby is ready to feed reliably from the breast. A limited ability to suck and swallow usually appears from 32 weeks' gestation, but it remains unpredictable, unreliable and uncoordinated until 36 weeks' gestation. In the event that breastfeeding cannot be initiated immediately after birth, the mother should be encouraged to start expressing breast milk, to be given by nasogastric tube or cup and spoon. Partial breastfeeding can also help the mother to sustain her lactation, but in any event she should regularly express milk.

Further information on care of the prematurely born infant can be found in Section 3.

## 2.6.G Prolapsed umbilical cord

### Incidence

Prolapse of the umbilical cord occurs in approximately 0.2% of all births, mostly in multiparous mothers. There is a significant risk of fetal death due to mechanical compression of the cord, and spasm of the cord vessels when they are exposed to cold air.

### Risk factors for cord prolapse

The presenting part does not remain in the lower uterine segment due to any of the following causes.

#### Fetal causes

- Malpresentations (e.g. complete or footling breech, transverse and oblique lie).
- Prematurity or low birth weight.
- Polyhydramnios.
- Multiple pregnancy.
- Anencephaly.
- High head.

FIGURE 2.6.G.1 Sagittal view showing compressed cord.

**FIGURE 2.6.G.2** Prolapsed cord presenting. Reproduced with permission from Macdonald S, Magill-Cuerden J (ed.) *Mayes' Midwifery: a textbook for midwives*. Elsevier Health Sciences; 2010. © Elsevier

#### Maternal causes

- Contracted pelvis.
- Pelvic tumours.

#### Other predisposing factors

- Low-grade placenta praevia.
- Long cord.
- Sudden rupture of membranes in polyhydramnios.
- Artificial rupture of membranes (ARM).
- Manual rotation of the fetal head.

### Management of cord prolapse

The longer the time between diagnosis of cord prolapse and delivery, the greater the risk of stillbirth and neonatal death. If the baby is dead, deliver in the safest way for the mother.

- 1 Assess fetal viability. If the baby is alive and of a viable gestation, and fetal heart sounds are heard with a Pinard's stethoscope or ideally a hand-held ultrasound fetal heart rate detector (e.g. Sonicaid), urgently relieve pressure on the cord by placing the woman in the knee-elbow or exaggerated Sims' position (Figure 2.6.G.3). Care should be taken not to stimulate the cord by handling it. Exposure to low temperatures should also be prevented if possible. This gives time for decision making.
- 2 Discontinue oxytocin if it is being used. You can buy time to allow the baby to be delivered by giving tocolysis with terbutaline 250 micrograms every 6 hours subcutaneously.

- 3 If the fetus is alive, prepare for either emergency vaginal delivery or emergency Caesarean section (if this can be undertaken safely).
- 4 If the cervix is fully dilated, and delivery is likely to be achievable within 5 minutes, encourage the patient to push and prepare to expedite the delivery by use of forceps or ventouse. The choice of instrument will depend on availability, operator experience and the position of the fetal head. If appropriate, forceps delivery is usually the most rapid method of achieving delivery, but must not be used by inexperienced staff. Rapid delivery is far more likely to be achieved in a multiparous woman.
- 5 If Caesarean section is safe and the only option (i.e. the cervix is not fully dilated, and the fetus is alive and viable), fill the bladder to raise the presenting part off the compressed cord for an extended period of time, so that the woman or girl can be transferred to the operating theatre. Insert 500 mL of sterile IV fluid into the bladder using an IV giving set attached to a Foley catheter. Inflate the balloon of the Foley catheter, clamp it and attach drainage tubing and a urine bag. The full bladder may also decrease or inhibit uterine contractions. The bladder must be emptied by unclamping the catheter before opening the peritoneal cavity for Caesarean section. **Mark the mother's abdomen to ensure that this is not forgotten. At skin incision, the bladder clamp must be released and the bladder emptied.**
- 6 Ensure that venous access is in place with a reliable IV cannula.
- 7 Transfer the woman or girl to the operating theatre in the exaggerated Sims' position on a trolley.

**FIGURE 2.6.G.3** Maternal positions for immediately relieving pressure on prolapsed cord.

**FIGURE 2.6.G.4** Treating prolapse of the cord by elevation of the fetal presenting part by inflating the bladder with sterile IV fluid.

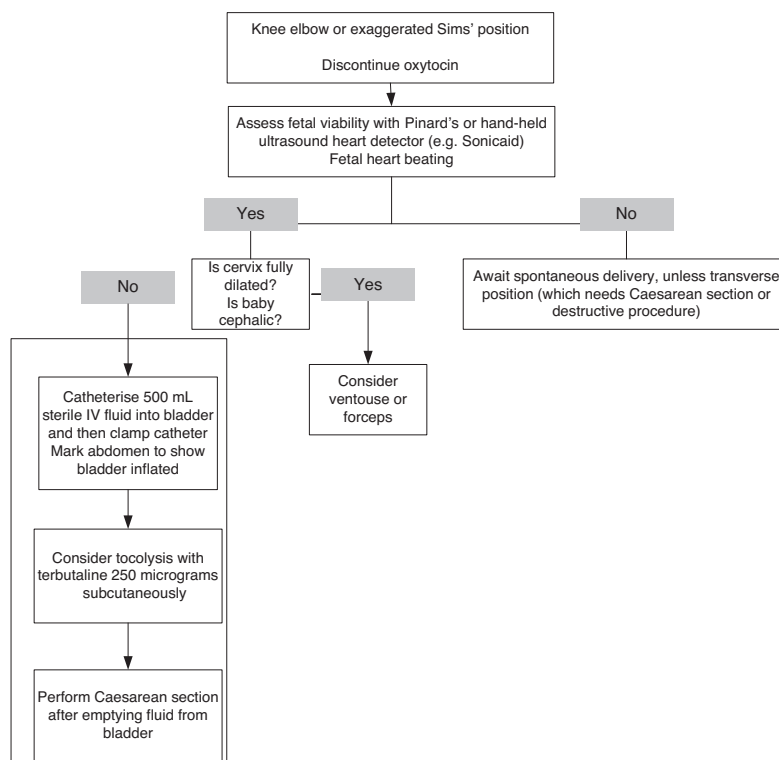

FIGURE 2.6.G.5 Pathway of care for prolapsed cord.

## 2.6.H Inverted uterus

### Introduction

#### Definition

This occurs when the uterus, after or during delivery of the placenta, is inverted and may appear at the introitus. The inverted uterus has the endometrium and sometimes the placenta 'on the outside'.

#### Prevention

Prevent an inverted uterus by avoiding cord traction until the uterus is contracted and placental separation has occurred, and ensuring that the uterus is held back with one hand during cord traction.

#### Clinical signs

An inverted uterus most commonly presents as a pelvic mass, sometimes protruding from the vagina. If the inverted uterus does not protrude from the vagina, it may go undetected, resulting in a sub-acute or chronic inversion which is very dangerous and may even present as a sudden unexpected maternal death.

Symptoms and signs include severe lower abdominal pain in the third stage of labour, haemorrhage, shock out of proportion to blood loss, the uterus not being palpable on abdominal examination, and vaginal examination revealing a mass in the vagina.

Early recognition is vital, as **shock** is the most common complication. Shock out of proportion to blood loss may be due to increased vagal tone, which may also produce

a **bradycardia** (< 60 beats/minute), worsening the shock and confusing its diagnosis. Inversion is associated with haemorrhage in over 90% of cases. Alternatively, concealed bleeding may produce tachycardia and other signs of shock.

Incomplete inversion presents more subtly with continuing postpartum haemorrhage despite a contracted uterus. The fundus of the uterus may feel dimpled.

Suspect a diagnosis of inverted uterus if there is:

- shock with little obvious bleeding
- continuing postpartum haemorrhage despite an apparently well-contracted uterus
- associated lower abdominal pain
- a dimpled uterine fundus
- a fundus that is not palpable abdominally.

### Management

**The uterus must be replaced as soon as inversion is recognised, as a matter of urgency, as this becomes more difficult over time. Call for help and try to push it back while ABC resuscitation is being undertaken.**

#### Primary assessment and resuscitation

Call for senior help, including a surgeon and an anaesthetist.

If shock is present, manage ABC as described below.

#### Manual replacement of the uterus

As soon as possible, and **wearing sterile gloves**, attempt manual replacement of the uterus by pushing the fundus

back through the cervix (the longer the delay, the more difficult it will be to achieve resolution).

**It is important that the part of the uterus that came out last (the part closest to the cervix) goes in first.**

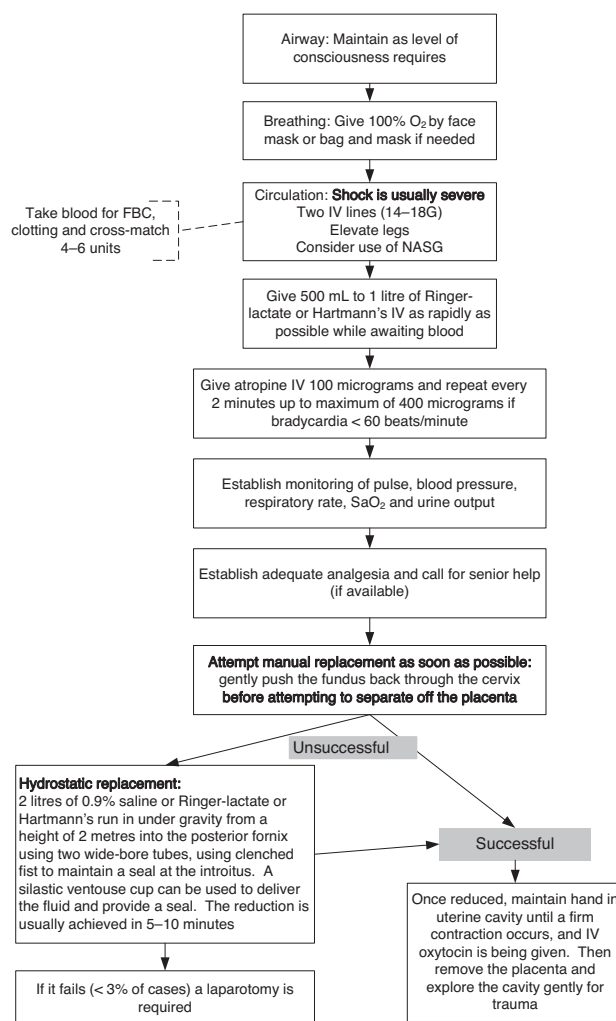

**FIGURE 2.6.H.1** Bimanual replacement of inverted uterus. Reproduced with the permission of Medical Aid Films, [www.medicalaidfilms.org](http://www.medicalaidfilms.org)

**Do not attempt to separate the placenta until the inversion has been corrected.**

However, if the inversion has been present for some time (e.g. if it occurred at home), and replacement is not possible without placental removal, then be prepared for possible severe bleeding if this is undertaken.

### Hydrostatic correction

- If manual replacement is unsuccessful, hydrostatic correction should be attempted.
- Place the woman in the steep Trendelenburg position (lower her head about 0.5 metres below the level of the perineum).
- Prepare a high-level sterile douche system with a large nozzle, long tubing (2 metres) and a reservoir (1–2 litres of sterile Ringer-lactate or Hartmann's solution at room temperature, not from a refrigerator).
  - **Note:** This can also be done using Ringer-lactate or Hartmann's solution and an ordinary IV administration set.
- Identify the posterior fornix. This is easily done in partial inversion when the inverted uterus is still in the vagina. In other cases, the posterior fornix is recognised by the place where the ridged vagina becomes the smooth vagina.
- Place the nozzle of the douche in the posterior fornix.
- At the same time, with the other hand hold the labia sealed over the nozzle and use the forearm to support the nozzle.
- Ask an assistant to start the douche at full pressure (raise the water reservoir to at least 2 metres). Ringer-lactate or Hartmann's solution will distend the posterior fornix of

**FIGURE 2.6.H.2** Pathway of care for inverted uterus. FBC, full blood count; NASG, non-pneumatic anti-shock garment.

the vagina gradually so that it stretches. This causes the circumference of the orifice to increase, relieves cervical constriction, and results in correction of the inversion.

- If a Silc Cup ventouse is available, this can be used to occlude the vagina and give a seal. Two IV infusion sets are inserted into the narrow end while the wide end lies against the inverted uterus vaginally.
- Terbutaline, 250 micrograms subcutaneously, may help to stop any uterine contractions that prevent correction of the inversion.

### Manual correction under general anaesthesia

If hydrostatic correction is not successful, try manual repositioning under general anaesthesia, using halothane. Halothane is recommended because it relaxes the uterus, but be aware of the risk of possible atonic uterus and haemorrhage.

### Airway

- Use an opening manoeuvre if the airway is not open or is partially obstructed. Keep the airway open. If there is an improvement but the airway closes without active opening support, consider using an airway adjunct to support the airway.
- Suction only under direct vision and only if necessary.
- The airway may need to be secured by intubation using experienced senior help (if available).

### Breathing

Provide a high concentration of oxygen through a face mask with a reservoir bag if there is adequate spontaneous respiration. Give 100% oxygen (mask with reservoir and a flow rate of at least 6 litres/minute) regardless of SaO<sub>2</sub>.

For inadequate ventilation or depressed conscious level (P or U on the AVPU scale), respiration should be supported with oxygen via a **bag-mask**, and experienced senior help should be summoned (if available).

### Circulation

#### Primary assessment suggesting shock:

- **Fast, weak pulse** ( $\geq 100$ –110 beats/minute). Normal heart rates in a pregnant mother at rest are 60–90 beats/minute. Tachycardia is the first sign of shock.
- **Bradycardia** (< 60 beats/minute) may occur as a result of increased vagal tone due to the inversion.
- **Low-volume (weak) pulse.**
- Pallor (especially of the inner eyelid, palms or around the mouth).
- Sweatiness or cold clammy skin.
- **Prolonged capillary refill time** (> 3 seconds).
- **Rapid breathing** (> 30 breaths/minute). Normal respiratory rates in a pregnant mother at rest are 15–20 breaths/minute. Tachypnoea can be due to acidosis.

- **Low blood pressure** (systolic < 90–100 mmHg) **is a very late sign.** Healthy women and girls can maintain a normal or even high blood pressure while large volumes of blood are lost.
- Anxiety, reduced conscious level, confusion or unconsciousness.

If the woman or girl is shocked, obtain vascular access to give large volumes quickly. Insert two wide-bore IV cannulae (14- to 16G) and send blood for a full blood count, cross-matching (2 units) and clotting. If peripheral veins are difficult to access, the external jugular vein or long saphenous vein cut-down are good alternatives.

- Give an initial **rapid** bolus of 500 mL to 1 litre of Ringer-lactate or Hartmann's solution **or blood if available.** It is essential that the bolus is given as rapidly as possible. In the absence of syringe pumps, they should be pushed in manually using a 20- to 50-mL syringe (using a three-way tap and link to an IV giving set).
- Further 500- to 1000-mL boluses may be required in the first hour. Once more than 2 litres have been given IV, complications such as pulmonary or cerebral oedema may occur. If available, expert help, including CVP monitoring, is valuable.
- A blood pressure cuff can be used to speed up infusions in emergency situations. Wrap the cuff around the blood/fluid bag and place it inside a non-compressible bag.
- Keep the patient warm but do not overheat them, as this will cause peripheral vasodilatation and reduce the blood supply to vital centres. Hypothermia will exacerbate poor peripheral perfusion, acidosis and coagulation abnormalities.
- **Elevate the legs (raise the foot of the bed).**
- Give O-negative or group-specific blood if there is not time for full cross-matching. Have O-negative blood ready in the ward at all times if possible.
- Consider giving atropine 100 micrograms IV, and repeat every 2 minutes up to a maximum of 400 micrograms IV if bradycardia is < 60 beats/minute.
- Consider using the non-pneumatic anti-shock garment (NASG).

### Post-procedure care

Once the inversion is corrected, infuse IV oxytocin, 40 units in 500 mL of Ringer-lactate or Hartmann's solution, over 4 hours. **If the uterus does not contract after oxytocin**, give misoprostol 3 tablets each of 200 micrograms orally or 600 micrograms of powder sublingually if the patient is conscious, or 4 × 200 micrograms rectally if she is drowsy. The patient must be observed closely for haemorrhage.

Give a single dose of prophylactic antibiotics after correcting the inverted uterus. Use ampicillin 2 grams IV *plus* metronidazole 500 mg IV, and give appropriate analgesia.

## 2.6.1 Hyperemesis gravidarum

### Introduction

Some nausea and vomiting is common in early pregnancy, with nausea affecting 70–85% of women. Around 50% of pregnant women experience vomiting. However, in a small proportion of patients severe vomiting (hyperemesis) can occur. This condition is more common if there is a larger than normal placental mass (e.g. in multiple pregnancy and molar pregnancy). Hyperemesis peaks at 11 weeks, with 90% of cases resolved at 16 weeks.

### Associated conditions

Severe hyperemesis requiring hospital care is associated with the following:

- depression and severe stress
- multiple pregnancy
- molar pregnancy.

### Consequences of hyperemesis

Consequences that are severe enough to require hospital care include the following:

- ketosis
- hypochloraemic alkalosis, hypokalaemia and hyponatraemia
- malnutrition with anaemia and hypoalbuminaemia
- ulcerative oesophagitis
- Wernicke's encephalopathy from thiamine deficiency
- worsened depression, may result in the patient seeking a termination of pregnancy
- hyperemesis is dangerous in type 1 diabetes and can result in ketoacidosis.

### Investigations

- Ultrasound examination to exclude molar or multiple pregnancy.
- Urine for ketones and to exclude urinary tract infection.
- Blood for haemoglobin, urea and electrolytes.
- Special investigations as indicated to exclude serious medical problems affecting the gastrointestinal, genitourinary, neurological, metabolic or endocrine and psychological systems.

### Treatment of severe hyperemesis

Intravenous 0.9% saline, 1 litre given over 4 hours initially and then repeated as required, is the most effective treatment for severe hyperemesis with dehydration.

Small volumes (100–200 mL every 2–3 hours) of WHO oral rehydration salts (ORS) powder dissolved in 1 litre of water giving Na<sup>+</sup> 75 mmol/litre, K<sup>+</sup> 20 mmol/litre and glucose 75 mmol/litre can be given in addition to IV fluids until vomiting settles and if tolerated.

After IV fluids have been started, anti-emetic drugs may not be required, but if vomiting continues try prochlorperazine 12.5 mg IM and then orally 5 to 10 mg three times daily. Alternatives include cyclizine, 50 mg IM, IV or orally TDS domperidone 10 mg orally or 30–60 mg rectally four times a day, and metoclopramide 10 mg IM, IV or orally three times

a day. If suppositories are available, rectal administration is ideal as it can be self administered and avoids the oral route in the nauseous and vomiting patient. It is often necessary to use a combination of anti-emetics. If this is done it is often best to combine drugs with different mechanisms of action (e.g. cyclizine and metoclopramide) and to stagger their administration.

Supplements with thiamine should be given (IV if available) if there is evidence suggesting a severe deficiency may be present (Wernicke–Korsakoff syndrome). It should also be used prophylactically if the vomiting has been severe and/or protracted. See below for dosing.

If available, urea and electrolytes should be monitored (ideally daily) in women with severe hyperemesis. Women are at particular risk of hypokalaemia if the vomiting is severe and protracted. In a vomiting patient who is not tolerating any diet, potassium replacement should be considered even where blood measurement is not available. The daily requirement of potassium is approximately 60 mmol in a 60 kg woman, and will be higher in the vomiting patient.

Replacement should be undertaken with great care as too rapid replacement is dangerous.

A reasonable approach would be to add 20 mmol to 1 litre of 0.9% saline and to administer over 8 hours (42 dpm when using a standard giving set with a drop factor of 20). This provides a large margin of error as the infusion could be increased to >100 dpm before becoming hazardous.

Ringer's lactate does contain 5 mmol of potassium/litre and will provide some replacement if potassium is not available.

Hyperemesis is a risk factor for venous thromboembolism (DVT and PE). If a patient is admitted with severe hyperemesis she should be treated with anti-embolic stockings (if available).

### Wernicke–Korsakoff syndrome

Symptoms of Wernicke's encephalopathy include the following:

- confusion
- loss of muscle coordination (ataxia)
- leg tremor
- vision changes
- abnormal eye movements (back-and-forth movements called nystagmus)
- double vision
- eyelid drooping.

Symptoms of Korsakoff syndrome include the following:

- inability to form new memories
- loss of memory, which can be severe
- making up stories (confabulation)
- seeing or hearing things that are not really there (hallucinations).

### Treatment of severe hyperemesis where possible symptoms or signs of Wernicke–Korsakoff syndrome are present

Give an IV infusion of 10 mL of Pabrinex (Vials 1+2) in 100 mL of 0.9% saline over 1 hour (vials contain thiamine, ascorbic acid, nicotinamide, pyridoxine and riboflavin).

Subsequently, give oral thiamine 50 mg three times daily until vomiting has stopped.

**Other management on discharge from hospital**

Withhold iron tablets until vomiting has resolved, but ensure that they are taken subsequently, as iron-deficiency

anaemia may have been an important consequence of the hyperemesis.

Try to help with any depression that is present and also, if resources to address intimate partner violence are available in the community, make sensitive inquiries of the woman or girl in case this is a contributing factor.

## 2.7

## Medical disorders complicating pregnancy and delivery

### 2.7.A Heart failure during pregnancy, including rheumatic heart disease

**BOX 2.7.A.1 Minimum standards**

- Oxygen.
- Furosemide.
- Digoxin.
- Nitroglycerine sublingual tablets.
- Blood transfusion.
- Morphine.

**Introduction**

Serious cardiac pathology may present either as heart failure where respiratory distress is the most obvious finding, or as cardiogenic shock (see shock section later).

**Causes of heart failure during pregnancy**

There are five main causes of heart failure in pregnancy:

- 1 severe anaemia
- 2 structural heart disease
- 3 circulatory overload (e.g. excessive IV fluids)
- 4 hypertension in severe pre-eclampsia
- 5 hypertrophic cardiomyopathy (HCM) and peripartum cardiomyopathy.

Heart failure can result from:

- left ventricular volume overload (aortic and mitral valve incompetence) or excessive pulmonary blood flow (e.g. congenital heart defects)
- left heart obstruction (aortic stenosis, mitral stenosis, hypertension)
- primary pump failure (severe anaemia, myocarditis, cardiomyopathy or arrhythmia)
- over-transfusion (a particular risk in hospital with IV blood or fluid infusions, especially in the anaemic mother).

**Clinical signs**

These include the following:

- respiratory distress (raised rate and some chest wall recession)
- tachycardia out of proportion to respiratory difficulty

- raised jugular venous pressure
- gallop rhythm/murmur
- enlarged liver
- basal lung crepitations.

**Jugular venous pressure**

Normal levels of jugular venous pressure (JVP) are 4–5 cm above the sternal angle. In heart failure the JVP can be raised so that the external jugular vein is filled up to or above the angle of the jaw (see Figure 2.7.A.1).

**FIGURE 2.7.A.1** Clinical measurement of central venous pressure.

**Treatment of severe decompensated heart failure**

- Assess ABC.
- Sit the patient upright and **ensure bed rest**.
- Give a high concentration of **oxygen** via face mask with reservoir bag.
- If there are signs of shock (poor pulse volume or low blood pressure with extreme pallor and depressed conscious level), treat for **cardiogenic shock** with inotropes (if available).
- If there are signs of pulmonary oedema, give IV **furosemide 40 mg** (and repeat as required).

- Provided the patient is not hypotensive (systolic blood pressure > 90 mmHg) and has no serious obstructive valvular disease, give a **glyceryl trinitrate** tablet 500 micrograms sublingually and repeat up to a total of 3 tablets.
- Give **morphine** 3 mg over 5 minutes, and consider repeating after 15 minutes. Morphine is effective in reducing the afterload and, in addition, will reduce anxiety and pain both of which are likely to make heart failure worse.
- For patients with persisting heart failure load with **digoxin IV**, 250–500 micrograms over 10 minutes, then after 6 hours 125–250 micrograms over 10 minutes, then after a further 6 hours 125–250 micrograms over 10 minutes.

Or give an **oral digoxin** loading dose (instead of IV) of 375–750 micrograms, then after 6 hours 187.5–375 micrograms, then after a further 6 hours 187.5–375 micrograms.

- **Maintenance digoxin dose IV or oral:**
  - 125–750 micrograms once daily.
  - Reduce the dose in renal impairment. Be alert for low K<sup>+</sup> levels.
- Consider thromboprophylaxis. This treatment must take into account any bleeding risk and the timing of delivery.
- Check for severe anaemia (especially if the haemoglobin concentration is < 5.0 g/dL), for which partial exchange transfusion may be helpful. **Partial exchange transfusion can be achieved with a cannula in a large vein in the antecubital fossa. Withdraw 25 mL of anaemic blood and infuse 50 mL of new blood over 5 minutes, and repeat up to 10 times.** An alternative is careful transfusion of packed cells (hang the bag vertically for 15 minutes) to allow the red blood cells to separate from the plasma. Transfuse only the red blood cell component with 40 mg IV furosemide for each unit of 500 mL infused.

The following are useful investigations if available:

- full blood count (to exclude severe anaemia)
- serum urea and electrolytes
- infection screen, including blood cultures
- 12-lead electrocardiogram
- chest X-ray
- echocardiogram.

#### **Subsequent treatment of heart failure**

- Dietary sodium restriction.
- Loop diuretics (furosemide) for moderate/severe pulmonary oedema,
- Treatment with oral hydralazine or oral nifedipine (modified release version) as a vasodilator (instead of glyceryl trinitrate used in the acute scenario above).
- Treatment with a B-blocker (preferably a B1 cardio-selective B-blocker such as atenolol) can be beneficial. They are NOT used in the acute presentation of a patient with severe decompensated heart failure. They are contraindicated in asthma and may be associated with intra-uterine growth restriction, but are not associated with congenital malformations.
- Continued treatment with digoxin (as above) should be considered if significant symptoms persist.

- Treatment of any underlying anaemia or poor nutritional status.
- Once the baby is delivered, treatment with hydralazine or nifedipine may be replaced with an ACE inhibitor such as enalapril or lisinopril. ACE inhibitors cause congenital abnormalities and therefore should not be used antenatally. They are contraindicated if the patient is hypovolaemic and in renal artery and aortic stenosis.

#### **Management of heart failure during labour**

- The mother must deliver sitting up.
- Give oxygen from a face mask throughout labour.
- Limit infusion of IV fluids to decrease the risk of circulatory overload, and maintain a strict fluid balance chart.
- Ensure adequate analgesia.
- **If an oxytocin IV infusion is required**, use a higher concentration at a slower rate while maintaining a fluid balance chart (e.g. the concentration may be doubled if the number of drops per minute is decreased by half).
  - Increase the rate of oxytocin infusion until regular strong contractions are established, and then maintain infusion at that rate.
- Avoid sustained, bearing-down efforts during the second stage if possible.
- If it is necessary to decrease the woman's workload during delivery, perform an episiotomy and assist delivery by vacuum extraction or forceps.
- Ensure active management of the third stage of labour. Oxytocin given on delivery of the baby must be given very slowly IV (5 units diluted in 20 mL of 0.9% saline over 5–10 minutes) to avoid hypotension.
- **Do not give ergometrine.**

**Note:** Heart failure is not an indication for Caesarean section.

#### **Management of anaesthesia if Caesarean section is needed**

It is assumed that epidural anaesthesia/analgesia is unlikely to be possible or appropriate in low-resource settings. Avoid spinal anaesthesia if there is a fixed cardiac output, such as aortic/mitral stenosis or heart failure associated with valvular disease. If you are giving a general anaesthetic, take precautions against aspiration and minimise the risk of an increase in blood pressure associated with intubation by premedication with either morphine (5 mg initially IV) or lignocaine (1 mg/kg IV). If the patient is considered to have insufficient cardiovascular stability for general anaesthetic, undertake Caesarean section under local infiltration anaesthesia.

In all of the above situations the surgeon should be ready to start operating **immediately** when anaesthesia is established, so that the operating time is as short as possible. As above, oxytocin given for active management of third stage must be given very slowly IV (5 units diluted in 20 mL of 0.9% saline over 5–10 minutes) to avoid hypotension.

Post-operative management must ensure adequate analgesia with morphine.

## Cardiac consequences of rheumatic heart disease and their effects on pregnancy

### Introduction

After an episode of acute rheumatic fever, there may be permanent valve damage. Rheumatic heart disease occurs when acute valve inflammation is followed by scarring and fibrosis, resulting in various degrees of shortening, thickening, rigidity, deformity, retraction and fusion of the valve cusps. The commonest valve lesions are mitral regurgitation, mitral stenosis and aortic regurgitation. Rheumatic heart disease is most severe and progressive in the following:

- patients who initially have severe carditis
- patients who have recurrent episodes of acute rheumatic fever. The prognosis is more favourable if recurrences are prevented. After single episodes, residual cardiac disease may disappear or improve, and valve damage only worsens in a few cases. It is therefore crucial to maintain continuous antibiotic prophylaxis to prevent further valve damage.
- Asymptomatic rheumatic valve disease often becomes clinically relevant during pregnancy. A history of rheumatic fever should be sought at booking and ideally the heart auscultated for murmurs. It should be remembered as a differential diagnosis in a women presenting with shortness of breath, a cardiac arrhythmia or heart failure.

### When a cardiology referral and/or surgical intervention is not available

- Medical management is supportive, aiming to maximise cardiac function. The most dangerous period is delivery and shortly afterwards. In general, the more normal the delivery the less stress there is on the heart.
- Regular follow-up and rational drug therapy can make a significant difference. Use routine medications (diuretics, B-blocker, digoxin and nitrates) to maximum effect.
- Bed rest and the avoidance of heavy work are essential.
- Treat anaemia and any other coexisting conditions.
- Advise hospital delivery.
- Venesection can be used to decrease venous load for the patient in life-threatening situations where preload is high.

**Note that there is a risk of teratogenicity with ACE inhibitors during the first trimester, and problems with placental and renal function later in pregnancy. There is also diminished placental perfusion with diuretics although these should not be withheld if clinically indicated. ACE inhibitors may be used after delivery and during breastfeeding.**

### Effects of rheumatic heart disease

#### Mitral regurgitation

Mitral regurgitation is the commonest valve lesion.

#### Clinical features

These include the following:

- easy fatigue (caused by low cardiac output)
- shortness of breath on exertion (caused by pulmonary oedema and inability to increase cardiac output)
- orthopnoea, paroxysmal nocturnal dyspnoea and haemoptysis
- hyperdynamic apical impulse

- apical impulse displaced laterally and inferiorly
- a blowing apical pansystolic murmur radiating to the left axilla; there may be a third heart sound and a short low-frequency mid-diastolic murmur from increased trans-mitral flow
- there may be basal crepitations
- chest X-ray demonstrates cardiomegaly and left atrial enlargement (a double density on the right heart border and elevation of the left main bronchus)
- the ECG demonstrates left atrial enlargement (broad bifid P waves in lead II and a prominent negative component to the P in V1) and left ventricular hypertrophy
- signs of pulmonary hypertension.

#### Management

- Urgent referral for a cardiology opinion, as surgery is likely to be necessary (if available).
- Annual echocardiograph (if available), as progressive left heart dilation may result in irreversible left ventricular dysfunction if referral is delayed until symptoms develop.
- Medical treatment for heart failure, but patients who are unwell enough to require this may be more appropriately treated by mitral valve repair or mitral valve replacement with a mechanical valve or bioprosthesis, if possible locally.

#### Mitral stenosis

##### Features

- Mild stenosis does not cause symptoms, moderate stenosis causes shortness of breath on exertion, and severe stenosis causes easy fatigue, shortness of breath at rest, orthopnoea (shortness of breath on lying down), paroxysmal nocturnal dyspnoea and haemoptysis.
- There is a low-frequency mid-diastolic murmur that is maximal at the apex, accentuated by exercise.
- There is a loud first heart sound and diastolic opening snap.
- The murmur becomes longer as the severity of stenosis increases.
- In severe cases, there are signs of pulmonary hypertension.
- Chest X-ray and ECG show left atrial enlargement when there is moderate mitral stenosis, and chest X-ray shows pulmonary oedema when stenosis is severe.

##### Management

- Symptoms are treated with diuretics and a low-sodium diet. Digoxin is indicated only in rare cases where there is atrial fibrillation secondary to left atrial enlargement.
- Symptomatic patients and those with pulmonary hypertension should be referred for cardiology review (if available), as surgery is often necessary (open or closed mitral commissurotomy, mitral valve replacement and percutaneous catheter balloon mitral commissurotomy).

#### Aortic regurgitation

- This is less common than mitral regurgitation, and frequently occurs in combination with mitral valve disease.
- Symptoms occur when left ventricular dysfunction develops secondary to chronic left ventricular volume overload.
- Once the symptoms have appeared, deterioration is often rapid.
- Symptoms include exercise intolerance, shortness of

breath on exertion, orthopnoea (shortness of breath on lying down), paroxysmal nocturnal dyspnoea, haemoptysis and chest pain.

- Examination reveals a blowing decrescendo early diastolic murmur that is maximal at the mid to lower left sternal border. The murmur is loudest when sitting forward with the breath held in expiration.

#### Signs of moderate to severe aortic regurgitation

- The murmur lengthens and may be present throughout diastole.
- Hyperdynamic apex.
- Apical impulse displaced laterally and inferiorly.
- Wide pulse pressure.
- Collapsing pulses.
- Basal crepitations.
- Visible pulsations in the suprasternal notch and neck vessels.
- Systolic murmur at the upper right sternal border (from increased aortic valve flow).

#### Management

- Cardiology assessment, as surgery may be necessary (if available). Marked cardiomegaly on chest X-ray or multiple ventricular ectopics on the ECG should prompt referral.
- An echocardiogram is needed at least annually (if available), as it is important to assess left ventricular dilation and function to ensure that surgery is performed before irreversible left ventricular dysfunction develops.
- Exercise tolerance may be improved by medical treatment for heart failure.

- Surgical options include aortic valve reconstruction, aortic valve replacement with an aortic homograft or mechanical valve, and transferring the patient's own pulmonary valve to the aortic position (Ross procedure).

#### Aortic stenosis

The two commonest causes of aortic valve stenosis are progressive wear of a congenital bicuspid aortic valve and rheumatic fever (the most common cause in developing countries, and usually also with aortic regurgitation).

#### Clinical features

- Chest pain (angina from inadequate coronary artery perfusion).
- Fainting, usually with exertion or excitement.
- Shortness of breath due to heart failure.
- Sudden death.
- On examination, delayed upstroke and reduced magnitude of the carotid pulse and an ejection systolic heart murmur.
- The ECG shows left ventricular hypertrophy and sometimes ST changes of myocardial ischaemia.
- The chest X-ray shows a normal sized heart, dilated aortic root and pulmonary venous congestion. Sometimes there is calcification of the aortic valve.

#### Management

- Avoid strenuous exercise.
- Avoid endocarditis.
- Refer for a specialist opinion if possible.
- Diuretics can be helpful, but surgery is usually required.

## 2.7.B Asthma

### BOX 2.7.B.1 Minimum standards

- Oxygen.
- Salbutamol by metered-dose inhaler and nebuliser.
- Aminophylline.
- Magnesium sulphate.
- Adrenaline.
- Prednisolone/hydrocortisone.

#### Assessment

##### Features of severe asthma

- Too breathless to feed or talk.
- Recession/use of accessory muscles.
- Respiratory rate > 40 breaths/minute.
- Pulse rate > 120 beats/minute.

##### Features of life-threatening asthma

- Conscious level depressed/agitated.
- Exhaustion.
- Poor respiratory effort.
- SaO<sub>2</sub> < 85% in air/cyanosis.
- Silent chest.

associated with worsening of the symptoms in one-third of affected mothers.

- A chest X-ray is indicated only if there is severe dyspnoea, uncertainty about the diagnosis, asymmetry of chest signs (possible pneumothorax) or signs of severe infection.
- Transcutaneous PCO<sub>2</sub>, arterial or capillary blood gases (if available) can be helpful in very severe asthma.
- Continuous pulse oximetry is valuable (if available), as hypoxaemia is a major feature of all severe asthma attacks.
- **Do not give prostaglandins other than misoprostol (the latter is safe in pregnancy).** For the prevention and treatment of postpartum haemorrhage, give oxytocin 10 units IM or ergometrine 500 micrograms IM or both (Syntometrine IM).
- **Do not give labetalol for hypertension in patients with asthma.**
- The priority of treatment is to maintain good control of the patient's asthma. This will reduce the likelihood of acute exacerbations which can be life-threatening. In order that control is maintained the following are recommended:
  - It should be emphasised that inhaled salbutamol and steroids are not harmful to the fetus and should be continued in pregnancy.

Asthma complicates 3–4% of pregnancies. Pregnancy is

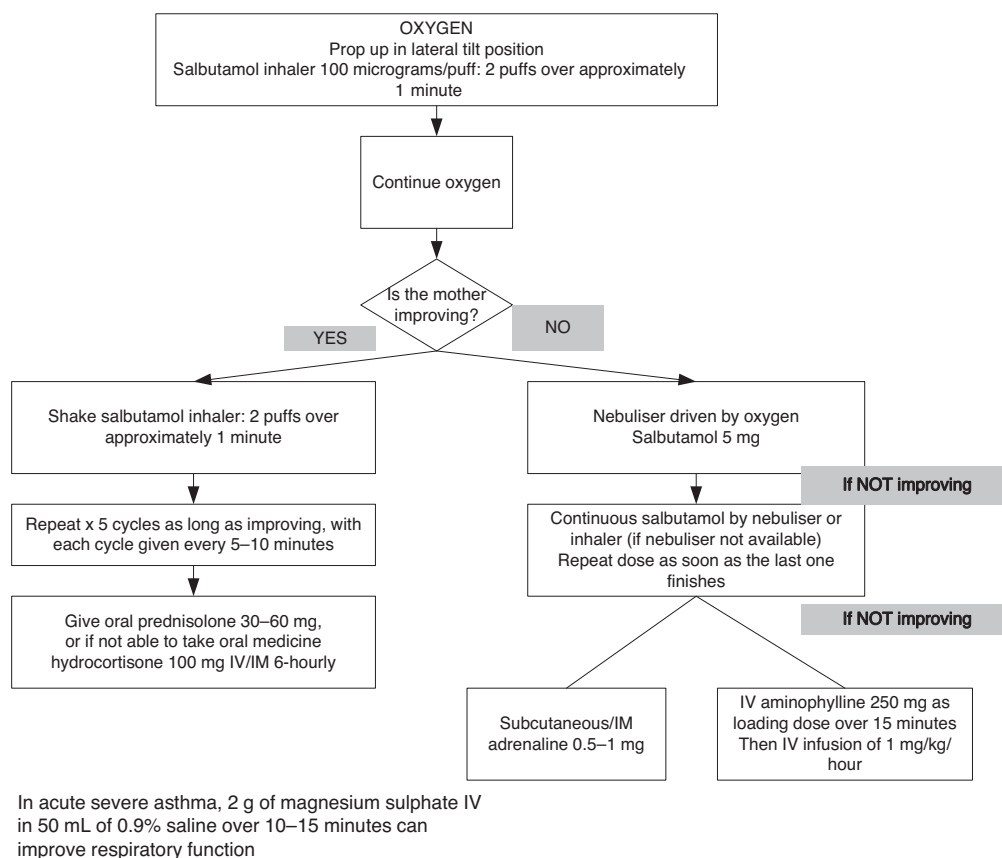

FIGURE 2.7.B.1 Pathway of care for pregnant mother with severe asthma.

- The aim should be for the patient to need her salbutamol inhaler no more than 1–2 times/day. If use in excess of this occurs, the patient should be commenced on inhaled steroids or have her current dose of inhaled steroids increased.
- If the maximum dose of inhaled steroids is reached, then long acting  $B_2$ -agonists and slow release theophylline should be considered if available.
- If not available, or ineffective, oral prednisolone can be added at the lowest dose required to maintain control. Oral prednisolone is associated with an increased risk of infection and gestational diabetes, and complicates control of established diabetes. Its long term use has other potential side-effects for the mother, such as osteoporosis, but it should not be withheld if required to maintain control of maternal disease.

### Emergency treatment of severe asthma

- Assess ABC and resuscitate as needed.
  - Give a high concentration of **oxygen** via a face mask with reservoir bag or nasal cannula. Attach a pulse oximeter and maintain  $SaO_2$  in the range 94–98%.
  - Sit the patient up.
  - Give nebulised salbutamol 5 mg driven with oxygen half-hourly to 4-hourly via a nebuliser (or 10–20 puffs of a beta-2-agonist inhaler, such as salbutamol or terbutaline, giving one puff at a time through a spacer with a mouthpiece or face mask).
  - Give oral prednisolone 30–60 mg, or if the patient is vomiting, IV/IM hydrocortisone 100 mg, followed by 100 mg 6-hourly. (**Note:** steroids will not show benefits for a number of hours.)
- If the patient is not responding, or their condition is deteriorating:
- **Nebulised salbutamol** may be given continuously.
  - In acute severe asthma, 2 g of **magnesium sulphate** IV in 50 mL of Ringer-lactate or Hartmann's solution over 10–15 minutes can produce significant bronchodilatation.
  - As an alternative to magnesium sulphate, and if the patient is not already on oral theophylline or other methylxanthines, give a loading dose of IV **aminophylline** 250 mg over 15 minutes, monitoring the ECG for arrhythmias (if possible), followed by 1 mg/kg/hour by IV infusion.
  - **IV salbutamol** 250 micrograms over 10 minutes is an **alternative** to magnesium sulphate or aminophylline, followed by IV infusion of 1–5 micrograms/kg/minute (but monitoring ECG and checking  $K^+$  levels regularly is necessary; extra potassium may be needed, and monitoring of plasma  $K^+$  levels is essential if this drug is given IV).
  - In severe cases in the absence of other measures, **adrenaline** can be effective. It should be given subcutaneously or IM (dose = 500 micrograms to 1 mg), but may be given IV in life-threatening asthma as follows.
    - Place 1 mg of adrenaline in 10 mL of 0.9% saline and give 1 mL of this solution. Wait for 1 minute and then keep on repeating 1 mL doses IV every minute until the patient improves or the whole 1 mg (10 mL) has

been given. The risk of cardiac side effects (tachycardia, cardiac arrhythmias) is low if adrenaline is given in this way.

- In patients with poor respiratory effort, depressed conscious level and poor oxygenation despite maximum oxygen therapy:
  - Attempt to support ventilation with a bag-valve-mask.
  - Summon experienced support (an anaesthetist) if available, and consider intubation for mechanical ventilation with IV ketamine or halothane induction.

#### Indications for intubation and positive pressure ventilation (if available)

These include the following:

- increasing exhaustion
- progressive deterioration in clinical condition (e.g. a silent chest)
  - oxygenation decreasing and/or oxygen requirement increasing
  - $p\text{CO}_2$  increasing (if measurable from arterial/capillary gas)
- sudden deterioration
- massive atelectasis
- pneumothorax.

If the patient is responding and improving, continue inhaled salbutamol as often as indicated.

#### Other measures

- Reassure the patient, and avoid upsetting them by performing unnecessary invasive procedures.
- Give IV steroids to cover labour/delivery for prevention of Addisonian crisis in patients with a history of taking significant doses of oral steroids in the recent past, especially if long term.
- Restrict IV fluids to two-thirds of the normal requirements.

- Give antibiotics only if there are signs of infection (fever and other signs of pneumonia; chest X-ray may be helpful).
- When the patient has recovered, review their maintenance treatment and inhaler technique.

#### How to give drugs such as aminophylline or magnesium sulphate safely IV without syringe drivers or pumps

- Bolus doses:
  - The safest way to give these is slowly by hand using the syringe.
- IV infusions:
  - Where volume overload is not an issue, the simplest method is to add the drug (e.g. aminophylline) to 500-mL bags of Ringer-lactate or Hartmann's solution or other available/appropriate fluid and run over 12–24 hours.
  - Where volume overload is an issue, a microburette (if available) can be used to give small volumes of IV fluids or drugs safely (see Figure 2.7.B.2). The chamber in the figure holds 100 mL (1 drop/second = 1 mL/minute).

FIGURE 2.7.B.2 Burette for careful infusion.

## 2.7.C Anaphylaxis

### BOX 2.7.C.1 Minimum standards

- Adrenaline.
- Hydrocortisone and prednisolone.
- Nebulised adrenaline.
- Antihistamine.
- Nebulised or inhaled salbutamol.

### Introduction

Anaphylaxis is an allergic reaction to ingested, inhaled or topical substances, which may present as one or more of **stridor**, **shock** or **respiratory distress**. Common causes include allergy to penicillin, to radiographic contrast media, to blood transfusion, to insect bites and to certain foods, especially nuts. Anaphylaxis can occur with any drug.

### Clinical features

Consider the possibility of anaphylaxis in a patient with any of the symptoms and signs listed in Table 2.7.C.1, especially when any of the following are present:

- a history of previous severe reaction
- rapidly progressive or increasingly severe symptoms
- a history of asthma, eczema or rhinitis (atopy)
- current treatment with beta-blockers.

This condition is potentially life-threatening, and may result in a change in conscious level, collapse, and respiratory or cardiac arrest. Some patients carry their own adrenaline.

### Treatment

- Remove or stop the allergen if possible.
- Adrenaline 1 mg is given IM, unless there is intractable shock or cardiac arrest on presentation, in which case give adrenaline IV as follows:
  - Place 1 mg of adrenaline in 10 mL of 0.9% saline and give 0.5–1 mL of this solution. Wait for 1 minute and then keep on repeating 1 mL doses IV every minute until the patient improves or the whole 1 mg (10 mL) has been given.
- IV/IM hydrocortisone, 100–300 mg (if IV by slow injection) or oral prednisolone 40 mg stat.
- Nebulised adrenaline if there is stridor.
- Nebulised salbutamol 5 mg by oxygen driven nebulizer or adrenaline if there is wheezing.
- Antihistamine: chlorphenamine 10–20 mg by slow intravenous injection.
- Intubation and ventilation (if available) will be required for severe cases.

TABLE 2.7.C.1 Anaphylaxis: symptoms and signs

	<b>Mild</b>
Symptoms	Burning sensation in mouth Itching of lips, mouth and throat Feeling of warmth Nausea Abdominal pain
Signs	Urticarial rash Angio-oedema Conjunctivitis
	<b>Moderate</b>
Symptoms	Coughing and/or wheezing Loose bowel movements Sweating Irritability
Signs	Bronchospasm Tachycardia Pallor
	<b>Severe</b>
Symptoms	Difficulty breathing Collapse Vomiting Uncontrolled defecation
Signs	Severe bronchospasm Laryngeal oedema Shock Respiratory arrest Cardiac arrest

**Mild anaphylaxis can lead to moderate and then severe anaphylaxis, and then to death, unless treated.**

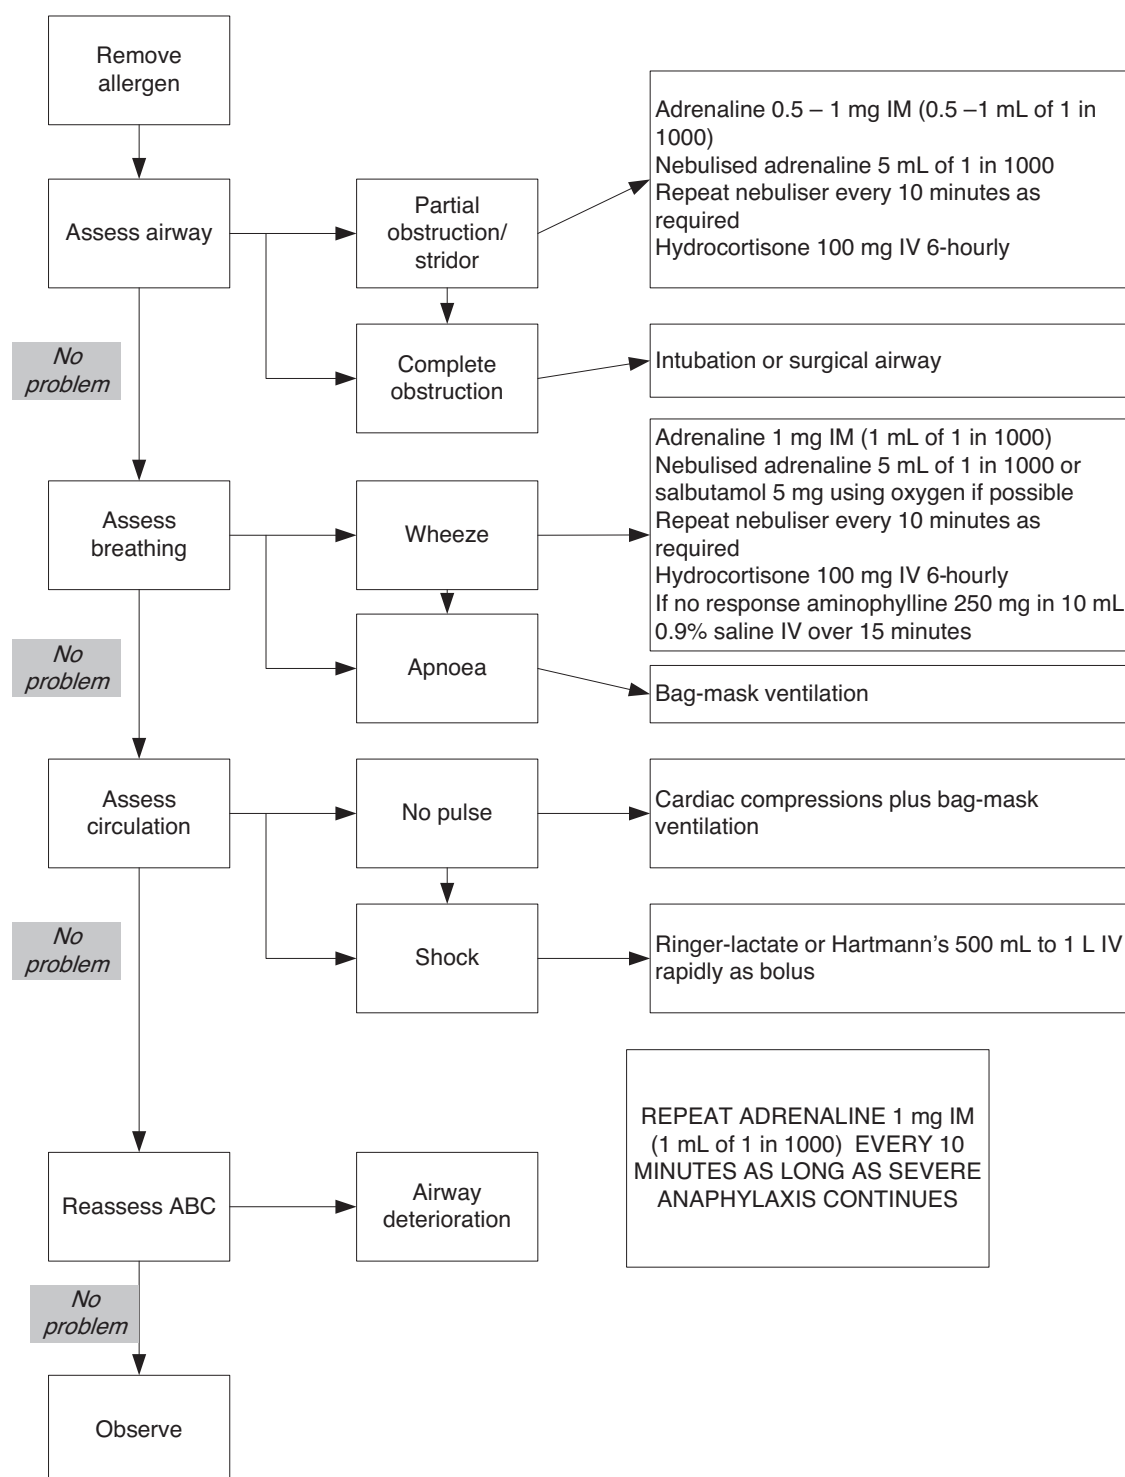

FIGURE 2.7.C.1 Pathway of care for anaphylaxis in pregnancy. ABC, airway, breathing and circulation.

Two children with pneumonia receiving oxygen from one oxygen concentrator; the only one available in a ward of 26 beds.

Two senior midwives in Liberia trained in advanced obstetrics undertaking an emergency Caesarean section.

---

## 2.7.D Diabetes mellitus

### BOX 2.7.D.1 Minimum standards

- Insulin.
- Blood glucose measurements.
- 0.9% saline or Plasma-Lyte 148.
- Oral and IV potassium.
- Mannitol.
- Nasogastric tube.

### Introduction

Diabetes mellitus is associated with increased maternal mortality and morbidity, as well as increased perinatal mortality and morbidity, including congenital malformations. Pregnancy causes changes in the maternal physiology to make it a diabetogenic state. Women who have pre-existing diabetes have an increased insulin requirement in pregnancy. Previously healthy women may develop gestational diabetes. Both type 2 diabetes and gestational diabetes are more common in certain ethnic groups, including South Asians, and are more common in those with a high body mass index (BMI).

Before the discovery of insulin, maternal mortality in diabetics and perinatal mortality in their infants were extremely high. Insulin has led to a dramatic improvement in maternal survival, but in comparison with non-diabetic pregnancy there is still a three- to fivefold increase in perinatal mortality, and an increase in congenital malformations. These risks can be reduced by strict attention to the control of the diabetes both before and during pregnancy.

Diabetes predisposes to pre-eclampsia.

### Management

#### Before pregnancy

- Advise any diabetics of reproductive age about the importance of close monitoring and modified treatment in pregnancy.
- Obesity: give dietary advice.
- Tight control of diabetes: aim for blood glucose levels of less than 7.5 mmol/litre and HbA1c levels within normal limits.
- The mother should take folic acid 5 mg daily if planning pregnancy.

#### In early pregnancy

- Nausea and vomiting are common.
- Hypoglycaemia is common in insulin-treated diabetes. Provide glucagon at home if possible, and explain its use to other household members. Alternatively, counsel the patient to keep sugar-containing foods close by. Inform the patient and others about the signs of hypoglycaemia.
- It is not always necessary to convert mothers treated with oral hypoglycaemic agents to insulin. Metformin is commonly used in these circumstances (initially 500 mg with breakfast for 1 week, then 500 mg twice daily with breakfast and tea, and then 500 mg three times daily with breakfast, lunch and tea).
- As soon as possible, assess the gestational age. Early ultrasound scan can detect anencephaly, but 20 weeks'

gestation is usually the best time to look at the spine and heart if facilities are available.

### During pregnancy

#### Type 1 diabetes (insulin dependent)

Close control of diabetes is needed. Expect insulin requirements to increase by up to 50% above pre-pregnant levels. There is an increased risk of congenital abnormalities, macrosomia, polyhydramnios, preterm labour and pre-eclampsia. Plan delivery with care. The risks of infection and development of diabetic ketoacidosis are high. Signs of hyperglycaemia include a gradual onset of drowsiness and polyuria, dehydration, hypotension, difficulty breathing, and a ketotic smell to the breath. Signs and symptoms of hypoglycaemia may be of rapid onset, leading to unconsciousness, particularly if the mother has taken insulin but has not taken her usual food. Awareness of impending hypoglycaemia in those with type 1 diabetes is often reduced in pregnancy. These patients must be advised about the possible effects on safety during driving.

The insulin requirement often escalates rapidly, especially in the late second and early third trimester, and in order to maintain control of the blood glucose, frequent medical review every 1 to 2 weeks coupled with frequent self-assessment of blood glucose levels, is likely to be required for women with type 1 diabetes.

#### Type 2 diabetes

Women who are diet-controlled before pregnancy require careful monitoring of blood sugar levels in pregnancy, and may need metformin and/or insulin.

### Gestational diabetes

This is often undiagnosed, and should be suspected if any of the following are present:

- a family history of diabetes
- a past history of a large baby, stillbirth or gestational diabetes
- recurrent glycosuria
- a high BMI (overweight)
- a relevant ethnic background.

All women with diabetes should ideally be monitored more regularly in the antenatal clinic for complications such as

### Diagnosis of diabetes with a glucose tolerance test

TABLE 2.7.D.1 Seventy-five-gram oral glucose loading dose results

	Fasting plasma glucose concentration (mmol/litre)	2-hour plasma glucose concentration (mmol/litre)
Diabetes	> 8	> 11
Gestational impaired glucose tolerance	6–8	9–11
Normal	< 6	< 9

pre-eclampsia, polyhydramnios and a large or small for gestational age infant.

### Management of delivery in women with diabetes

For spontaneous labour, induction of labour and elective Caesarean section:

- 1 Measure glucose on admission and hourly during labour.
- 2 Site an IV line with 500 mL of 0.9% saline containing 10% dextrose and potassium chloride 10 mmol, and give at a rate of 60 mL/hour.

Avoid the routine use of insulin in labour in low resource settings because of lack of experience and lack of blood glucose stick tests. In mothers who were using insulin during pregnancy and those where blood glucose is > 7 mmol/litre on two successive occasions one hour apart in labour, the insulin requirements shown in Table 2.7.D.2 below can be used.

**TABLE 2.7.D.2 Insulin requirements**

Blood glucose concentration (mmol/litre)	Hourly subcutaneous injections of insulin
< 2.0	No insulin; dextrose only
2.0–4.0	1 unit
4.1–9.0	2 units
9.1–11.0	3 units
11.1–16.9	4 units

NOTE: for blood glucose, 1 mmol/litre = 18 mg/dL

- If the glucose level is > 17 mmol/litre, expert advice should be sought.
- Aim for a glucose level of 4–9 mmol/litre.
- Reduce insulin by half at delivery, and aim to resume the pre-pregnancy insulin dosage 24 hours after delivery. If the mother is breastfeeding, her insulin requirement may be lower.
- Women who have developed gestational diabetes usually have normal blood glucose levels soon after the delivery of the placenta. Their diabetic medication should be stopped postnatally, and their blood sugar levels should be monitored.
- Mothers who have had gestational diabetes should have a glucose tolerance test at 6 weeks postnatally. They are at risk of developing type 2 diabetes, and appropriate dietary and lifestyle advice should be provided. A fasting blood glucose test annually should also be recommended.

### Diabetic ketoacidosis (DKA)

DKA is the commonest endocrine emergency, and should be suspected in patients with any of the following:

- dehydration
- abdominal pain
- ketone smell on the breath
- acidosis
- acidotic breathing
- unexplained coma.

### Patients die from hypokalaemia and cerebral oedema.

Patients who are 5% dehydrated or less and are not

clinically unwell usually tolerate oral rehydration and subcutaneous insulin.

Patients who are more than 5% dehydrated, or who are vomiting or drowsy or clinically acidotic, need emergency care as follows.

### Primary assessment and resuscitation

#### Airway

- If the airway is not open, use an airway-opening manoeuvre, and consider an airway adjunct such as an oropharyngeal airway or intubation (if available and subsequently supported).
- The nares and oropharynx may need gentle suctioning under direct observation.
- If the patient is unconscious and the airway is unprotected, the recovery position should be adopted to minimise the risk of aspiration of vomit.

#### Breathing

Give a high concentration of oxygen through a face mask with a reservoir, if the airway is adequate.

If breathing is inadequate, ventilate with oxygen via a bag-valve-mask-reservoir device, and ask for experienced senior help to intubate (if this is available and sustainable).

#### Circulation

- Gain IV access using a short wide-bore cannula (14- to 16G).
- External or internal jugular vein access is an option if peripheral access is impossible. Long saphenous vein cut-down may also be considered.
- Take blood for a full blood count, urea and electrolytes, blood culture, cross-matching, glucose stick test and laboratory blood glucose (if available).
- Give a 500-mL rapid IV bolus of 0.9% saline or Plasma-Lyte 148.
- An antibiotic such as cefotaxime 1 gram IV 6-hourly, or the locally available equivalent, is an appropriate antibiotic for those in whom an infection is likely to have precipitated the DKA. Although, of course, antibiotic therapy must be tailored to the specific cause.

#### Diagnosis

- History:
  - polydipsia
  - polyuria
  - weight loss.
- Clinical:
  - acidotic respiration
  - dehydration
  - drowsiness
  - abdominal pain and/or vomiting.
- Biochemical:
  - high blood glucose on finger-prick test
  - ketones and glucose in urine.

### Secondary assessment and emergency treatment

The following in particular need to be assessed.

#### Degree of dehydration

- 3%: dehydration is only just clinically detectable
- 3–5%: dry mucous membranes and reduced skin turgor

- 5–8%: as above, with sunken eyes and poor capillary return
- > 8% with shock: severely ill with poor perfusion, thready rapid pulse and reduced blood pressure.

### Conscious level

- Assess AVPU.
- Institute hourly neurological observations.
- If the patient is less than **Alert** on admission, or their conscious level deteriorates, record the Glasgow Coma Scale score.
- Consider instituting cerebral oedema management (if available).

### Cerebral oedema

Look for irritability, slow pulse, high blood pressure and papilloedema (a late sign).

### Infection

DKA can cause a leucocytosis but not fever. If fever is present, look for and treat infection.

### Ileus

- Insert a nasogastric tube.
- Ensure by clinical assessment, and by abdominal X-ray if appropriate, that there is no other cause of the acute abdomen, including intestinal obstruction.

### Observations

- Strict fluid balance and urine testing of every sample.
- Hourly capillary blood glucose measurements.
- Twice daily weights.
- Initially hourly or more frequent neurological observations.
- Report immediately to medical staff (even at night) symptoms of headache or any change in either conscious level or behaviour.
- Report any changes in the ECG trace, especially T-wave changes (monitoring for hypokalaemia).

### Investigations

- When it is safe to do so, weigh the patient. If this is not possible, use recent clinic weight or an estimated weight.
- Blood glucose.
- Urea and electrolytes (if available).
- Bicarbonate or arterial blood gases (if available).
- Haematocrit and full blood count.
- Blood culture.
- Urine microscopy, culture and sensitivity; check for ketones.
- Monitor the ECG to observe T waves (if available):
  - **hypokalaemia** causes flat T waves
  - **hyperkalaemia** causes peaked T waves.
- Other investigations if indicated (e.g. if fever is present).

### Additional emergency treatment

#### General

- After resuscitation with fluid boluses, calculate the fluid requirement (see below).
- Avoid excessive fluid replacement, as this is a risk factor for cerebral oedema.
- **Do not give hypotonic IV solutions** (e.g. 0.18% saline with 4% glucose, or 5% glucose): they are risk factors for cerebral oedema.
- Continue to give IV fluids until the patient is drinking.

- After fluids are running, calculate the rate of insulin infusion (blood glucose levels will already be falling).
- Use a continuous low-dose IV infusion of insulin (there is no need for an initial bolus), or in resource-limited situations use regular subcutaneous injections of short-acting insulin based on a sliding scale according to blood glucose measurements. Details below.
- Continue to give IV fluids until the patient is tolerating enteral fluids.

### Fluid and electrolyte management

- Calculate the patient's fluid requirement. This is equal to maintenance plus deficit (see Figure 2.7.D.1).
  - Maintenance
  - Deficit (litres) = percentage dehydration × body weight (kg)/100
  - Only plan to correct up to an 8% deficit, as any more risks over-infusion.
- Ignore the volume of fluids used to resuscitate/treat shock.
- Give the total fluid requirement over 24 hours:

Glucose > 12 mmol/litre: give 0.9% saline or Plasma-Lyte 148.

Glucose < 12 mmol/litre: give 0.9% saline or Plasma-Lyte 148 containing 5% dextrose (by adding 100 mL of 50% glucose to 900 mL of 0.9% saline or Plasma-Lyte 148).

Sodium 135–155 mmol/litre: correct by rehydration over 24 hours.

Sodium > 155 mmol/litre: correct by rehydration over 48 hours using 0.9% saline or Plasma-Lyte 148.

Expect the sodium level to rise initially as the glucose level falls and water is removed from the circulation.

If the plasma sodium level initially falls (as well as the glucose level), this may precipitate cerebral oedema.

### Bicarbonate

- **Administration of bicarbonate is rarely, if ever, necessary.**
- Continuing acidosis usually indicates insufficient fluid resuscitation.
- Consider the use of bicarbonate in patients who are profoundly acidotic (pH < 7.0 if measurable) and shocked. Its only purpose is to improve cardiac contractility in severe shock.

The maximum volume of 8.4% sodium bicarbonate for half-correction of acidosis is calculated according to the following formula, and given over 60 minutes:

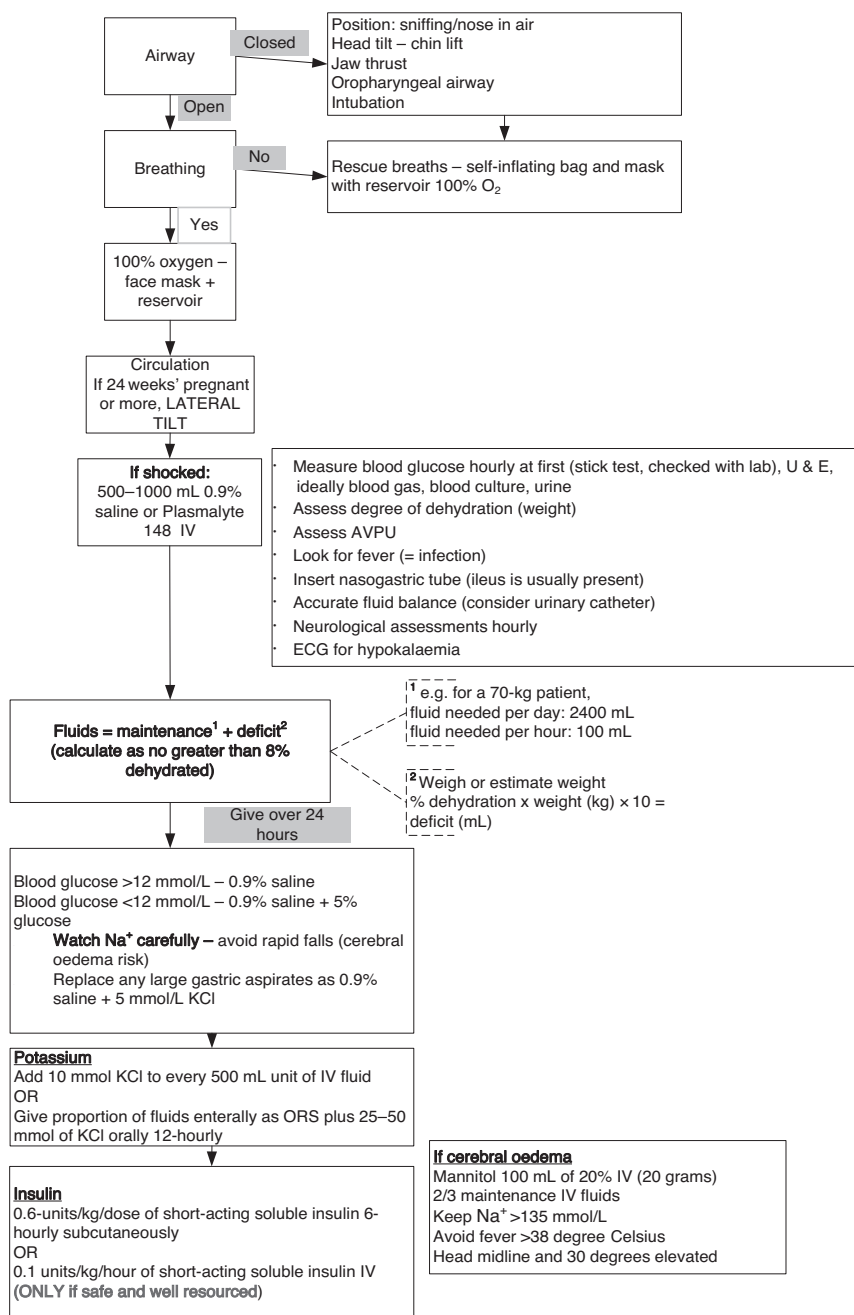

$$\text{Volume (mL 8.4\% NaHCO}_3\text{)} = \frac{\frac{1}{3} \times \text{weight (kg)} \times \text{base deficit (mmol/litre)}}{2}$$

If blood gas analysis cannot be undertaken:

- The kidneys will resolve the acidosis (if they are working) if the patient receives adequate fluid and insulin therapy.
- If you cannot measure pH, then do not give bicarbonate except in extremis.

### Potassium

In diabetic ketoacidosis there is always massive depletion of total body potassium, although initial plasma levels may

**FIGURE 2.7.D.1** Pathway of care for severe diabetic ketoacidosis in pregnancy. AVPU scale: alert, responds to verbal stimulus, responds to pain, unresponsive; ORS, oral rehydration solution.

be low, normal or even high. Levels in the blood will fall once insulin is started.

Do not give potassium if any of the following are present:

- anuria
- peaked T waves on the ECG
- serum potassium level > 7.0 mmol/litre.

If biochemical assessment of the K<sup>+</sup> is not possible, it should be assumed that K<sup>+</sup> replacement is necessary as long as the urine output is adequate, and there are no peaked T-waves present on the ECG (where available).

- In resource-limited settings, hypokalaemia is most safely corrected enterally using ORS with or without

additional oral potassium supplements (aim for a total of 100 mmol/day).

- Potassium rich foods may also be given, e.g. coconut milk and bananas.
- If oral supplementation is not possible or the patient is severely ill: start IV potassium supplements with 20mmol/litre of IV fluid given after the start of initiating therapy with insulin and fluids as long as sufficient urine is being passed at > 30 mL/hour.
- Run the IV infusion (20mmol in 1 litre over 4 to 8 hours (42 to 84 drops per minute (dpm) if using a standard IV giving set with a drop factor of 20). It should not be given at a rate exceeding 20 mmol in 2 hours (126 dpm) as this is dangerous. Given the difficulty in accurately

monitoring transfusion rates without an electronic pump, a large margin of error should be used.

- Stop IV supplementation when the patient can take oral supplements.

### Insulin

In **resource-limited settings**, give subcutaneous doses of short-acting soluble insulin 6-hourly at 0.6 units/kg/dose (i.e. 0.1 units/kg/hour). Give half the dose if the blood sugar level is falling too fast.

Always have an IV glucose solution (10% or 50%) available to treat any hypoglycaemia that develops.

In **well-resourced settings**, make up a solution of 1 unit/mL of human soluble insulin (e.g. Actrapid) by adding 50 units of insulin to 50 mL of 0.9% saline or Plasma-Lyte 148 in a syringe pump. Using a Y-connector, attach this to the IV fluids that are already running. Do not add insulin directly to the fluid bags. The solution should then run at 0.1 units/kg/hour (0.1 mL/kg/hour).

- If the blood glucose level falls by more than 5 mmol/litre/hour, reduce the infusion rate to 0.05 units/kg/hour.
- If the blood glucose level is less than 12 mmol/litre, and a dextrose-containing fluid has been started, consider reducing the insulin infusion rate.
- Do not stop the insulin infusion while dextrose is being infused, as insulin is required to switch off ketone production.
- If the blood glucose level falls below 7 mmol/litre, consider adding extra glucose to the infusion.
- If the blood glucose level rises out of control, re-evaluate the patient for sepsis or another condition.
- Discontinue the insulin infusion 30 minutes after the first subcutaneous injection, to avoid rebound hyperglycaemia.

### Other management

#### Urine output

- Urinary catheterisation may be useful in patients with impaired consciousness.
- Document all fluid input and output.
- Test all urine samples for glucose and ketones.
- If a massive diuresis continues, the fluid input may need to be increased.

#### Gastric aspirate

- If large volumes of gastric aspirate occur, replace these volume for volume with 0.9% saline or Plasma-Lyte 148 plus 5 mmol/litre potassium chloride (KCl).

### Biochemistry

- Check urea and electrolytes, blood pH/bicarbonate (if available), and laboratory blood glucose 2 hours after the start of resuscitation, and then at least 4-hourly.
- Do not expect ketones to have disappeared completely before changing to subcutaneous insulin.

**Never give an IV insulin infusion without a syringe driver. This is not safe. It is better to use a sliding scale of subcutaneous rapid-acting insulin.**

### Cerebral oedema

Cerebral oedema in DKA:

- is unpredictable
- occurs more often in new diabetics
- has a mortality of around 80%.

### Signs and symptoms

These include the following:

- headache
- confusion
- irritability
- reduced conscious level
- fits
- small pupils
- increasing blood pressure
- slowing pulse
- possible respiratory impairment.

### Management

- Exclude hypoglycaemia.
- Give 20 grams of 20% mannitol over 15 minutes **as soon as cerebral oedema is suspected**. Repeat every 4–6 hours.
- Restrict IV fluids to two-thirds maintenance, and replace the deficit over 72 hours rather than 24 hours.
- Arrange for the patient to be intubated. Keep the PaCO<sub>2</sub> in the range 3.5–5.0 kPa (if this is possible and sustainable).
- Keep the sodium (Na<sup>+</sup>) concentration higher than 135 mmol/litre.
- Keep the head in the midline and 30-degrees elevated.

If there is a fever, treat it actively with environmental measures, or with paracetamol, if more than 38.0°C.

## 2.7.E Reduced consciousness and coma

### Introduction

In resource-limited countries, severe pre-eclampsia, eclampsia, malaria, meningitis (including TB), HIV infection, head injury and drug ingestion are the most common causes of reduced conscious level and coma in pregnancy.

### Pathophysiology

Raised intracranial pressure (RICP) is an important component of the most severe cases. This can occur gradually

or rapidly (e.g. due to intracranial bleeding or cerebral oedema). The initial physiological compensating mechanisms include a reduction in the volume of cerebrospinal fluid and in the volume of venous blood within the cranium. However, when these fail, the cerebral perfusion pressure (CPP) falls and arterial blood flow to the brain is reduced.

Cerebral perfusion pressure (CPP) = mean arterial pressure (MAP) – intracranial pressure (ICP).

A severely increased pressure within the skull will

cause pressure effects which are classically recognised in two main sites where brain tissue is pushed against the bone:

- 1 **Central syndrome:** cerebellar tonsils herniate through the foramen magnum. This is known as **coning**. The syndrome consists of slowing pulse, rising blood pressure and irregular respiration.
- 2 **Uncal syndrome:** the uncus (part of the hippocampal gyrus) is pushed through the tentorium. It may be unilateral. This leads to third cranial nerve compression and ipsilateral dilated pupil, followed by oculomotor palsy and failure of lateral gaze. Later effects include hemiplegia.

**Raised intracranial pressure (RICP)**

In a patient with impaired conscious level or with a Glasgow Coma Scale score of < 9, who was previously well and is not post-ictal, the following signs indicate raised ICP:

Absolute signs of raised ICP:	
Papilloedema	
Absence of pulsation of retinal vessels	

Signs suggesting raised ICP:	
Abnormal oculo-cephalic reflexes <b>Do not test patients with neck injuries in this way</b>	(a) Rotation of the head to the left or right normally causes the eyes to move in the opposite direction; abnormal if there is no response or a random response (b) Flexure of neck usually causes eye gaze deviation upwards; abnormal if there is loss of this reflex
Abnormal posture May need to be elicited by a painful stimulus	(a) Decorticate: arms flexed, legs extended (b) Decerebrate: arms extended, legs extended (see Figure 5.16.A.3)
Abnormal pupillary responses	Unilateral or bilateral suggests raised ICP
Abnormal breathing patterns	Ranges from hyperventilation to Cheyne–Stokes breathing to apnoea
Cushing’s triad	Slow pulse, raised blood pressure and abnormal pattern of breathing – a late sign of raised ICP

**Primary assessment and resuscitation ABC**

**Call for help. Ideally an anaesthetist should be present to manage the airway and support breathing.**

The first steps in the management of the patient with decreased conscious level are to assess and if necessary support airway, breathing and circulation.

**Airway**

The patient with a reduced level of consciousness is more likely to have a compromised airway as the tongue falls into the back of the mouth. There is also a risk of aspiration.

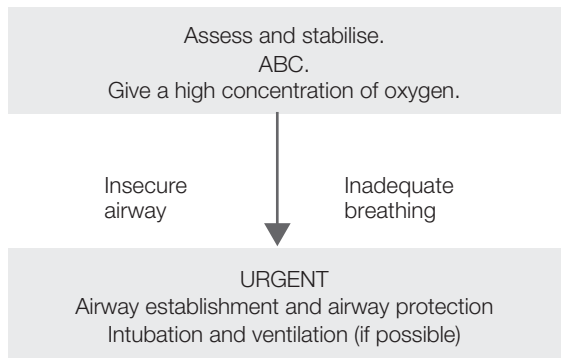

**Look, listen and feel**

Assess the airway, open it if closed and keep it open, either by assigning someone to continue airway-opening

**FIGURE 2.7.E.1** The semi-prone or recovery position.

manoeuvres or by using adjuncts such as an oropharyngeal airway (see Section 1.13). Never use such an airway if the patient is conscious enough to have a gag reflex, as it may worsen airway obstruction and cause vomiting. Give oxygen at a rate of 15 litre/minute or as high a flow rate as is available, via a tight-fitting face mask with a reservoir bag. If an anaesthetist is present, intubation can be performed to protect the airway; otherwise adopt the recovery position (see Figure 2.7.E.1). Careful suction of the nose and/or mouth may be helpful.

The patient will require support if:

- breathing is insufficient
- gag or cough reflex is absent
- GCS score is < 9, or AVPU score is P or U
- there is impending herniation due to raised ICP
- there is evidence of effects of inadequate breathing on other systems.

If the airway is adequate, give high concentration O<sub>2</sub> and support breathing if required.

**Breathing**

Assess the breathing for depth and frequency, and give high-flow oxygen via a face mask and reservoir bag. If breathing is absent or inadequate (gasping or agonal breaths only), provide assisted ventilation using a bag-valve-mask with a reservoir and oxygen.

Inadequate airway and breathing in coma can lead to a rise in arterial pCO<sub>2</sub> that can cause a dangerous rise in intracranial pressure.

**Circulation**

Inadequate perfusion of blood to the brain initially produces confusion and later causes coma. Measurement of the blood pressure in addition to other markers for shock is

crucial in recognising hypovolaemia after haemorrhage, or unconsciousness after an eclamptic fit with hypertension.

If the intracranial pressure is high, cerebral perfusion will be compromised if hypotension occurs. However, excessive fluid administration should be avoided.

- Establish IV access quickly.
- Take blood samples and send them to the lab for a full blood count, blood smear for malarial parasites, electrolytes, liver function tests, blood glucose and blood culture.

### Neurological failure

Assess neurological failure as follows:

- Use the AVPU scale.
- Check blood glucose levels: **If the blood sugar level is low or suspected to be low (< 2.5 mmol/litre or < 45 mg/dL),** give 100 mL of 25% glucose IV over 15 minutes (dilute 50 mL of 50% glucose with 50 mL of Ringer-lactate or Hartmann's solution) and then give 10% dextrose in Ringer-lactate or Hartmann's solution over 4 hours (add 100 mL of 50% glucose to each 400 mL of Ringer-lactate or Hartmann's solution infused).
- Check the pupils for **signs suggesting raised intracranial pressure (RICP) or opiate overdose.**
- Check for **neck stiffness** which may suggest meningitis.
- Look for other signs of raised intracranial pressure, as outlined above.

Further assessment of conscious level can be aided by the Glasgow Coma Scale score and documentation of pupil function.

**TABLE 2.7.E.1 Glasgow Coma Scale (GCS)**

Response	Score
<i>Eye opening</i>	
Spontaneously	4
To verbal stimuli	3
To pain	2
No response to pain	1
<i>Best motor response</i>	
Obeys verbal command	6
Localises to pain	5
Withdraws from pain	4
Abnormal flexion to pain (decorticate)	3
Abnormal extension to pain (decerebrate)	2
No response to pain	1
<i>Best verbal response</i>	
Orientated and converses	5
Disorientated and converses	4
Inappropriate words	3
Incomprehensible sounds	2
No response to pain	1
<i>Total</i>	

**A GCS score of < 9 is likely to need airway protection by intubation if skills are available to undertake this safely.**

**TABLE 2.7.E.2 Pupillary changes**

Pupil size and reactivity	Causes
Small reactive pupils	Metabolic disorders Medullary lesion
Pinpoint pupil	Metabolic disorders Narcotic/organophosphate ingestion
Fixed mid-sized pupils	Midbrain lesion
Fixed dilated pupils	Hypothermia Severe hypoxaemic/ischaemic brain injury Barbiturate ingestion (late sign) During and post seizure Anticholinergic drugs
Unilateral dilated pupil	Rapidly expanding ipsilateral lesion Tentorial herniation Third cranial nerve lesion Epileptic seizures

### Secondary assessment and emergency treatment

Secondary assessment occurs after stabilisation of ABCD. During secondary assessment, continue to monitor the patient, and if there is any change, reassess ABC and treat any residual problems.

### Diagnostic pointers

As soon as possible during resuscitation, gain as much information about the history as possible:

- the possibility of eclampsia, which means that magnesium sulphate may be required
- recent trauma
- endemic area for infections such as malaria, sleeping sickness and encephalitis
- pre-existing neurological problem
- past history of epilepsy
- ingestion of poisons
- underlying chronic condition (renal, cardiac, diabetes).

Remember to treat the treatable components. The cause of coma may not be certain, so it is always important to address ABC. If the patient's condition is unstable or deteriorating, return to ABC.

**Always consider the possibility of eclampsia and the need for magnesium sulphate.**

**If there is no other clear cause for the coma** treat with antibiotics for presumed meningitis (usually a third-generation cephalosporin, or whatever is locally available and appropriate), and in endemic areas, also treat as for cerebral malaria (see Section 2.8.D).

Take the patient's temperature (core and peripheral).

- **Fever** may be associated with sepsis (but lack of fever does not exclude sepsis) or poisoning (ecstasy, cocaine or salicylates).
- **Hypothermia** is found in poisoning with ethanol or barbiturates.

Rash: **purpura** suggests meningococcal disease; **bruises** suggest trauma (consider domestic violence).

Evidence of **poisoning**, ingestion or drug use: smell, residue around nose/mouth, needle tracks.

### Other issues in addition to ABC regarding the management of coma

The prognosis depends on the cause of coma and the state of the patient, in particular the level of consciousness on admission, and the initial response to appropriate interventions. The presumptive cause of coma guides the treatment. Consider the following interventions:

- Assess and **maintain electrolyte balance** (avoid **hyponatraemia**; use Ringer-lactate or Hartmann's solution plus added 5% glucose, **not 1/5 N dextrose saline**. Add 50 mL of 50% glucose to each 450 mL of Ringer-lactate or Hartmann's solution infused). If possible keep the serum sodium level in the normal range (135–145 mmol/litre).
- Treat seizures if present, and give prophylactic **anticonvulsants** if the patient has repeated seizures.
- Insert a **nasogastric tube** to aspirate the stomach contents. Perform gastric lavage in circumstances such as drug ingestion.
- Regulate the body temperature, and **avoid hyperthermia** (i.e. temperatures above 37.5°C).
- Undertake appropriate medical management of **RICP**, if noted:
  - Support ventilation (maintain a  $p\text{CO}_2$  of 3.5–5.0 kPa, if measurable).
  - Give mannitol, 20 grams of 20% mannitol IV over 15 minutes, 2-hourly as required, provided that the serum osmolality is not greater than 325 mOsm/litre (if measurable).
  - Give dexamethasone (for oedema surrounding a space-occupying lesion) 10 mg initially IV, then 4 mg IV 6-hourly for 48 hours.
- **Catheterisation** is needed for bladder care and output monitoring, as well as for avoidance of retention, which can worsen RICP.
- Plan for continued **regular clinical assessment**, mainly nursing observations.
- **Prevent the patient from falling out of the bed.**
- **Provide nutritional support:** parenteral and/or oral feeding to prevent malnutrition during the period of unconsciousness.
- **Skin care:** prevent bed sores by turning the patient.
- **Eye padding:** to avoid xerophthalmia.
- Family **counselling, support and consent** in the case of invasive procedures.
- Appropriate surgical intervention if indicated.
- **Chest physiotherapy** to avoid hypostatic pneumonia.
- Restrict fluids to 60% of maintenance if evidence of water retention is seen.
- Prevent **deep vein thrombosis** by physiotherapy.
- Maintain **oral and dental hygiene**.
- Give appropriate care for central and peripheral venous access to **avoid infection** by maintaining sterility when handling the sites.
- Prevent hospital-acquired infection.

### Reassessment

When the patient is stable, undertake a full examination of systems and neurological examination.

- Skin: rash, bruising, haemorrhage, neurocutaneous stigmata.

- Scalp: trauma.
- Ears/nose: discharge (blood, serous fluid, infection).
- Neck: tenderness, stiffness/rigidity.
- Odour: poisoning, ingestion, metabolic disorders.
- Abdomen: liver, spleen.
- Eyes: pupils, fundi (papilloedema, retinal haemorrhages, sub-conjunctival haemorrhages), movements.

Also assess the following:

- AVPU and Glasgow Coma Scale scores: re-evaluate regularly.
- Posture/tone: lateralisation.
- Deep tendon reflexes: lateralisation.
- If there are lateralising signs, and if the patient is stable enough, consider a CT scan (if available).

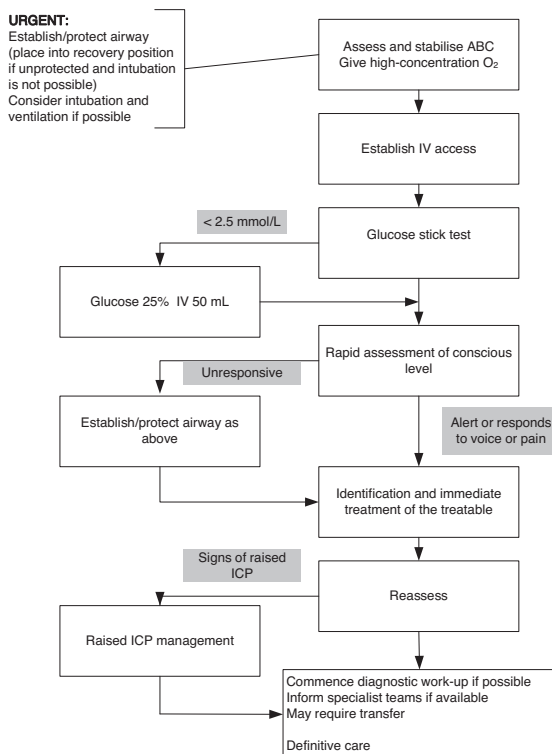

The CT scan may show cerebral oedema, haemorrhages, or hypoxic/ischaemic encephalopathy.

## Specific topics in coma

### Meningitis or encephalitis

The following organisms cause meningitis:

- *Neisseria meningitidis*:
  - risk of mortality (> 5%) and permanent serious neurological sequelae.
- *Haemophilus pneumoniae*:
  - less common where routine Hib vaccination is available.
- *Streptococcus pneumoniae*:
  - common in resource-limited countries
  - occurs with underlying immune compromise, especially HIV infection

**FIGURE 2.7.E.2** Pathway of care in coma. ABC, airway, breathing and circulation; ICP, intracranial pressure.

- may follow a head injury if there is damage to the dura and/or meninges.

There is a risk of coning and death if a diagnostic lumbar puncture is performed in a patient with significantly raised intracranial pressure.

#### **Diagnosis of meningitis or encephalitis**

Classic signs and symptoms include the following:

- headache

- vomiting
- neck stiffness
- opisthotonus
- photophobia
- rash
- altered consciousness.

Poisoning (see Section 7.4).

Malaria in pregnancy (see Section 2.8.D).

Eclamptic coma (see Section 2.5.E).

## 2.8

## Infections complicating pregnancy, delivery and after birth

### 2.8.A Pneumonia

#### **BOX 2.8.A.1 Minimum standards**

- Oxygen.
- Antibiotics (IV and oral).
- Chest X-ray.

#### **Clinical findings**

A high fever is usually associated with pneumonia and bacterial tracheitis. In the absence of stridor and wheeze, breathing difficulties in association with a significant fever are likely to be due to **pneumonia**.

Examination of the chest may show reduced air entry, bronchial breathing and crepitations. Pleuritic chest pain, neck stiffness and abdominal pain may be present if there is pleural inflammation. Pleural effusions and empyema are complications.

Always consider HIV infection and TB.

#### **Emergency treatment of pneumonia**

- Assess ABC.
- Give oxygen through nasal cannulae or mask depending on flow rate required to maintain saturation (if available) as below.
- Attach a pulse oximeter (if available).
- Maintain SaO<sub>2</sub> in the range 94–98%, with nasal cannulae at a flow rate usually up to 5 litres/minute or if necessary by face mask with higher flow rates.

- Give antibiotics for 7 days:
  - ampicillin 2 grams IV/IM 6-hourly *plus* gentamicin 80 mg IV/IM 8-hourly or 5 mg/kg IV/IM every 24 hours for most cases of community-acquired pneumonia
  - cefuroxime 500 mg IV/IM 8-hourly or flucloxacillin 500 mg IM or IV slowly every 6 hours for suspected or bacteriologically diagnosed *Staphylococcus aureus*
  - erythromycin 500 mg every 6 hours orally for *Chlamydia* or *Mycoplasma pneumoniae*
  - or whatever is available locally and appropriate.
- Sit the patient upright.
- Maintain hydration.
  - Extra fluid may be needed to compensate for fluid loss from fever.
  - Fluid restriction may be needed because of inappropriate ADH secretion, revealed by oliguria < 30 mL per hour or rising blood urea levels.
- Chest X-ray is indicated.
- Large pleural effusions/empyemas should be diagnosed where possible by ultrasound, and pleural drainage undertaken under ultrasound cover (do not place a chest drain into the heart, liver or an undiagnosed tumour or hydatid cyst) (see Section 8.3). **Remember that in advanced pregnancy the diaphragm is elevated.**
  - Effusions/empyemas adjacent to the heart on the left side may cause pericarditis and cardiac arrhythmias. (Listen regularly for a pericardial rub, and ideally monitor an ECG if available until the patient is stable.)

## 2.8.B Severe dehydration and gastroenteritis

**BOX 2.8.B.1 Minimum standards**

- IV fluids containing appropriate amounts of sodium.
- Low-osmolarity oral rehydration solution (ORS).
- Nasogastric tubes.
- Urea and electrolyte measurements.
- Accurate weighing scales.

### Introduction

Dehydration is loss of water, sodium and other essential electrolytes from the body. It causes death as a result of **shock** and **electrolyte emergencies** (see Section 2.5.A). Dehydration is a common cause of hospital admission, most commonly due to **acute gastroenteritis** and **diabetic ketoacidosis** (see Section 2.7.D).

A rapid clinical assessment (with support from biochemical tests, if **rapidly** available) in the very sick is the

basis for treatment. The majority of patients can be treated with low-osmolarity oral rehydration solution (ORS) (by mouth or by nasogastric tube).

In patients with coincidental severe malnutrition, it is safer to use ORS with a lower sodium content, such as ReSoMal.

### Classification of dehydration

Dehydration is classified according to clinical criteria. This may not apply in **severe malnutrition**, where caution is needed as signs may overlap and be misleading (see Section 5.10.B).

### No dehydration (< 3% weight loss)

There are no clinical signs with this degree of dehydration, although there will be thirst in the fully conscious patient. The woman or girl who is not fully conscious will not feel thirsty.

FIGURE 2.8.B.1 Pathway of care for gastroenteritis with severe dehydration (10% or more). ORS, oral rehydration solution.

**Some dehydration (3–9% weight loss)**

The following clinical signs are seen:

- increased thirst
- dry mucous membranes
- loss of skin turgor, tenting when pinched
- sunken eyes
- restless or irritable behaviour.

**Severe dehydration ( $\geq 10\%$  weight loss)**

The following clinical signs are seen:

- more pronounced effects of the signs seen in moderate dehydration
- lack of urine output
- hypovolaemic shock, including:
  - rapid and feeble pulse (radial pulse may be undetectable)
  - low or undetectable blood pressure
  - cool and poorly perfused extremities
  - decreased capillary refill time ( $> 3$  seconds): test this on the sternum of patients with light skins and on the thumbnail of those with dark skins
  - peripheral cyanosis
- rapid deep breathing (from acidosis)
- altered level of consciousness or coma.

**Emergency treatment of severe dehydration**

- Treat **shock** with an initial bolus of 1000 mL of Ringer-lactate or Hartmann's solution (see Section 2.5.A).
- Decide on the cause (e.g. acute gastroenteritis, diabetic ketoacidosis).
- Classify the extent of dehydration (see above).
- Calculate the **fluid deficit** (see below), add this to the maintenance and ongoing losses and give over 24 hours.
- The major danger in rehydration (once shock has been treated) is causing the plasma sodium level to fall rapidly. This may increase the transfer of water into the brain and result in **cerebral oedema**.
- Before the electrolyte results are known, or if such testing is not available, the safest fluid to give is Ringer-lactate or Hartmann's solution.

**If the serum sodium level is higher than 155 mmol/litre, aim to lower it slowly over 48 hours or longer.**

**Calculating fluid requirements****Deficit**

If an accurate recent pre-illness weight is available, subtract the current weight to estimate lost fluid (1 kg = 1 litre of fluid).

For example, a mother who weighed 70 kg is seen with diarrhoea and a weight of 65 kg.

In this case the estimated fluid loss is  $(70 - 65) \text{ kg} = 5 \text{ kg}$  = 5000 mL deficit (i.e. 7% dehydrated).

If no recent weight is available, or the weight value given is considered to be unreliable:

- Decide the degree of dehydration.
- Weigh the patient.
- Use the formula: **percentage dehydration  $\times$  weight (kg)  $\times 10 =$  deficit (in mL).**

For example, a mother whose weight is estimated to be 70 kg is 8% dehydrated.

In this case the estimated fluid loss is  $8 \times 70 \times 10 = 5600 \text{ mL}$  (233 mL/hour if replaced over 24 hours).

**Maintenance**

Estimated maintenance fluid requirements are **2400 mL/day** and **100 mL/hour**.

**Ongoing losses**

- **For each diarrhoeal stool:** 500 mL of ORS after each stool.
- **For each vomit:** 200 mL of ORS after each vomit. Give small frequent volumes (e.g. 20 mL every minute) with a spoon or syringe or cup.

**Add deficit to maintenance and ongoing losses and aim to replace these over 24 hours.**

For example, for a 70 kg mother who is 8% dehydrated, maintenance is 100 mL/hour, if there are no ongoing losses.

Total fluids needed per hour = 233 mL/hour (deficit) + 100 mL/hour (maintenance) = 333 mL/hour.

**Severe acute gastroenteritis in pregnancy**

Gastroenteritis is a common cause of dehydration and shock. Management starts with ABC, followed by assessment of the fluid deficit (extent of dehydration) and ongoing losses of fluid. Weigh the patient and keep an accurate fluid balance chart.

It is important to give fluids that:

- correct the deficit
- provide maintenance
- replace ongoing losses.

**Differential diagnosis**

Look for an abdominal mass or abdominal distension.

Consider the following:

- HIV infections
- surgical conditions, such as acute appendicitis, peritonitis or bowel obstruction (if suspected, resuscitate and call for surgical opinion)
- typhoid (high-grade fever, rash, hepatosplenomegaly and toxicity)
- antibiotic-associated colitis
- (rarely) inflammatory bowel disease.

**Treatment if not shocked**

- Start low-osmolarity oral rehydration solution (ORS) with 1–2 litres over 2–4 hours.
- The carer should give small amounts of ORS (e.g. using a small cup) frequently.
- Gradually increase the amount as tolerated, using a tablespoon, cup or glass.
- After 12–24 hours, review progress with regard to rehydration and progress to the maintenance phase or continue rehydration.

**Severe dehydration ( $\geq 10\%$  fluid deficit with or without clinical signs of shock)**

- If the patient is shocked, assess and manage ABC, give oxygen if available, and start IV fluids immediately (use two intravenous lines if possible: use long saphenous vein cut-down or the external jugular vein if venous access is difficult).

- Give a 500 mL or 1-litre bolus of Ringer-lactate or Hartmann's solution IV as rapidly as possible.
- Reassess pulse, perfusion (capillary refill time) and mental status, and repeat the bolus if these are still abnormal.
- **Do not use low-sodium-containing IV fluids such as 0.18% saline with 4% glucose, which can be dangerous (they can cause hyponatraemia and cerebral oedema).** Instead use Ringer-lactate or Hartmann's solution, ideally also containing 10% glucose (obtained by adding 100 mL of 50% glucose to each 500 mL).
- **Hypokalaemia is a major complication which needs urgent attention.** Ideally measure serum K<sup>+</sup> levels frequently. Provided that the patient is passing urine and IV potassium can safely be given, it should be added to the IV fluids given subsequent to the boluses given to treat shock. Ideally and if tolerated, potassium should be corrected by giving low osmolarity ORS enterally as soon as possible.

If it is necessary to add potassium to IV fluids given to correct dehydration, particularly if diarrhea is continuing and if measured serum K<sup>+</sup> is < 2.0 mmol/litre or there are ECG signs of hypokalaemia, namely ST depression, T-wave reduction and prominent U waves, and only if safe to do so, great care must be taken.

In acute depletion, an infusion at the rate of 0.1 to 0.2 mmol/kg/hour (6 to 12 mmol/hour for a woman weighing 60 kg) of IV potassium can be used and the serum K<sup>+</sup> level checked after 3 hours. The potassium for injection **must** be diluted before use and thoroughly mixed before being given. **The maximum concentration of potassium that can be given through a peripheral vein is 40 mmol/litre. The maximum infusion rate of potassium is 0.5 mmol/kg/hour.** Remember that Ringer-lactate or Hartmann's solution both already contain 5 mmol/litre of potassium.

**Note:** The injectable form of KCl usually contains 1.5 grams (i.e. 20 mmol of potassium in 10 mL), and can be given orally. The daily potassium requirement is 1–2.5 mmol/kg.

When shock has resolved, and the patient's level of consciousness has returned to normal, the remaining estimated deficit **must be taken by mouth or by gastric tube**, especially if **severe malnutrition** and/or **anaemia** is present (giving large fluid volumes IV can precipitate heart failure).

**Assess the patient's hydration status frequently.**

### Oral fluids

Recommendations for oral replacement therapy in gastroenteritis are as follows:

- Give low-osmolarity ORS (containing 75 mmol/litre of sodium) *or*, if the latter is unavailable, ORS containing 90 mmol/litre of sodium with an additional source of low-sodium fluid (e.g. water).
- The amount given should be in the range 300–500 mL/hour.
- Giving high-osmolarity fluids may contribute to hypernatraemia, whereas giving water alone, or low-salt drinks, may cause hyponatraemia.
- Oral glucose within ORS enhances electrolyte and water uptake in the gut.
- 'Home-made' ORS can be prepared by adding a pinch of salt (1 mL) and a handful of sugar (5 mL) to a glass of clean potable water (250 mL).

### Intravenous fluids

- Even in patients who are drinking poorly, try to give enteral fluids by mouth or by gastric tube until the IV infusion is running.
- Use Ringer-lactate or Hartmann's solution, which contains Na<sup>+</sup> 131 mmol/litre, K<sup>+</sup> 5 mmol/litre, HCO<sub>3</sub><sup>-</sup> 29 mmol/litre and Ca<sup>2+</sup> 2 mmol/litre.
- Hartmann's solution has no glucose to prevent hypoglycaemia. This can be corrected by adding 100 mL of 50% glucose to 500 mL of Ringer-lactate or Hartmann's, giving approximately a 10% glucose solution (adding 50 mL to 450 mL of Ringer-lactate or Hartmann's gives a 5% solution).
- Ringer-lactate or Hartmann's solution with 5% dextrose added has the advantage of providing glucose to help to prevent hypoglycaemia.
- See above regarding potassium supplementation.
- **It is dangerous to use plain 5% glucose solutions, or 0.18% saline plus 4% glucose. They do not contain adequate electrolytes, do not correct the acidosis or hypovolaemia, and can cause dangerous hyponatraemia.**
- All patients should start to receive some ORS (at the rate of about 300 mL/hour) when they can drink without difficulty, which is usually within 1–2 hours. This provides additional base and potassium, which may not be adequately supplied by the IV fluid. Alternatively, give as soon as possible by gastric tube.

### Over-hydration

Signs of over-hydration include the following:

- oedematous eyelids and generalised oedema, particularly ankle, facial and sacral oedema
- cardiac failure, especially in severe malnutrition or protein-losing enteropathy.
  - respiratory distress (raised rate and some chest wall recession)
  - tachycardia out of proportion to respiratory difficulty
  - raised jugular venous pressure
  - gallop rhythm/murmur
  - enlarged liver
  - basal lung crepitations.

A chest X-ray may be helpful for showing pulmonary plethora or oedema.

### Management of over-hydration

- Stop giving ORS, but give plain water and food.
- Do not give a diuretic unless the patient is in cardiac failure.

When the oedema has resolved, resume giving ORS.

#### Reassess the following:

- ABC
- circulatory and hydration status
- plasma electrolytes if possible
- urine output and urine electrolytes
- give fluid according to plan; do not forget ongoing losses
- reassess regularly (including biochemistry if possible)
- do not forget glucose.

## 2.8.C HIV/AIDS

### BOX 2.8.C.1 Minimum standards

- Prevention of mother-to-child transmission (PMTCT).
- Antiretroviral therapy (ART) for HIV-infected women.
- Health education and community support.

### Introduction

Prevention of mother-to-child transmission (PMTCT) of the human immunodeficiency virus (HIV) is possible, even in resource-limited settings, and the World Health Organization guidance (*Recommendations for a Public Health Approach*) published in 2010 on antiretroviral drugs for treating pregnant women and preventing HIV infection in infants suggests that elimination of mother-to-child transmission of HIV (MTCT) is a realistic public health goal.

Since the previous WHO guidance was published in 2006, new evidence has emerged on the use of antiretroviral prophylaxis to prevent MTCT, on the optimal time to initiate antiretroviral therapy (ART), and on safe feeding practices for HIV-exposed infants. This section draws heavily from the WHO 2010 and 2013 guidelines, which should be used and adapted within local settings. Once implemented, these recommendations could reduce the risk of MTCT to less than 5% in breastfeeding populations (from a background risk of 35%), and to less than 2% in non-breastfeeding populations (from a background risk of 25%), and will ensure increased maternal and child survival.

A woman will only know her HIV status if she has had an HIV test. HIV tests may be performed as a bedside point of care test (using capillary blood) or within a laboratory. An HIV-positive mother will pass her antibodies to her baby. These are harmless and are usually cleared by 18–24 months of age. It is transmission of the HIV virus that causes infection. An infant will have circulating maternal antibodies until 18–24 months of age, so the HIV antibody test is often not useful before this time, as it remains positive until the maternal antibodies have cleared.

When HIV infection is recent or the CD4 count is high, and a pregnant woman has no symptoms, HIV has little effect on pregnancy, and pregnancy has little effect on HIV. However, when HIV infection is advanced or the CD4 count is low, a woman is at risk of opportunistic infections, and HIV can directly affect the pregnancy, including increasing the risk of premature delivery, severe malaria and puerperal sepsis.

MTCT can occur when the baby is in the uterus, during delivery or during breastfeeding. Pregnant women should be encouraged to be tested for HIV because, if they are found to be HIV-positive, there are interventions at each of these stages that reduce the risk of MTCT, and there is also treatment to preserve the mother's own health. A negative HIV test provides an opportunity for health education, including promoting safer sex (e.g. use of condoms) to avoid the woman becoming HIV infected, particularly during pregnancy. Acquiring HIV during pregnancy carries a high risk of transmitting HIV to an unborn baby. HIV-negative women should be offered a repeat HIV test in the third trimester.

'Adult-to-child transmission' or 'vertical transmission' are other ways of describing MTCT, and are sometimes felt to imply less blame.

### Prevention of mother-to-child transmission and ART in pregnancy

The WHO 2010 guidelines state that a woman with a CD4 count of  $\leq 350$  cells/mm<sup>3</sup> (regardless of WHO clinical staging) or WHO clinical stage 3 or 4 (irrespective of CD4 count) (*WHO Case Definitions of HIV for Surveillance and Revised Clinical Staging and Immunological Classification of HIV-Related Disease in Adults and Children*, published in 2007) requires lifelong ART.

Updated consolidated ART guidelines published by the WHO in 2013 ([www.who.int/hiv/pub/guidelines/arv2013/art/artadults/en/index1.html](http://www.who.int/hiv/pub/guidelines/arv2013/art/artadults/en/index1.html)) now recommend that all pregnant and breastfeeding women should be commenced on ART (one simplified triple regimen), and that this should be maintained for at least the duration of MTCT risk (i.e. throughout breastfeeding). They suggest that, particularly in generalised epidemics, all pregnant and breastfeeding women with HIV should initiate ART as lifelong treatment. In pregnancy the focus is no longer on 'when or what to start' but on 'whether to stop' treatment after delivery. Ideally, a CD4 count should be obtained before deciding whether ART for PMTCT only (i.e. stopping after delivery) is an option.

As most women should continue ART following delivery, an effective link with HIV treatment programmes is essential.

The WHO 2013 guidelines are simplified, and they harmonise the approach to ART in adults and pregnancy. National programmes are encouraged to move from the previous Option 'A' to Option 'B' or 'B+'.

**Option B+:** all pregnant and breastfeeding women infected with HIV should be started on ART as lifelong treatment. This is particularly important in generalised epidemics where high fertility, long duration of breastfeeding, limited access to CD4 to determine ART eligibility, and high partner serodiscordance rates all increase the risks of transmission to the woman's partner and babies.

**Option B:** in some countries (e.g. where CD4 counts are available), in the case of women who are not eligible for ART for their own health, consideration can be given to stopping the ARV regimen after the period of risk of mother-to-child transmission has ended.

Single-dose nevirapine (sdNVP) for women in labour is no longer recommended (unless it is combined with other ART) because it causes the virus to develop high levels of drug resistance.

Option A (from the 2010 WHO guidelines) is no longer recommended, although some countries may not have the resources necessary to use options B or B+.

The treatment focus is shifting to consider ART for the mother's health, to utilise more effective ART drugs, and to extend coverage throughout the MTCT risk period. **All women should be started on ART in pregnancy.**

**TABLE 2.8.C.1 WHO guidelines for ART in pregnancy for HIV-infected women who have not had previous ART**

	For pregnant women for PMTCT only	For infants of mothers given a short course of ART for PMTCT
Option A (WHO 2010 guidelines)	AZT twice a day from 14 weeks sdNVP at onset of labour, and start AZT + 3TC for 7 days	Baby being breastfed: daily NVP from birth until at least 4–6 weeks of age <i>and</i> until 1 week after breastfeeding has stopped Baby being bottle-fed: daily NVP or sdNVP + AZT twice a day until 4–6 weeks
Option B	Preferred regimens: TDF + 3TC (or FTC) + EFV (as fixed-dose combination) Alternative regimens: AZT + 3TC + EFV or TDF + 3TC (or FTC) + EFV	Baby being breastfed: daily nevirapine (NVP) for 6 weeks Baby being bottle-fed: daily nevirapine (NVP) for 4–6 weeks or AZT twice a day for 4–6 weeks
	For pregnant women being given lifelong ART	For infants of mothers on lifelong ART
Option B+	Preferred regimens: TDF + 3TC (or FTC) + EFV (as fixed-dose combination) Alternative regimens: AZT + 3TC + EFV or AZT + 3TC + NVP or TDF + 3TC (or FTC) + NVP	Baby being breastfed: daily nevirapine (NVP) for 6 weeks Baby being bottle-fed: daily nevirapine (NVP) for 4–6 weeks or AZT twice a day for 4–6 weeks

### Women diagnosed with HIV during labour or immediately postpartum

If a woman is diagnosed with HIV infection during labour or immediately postpartum, ART should be commenced immediately for PMTCT. This regimen can be modified later when the woman has been assessed (with CD4 count) with regard to whether she requires lifelong ART for herself.

Postpartum, women should be assessed and a CD4 count obtained. Ideally they should continue their triple-drug ART regimen lifelong unless their CD4 count is > 500 cells/mm<sup>3</sup>.

It will take weeks for the maternal viral load to be reduced, and therefore it is important to give the mother ART in labour which will cross the placenta (and enter the baby) in addition to starting ART prophylaxis in the infant.

**TABLE 2.8.C.2 WHO guidance for ART for women diagnosed with HIV in labour/immediately postpartum**

	For the mother	For the infant
Option A	sd-NVP in labour and AZT + 3TC twice a day for 1 week	Baby being breastfed:
Option B	Start (triple) ART immediately. Continue until 1 week after exposure to breast milk has ended	Daily NVP from birth for 6 weeks, consider extending to 12 weeks
Option B+	Start (triple) ART immediately. Continue lifelong	Baby being bottle-fed: Daily NVP from birth for 6 weeks

If a woman is diagnosed with HIV infection postpartum and plans replacement (formula or bottle) feeding, refer her for HIV care and evaluation for treatment.

HIV-exposed infants (children born to women with HIV) should be given co-trimoxazole prophylaxis from 4–6 weeks of age, and this should be continued until HIV infection has been excluded and the infant is no longer at risk of acquiring HIV through breastfeeding (World Health Organization, *Guidelines on Co-Trimoxazole Prophylaxis for HIV-Related Infections among Children, Adolescents and adults: recommendations for a public health approach*, published in 2006).

### Delivery

Labour can be a worrying time for the HIV-positive woman, particularly because of possible underlying fears about her own HIV infection and the risk of infecting her baby. She will need reassurance and support, and it is important to ensure she knows that with all of the interventions that

are given her baby is more likely to be HIV-negative than infected.

Get close to her, greet her and be seen to shake hands with her, to help to reduce the stigma around touching those infected with HIV. Support her relatives, and encourage her to tell her partner so that he can be tested for HIV. Promote safer sex and advise her to use condoms to prevent transmission of HIV.

Standard precautions should be used when caring for women in labour, whether or not they have HIV infection. Always wear gloves when touching body fluids, and dispose of single-use syringes and needles safely.

#### During delivery, to reduce MTCT:

- avoid artificial rupture of membranes
- avoid prolonged rupture of membranes
- avoid unnecessary episiotomy, but also avoid a tear.

Both blood and placenta will contain HIV, so wear gloves, an apron and eye protection. Avoid direct contact of blood on your skin. Blood on intact skin should be washed off

immediately. HIV-positive blood on an open wound or splashed into the eye can transmit HIV and should be washed immediately (use soap and water for a wound, and water for an eye) and managed in the same way as a needlestick injury (with post-exposure prophylaxis with ART).

## Other considerations for managing HIV infection in pregnancy

### Anaemia

Screening for and treatment of anaemia should be routine in antenatal care for all pregnant women (World Health Organization, *Pregnancy, Childbirth, Postpartum and Newborn Care: a guide for essential practice*, 2nd edn, published in 2009). Iron supplements and folate supplements in areas with a high prevalence of iron deficiency are indicated for all pregnant women regardless of haemoglobin levels. Iron should be continued for 3 months after delivery. If possible, antenatal screening for anaemia should include laboratory measurement of haemoglobin levels, but anaemia can be assessed clinically if this is not available.

In women with severe anaemia, AZT should be avoided, and TDF or stavudine (d4T) should be used instead.

### Malaria and worm infestations

The prevention and treatment of malaria and worm infestations is necessary in high-prevalence areas (see Sections 2.8.D and 6.3.C).

### HIV-2 infection

HIV-2 is much less transmissible than HIV-1 (the MTCT risk is 0–4%).

Non-nucleoside reverse transcriptase inhibitors (NNRTIs) such as NVP and EFV are not effective against HIV-2, and a triple nucleoside reverse transcriptase inhibitor (NRTI) combination is recommended.

#### **BOX 2.8.C.2 Treatment of HIV-2 infection**

**Mother requires treatment:** AZT + abacavir (ABC) + 3TC

**PMTCT only:** AZT from 14 weeks and continued until delivery

**Infant of mother with HIV-2:** AZT twice a day until 4–6 weeks

### Tuberculosis

The risk of active TB increases in pregnancy, and is around 10 times higher in HIV-infected women. It is associated with increased maternal mortality, premature labour, low birth weight and tuberculosis in the infant. HIV-infected women must be assessed for TB at each visit; any woman with a cough, fever, night sweats and weight loss should be evaluated for TB and started on TB treatment. ART is also required regardless of the CD4 count. Commence TB treatment first, followed by ART as soon as clinically possible (within 8 weeks of starting TB treatment).

Rifampicin interacts with many antiretroviral drugs, especially the boosted protease inhibitors. As is the case for all adults, EFV is the preferred NNRTI for HIV/TB co-infected pregnant women (starting after the first trimester).

For those women on TB therapy who are unable to tolerate EFV, give a NVP-based regime or a triple NRTI regimen such as AZT + 3TC + ABC or AZT + 3TC + TDF. In the presence of rifampicin, start full-dose NVP (a lead-in dose is not required).

## Summary

Interventions during pregnancy, labour and delivery and postpartum can all significantly reduce the risk of MTCT of HIV. Therefore all pregnant women should be tested for HIV. The WHO 2007 guidelines ([www.who.int/hiv/pub/mtct/pmtct\\_scaleup2007/en/index.html](http://www.who.int/hiv/pub/mtct/pmtct_scaleup2007/en/index.html)) summarise the essential services required for good-quality antenatal care, and these are listed below.

### Package of routine quality antenatal and postpartum care for all women, regardless of HIV status

- 1 Health education, information on HIV and sexually transmitted infection (STI) prevention and care including safer sex practices, pregnancy including antenatal care, birth planning and delivery assistance, malaria prevention, optimal infant feeding; family planning counselling and related services.
- 2 Provider-initiated HIV testing and counselling, including HIV testing and counselling for women of unknown status at labour and delivery, or postpartum.
- 3 Couple and partner HIV testing and counselling, including support for disclosure.
- 4 Promotion and provision of condoms.
- 5 HIV-related gender-based violence screening.
- 6 Obstetric care, including history taking and physical examination.
- 7 Maternal nutritional support.
- 8 Infant feeding counselling.
- 9 Psychosocial support.
- 10 Birth planning, birth preparedness (including pregnancy/postpartum danger signs), including skilled birth attendants.
- 11 Tetanus vaccination.
- 12 Iron and folate supplementation.
- 13 Syphilis screening and management of STIs.
- 14 Harm reduction interventions for injecting drug users.

### Additional package of services for HIV-positive women

- 1 Additional counselling and support to encourage partner testing, adoption of risk reduction and disclosure.
- 2 Clinical evaluation, including clinical staging of HIV disease.
- 3 Immunological assessment (CD4 cell count) where available.
- 4 ART when indicated.
- 5 Infant feeding counselling and support based on knowledge of HIV status.
- 6 ART prophylaxis for PMTCT provided during the antepartum, intrapartum and postpartum periods.
- 7 Co-trimoxazole prophylaxis where indicated.
- 8 Additional counselling and provision of services as appropriate to prevent unintended pregnancies.
- 9 Supportive care, including adherence support.
- 10 TB screening and treatment when indicated; preventive therapy (INH prophylaxis) when appropriate.

- 11 Advice and support on other prevention interventions, such as safe drinking water.
- 12 Supportive care, including adherence support, and palliative care and symptom management.

### Essential postnatal care for HIV-exposed infants

- 1 Completion of ART prophylaxis regimen.
- 2 Routine newborn and infant care, including routine immunisation and growth monitoring.
- 3 Co-trimoxazole prophylaxis.
- 4 Early HIV diagnostic testing and diagnosis of HIV-related conditions.
- 5 Continued infant feeding counselling and support, especially after early HIV testing.

- 6 Nutritional support throughout the first year of life, including support for optimal infant feeding practices, and provision of nutritional supplements and replacement foods if indicated.
- 7 ART for HIV-infected children when indicated.
- 8 Treatment monitoring for all children receiving ART.
- 9 INH prophylaxis when indicated.
- 10 Adherence support counselling for caregivers.
- 11 Malaria prevention and treatment where indicated.
- 12 Diagnosis and management of common childhood infections and conditions, and integrated management of childhood illness (IMCI).
- 13 Diagnosis and management of TB and other opportunistic infections.

## 2.8.D Malaria

### Introduction

Malaria, particularly falciparum malaria, is an important cause of maternal mortality and postpartum morbidity, severe anaemia, miscarriage, intrauterine growth retardation, intrauterine death, stillbirth, premature delivery, low birth weight (LBW), and perinatal and neonatal morbidity.

*Plasmodium falciparum* malaria is the most dangerous type. *P. vivax* malaria is less dangerous. Malaria destroys red blood cells and can harm the placenta. The main danger with falciparum malaria is cerebral malaria, which causes coma and death.

In most endemic areas of the world, pregnant women are the main adult risk group for malaria. The burden of malaria infection during pregnancy is chiefly caused by *Plasmodium falciparum*, the most common malaria species in Africa. The impact of the other three human malaria parasites (*P. vivax*, *P. malariae* and *P. ovale*) is less clear. Every year at least 30 million pregnancies occur among women in malarious areas of Africa, most of whom reside in areas of relatively stable malaria transmission.

In sub-Saharan Africa, poor nutrition, micronutrient imbalances (particularly vitamin A, zinc, iron and folate), HIV co-infection, poverty and limited access to effective primary healthcare and emergency obstetric services exacerbate the impact of pregnancy-associated malaria.

In Africa, perinatal mortality due to malaria is around 1500 deaths per day. In areas where malaria is endemic, 20–40% of all babies born may have a low birth weight, increasing the likelihood of infant mortality.

Malaria in pregnancy is a particular problem for women in their first and second pregnancies, and for women who are HIV-positive.

Studies have shown that in high transmission zones more than 50% of women have placental malaria infections at birth. This increases the risk of HIV viral transfer (especially if the parasite load is high), and prevents the transfer of maternal antibodies protecting against measles.

### Malaria in pregnancy in low versus high transmission areas

The clinical presentation and severity of malaria in pregnancy differ in areas of high and low transmission due

to differences in the level of immunity of the population. Although these settings are presented as two distinct epidemiologic conditions, in reality the intensity of transmission and immunity in pregnant women occurs on a continuum, with potentially diverse conditions occurring within a country.

In areas of epidemic or low (unstable) malaria transmission, adult women have not acquired any significant level of immunity and usually become ill when infected with *P. falciparum* malaria. Pregnant women resident in areas of low or unstable malaria transmission are at a two- or three-fold higher risk of developing severe disease as a result of malaria infection than are non-pregnant adults living in the same area. In these areas, maternal death may result either directly from severe malaria or indirectly from malaria-related severe anaemia. In addition, malaria infection of the mother may result in a range of adverse pregnancy outcomes, including spontaneous abortion, neonatal death, and low birth weight (LBW).

In areas of high and moderate (stable) transmission of malaria, most adult women have developed sufficient immunity that, even during pregnancy, *P. falciparum* infection does not usually result in fever or other clinical symptoms. In these areas, the principal impact of malaria infection is associated with malaria-related anaemia in the mother, and with the presence of parasites in the placenta. The resulting impairment of fetal nutrition contributing to low birth weight is a leading cause of poor infant survival and development. In areas of Africa with stable malaria transmission, *P. falciparum* infection during pregnancy is estimated to cause as many as 10 000 maternal deaths each year, 8–14% of all low-birth-weight babies, and 3–8% of all infant deaths.

The strategy for management of malaria in the pregnant population in **areas of high transmission** should include screening and treating of positive cases, intermittent presumptive treatment (IPTp) for rapid diagnostic test (RDT)-negative cases and use of insecticide-treated bed nets (ITNs).

In high transmission areas, in women who are known to be HIV-positive, or where the prevalence of HIV exceeds 10%, IPTp should be given monthly (and at least four times during pregnancy), see below.

In **areas of low transmission** the risk of malaria infection during pregnancy is greater, and can result in maternal death, and in spontaneous abortion in up to 60% of cases. Silent malaria is rare. The strategy in these areas involves

ITNs, screening and treatment of positive cases, chemoprophylaxis if possible, and early diagnosis and prompt effective treatment of malaria.

**TABLE 2.8.D.1 Comparison of occurrence of complications in areas of high and low transmission**

Complication	Hyper-endemic areas	Low transmission
Hypoglycaemia	–	++
Severe anaemia	+++	+++
Pulmonary oedema	–	++
Acute renal failure	–	++
Hyperpyrexia	+	+++
Placental malaria	+++	+++
LBW babies	+++	+++
Abortions	–	+++
Congenital malaria	–	+++

A pregnant woman who has not lived in a malarious area has no immunity. Therefore if she goes to a malarious area she is at risk of developing severe malaria. She must take tablets to prevent malaria before she goes to that area and throughout her pregnancy, and sleep under a bed net when she gets there.

If a mother has had malaria before, she will have some immunity. Unfortunately, pregnancy reduces immunity. She is at risk from severe anaemia, but the other complications are unusual. Often her blood film will be negative, and she will have few symptoms. If she has fits they will probably be caused by eclampsia or meningitis, not malaria.

Partially immune primigravid mothers are at particular risk, especially during the last trimester. Early teenage primigravida are at greatest risk. This risk decreases with further pregnancies.

### Screening and treating pregnant women during antenatal care

Since in most African countries over 70% of pregnant women make multiple antenatal clinic visits, these provide a major opportunity for prevention of malaria, along with other important diseases that affect pregnant women.

The rationale for screening and treating all pregnant women for malaria during routine antenatal care is that **even one attack at any time during pregnancy can have serious consequences** (i.e. low birth weight and maternal anaemia).

There is a four-pronged approach to malaria prevention and control during pregnancy:

- 1 intermittent preventive treatment (IPTp)
- 2 insecticide-treated bed nets (ITNs), or preferably long-lasting insecticide-treated bed nets (LLINs)
- 3 indoor residual spraying (IRS) with insecticides
- 4 case management of malaria illness.

#### **Intermittent preventive treatment (IPTp)**

This involves providing all pregnant women with preventive treatment doses of an effective antimalarial drug during routine antenatal clinic visits. This approach has been shown to be safe, inexpensive and effective. A study in Malawi evaluating IPT showed a decline in placental infection (from

32% to 23%) and in the number of low-birth-weight babies (from 23% to 10%). It also found that 75% of all pregnant women took advantage of IPTp when it was offered.

The drug recommended at present is sulphadoxine/pyrimethamine (SP, also called Fansidar). Starting as early as possible in the second trimester, IPTp-SP is recommended for all pregnant women in Africa at each scheduled antenatal care (ANC) visit (four visits are recommended by WHO during every pregnancy) until the time of delivery, provided that the doses are given at least one month apart. SP should not be given during the first trimester of pregnancy; however, the last dose of IPTp-SP can be administered up to the time of delivery without safety concerns.

IPTp-SP should ideally be administered as directly observed therapy (DOT) of three tablets sulfadoxine/pyrimethamine (each tablet containing 500mg/25mg SP) giving the total required dosage of 1500mg/75mg SP.

In areas where malaria is very common and antenatal clinic attendance is poor, all mothers, especially all primigravida, should be given a dose of SP when they first come to the antenatal clinic after quickening (when the mother first feels the fetus moving).

Although high levels of resistance to SP occur in many countries, it is not known at what level of SP resistance IPTp still gives a positive outcome in terms of improved haemoglobin levels in the mother and higher birth weights. A preventative effect provided by SP seems to exist even at relatively high levels of resistance.

For pregnant women who are HIV-positive, the dosage schedule for IPT should be augmented to at least four doses of SP, starting in the second trimester, the doses being given at least 1 month apart. This increased frequency is also recommended for all pregnant women with unknown HIV status living in areas of high HIV prevalence (over 10%).

Women who are HIV-positive experience increased vulnerability to malaria in all pregnancies, not just the first two pregnancies.

**Note:** HIV patients who are receiving co-trimoxazole preventive therapy should not take IPTp as adverse effects can occur.

Research to assess the safety, efficacy and programme feasibility of other antimalarial drugs for use in IPTp is ongoing.

Weekly chloroquine has in the past been shown to be effective in preventing malaria in pregnancy, especially in the case of *P. vivax* malaria. Adherence to this regime and loss of efficacy in the case of *P. falciparum* malaria make this regime less appropriate.

### **Insecticide-treated bed nets (ITNs) and long-lasting insecticide-treated bed nets (LLINs)**

Nets decrease both the number of malaria cases and the malaria death rates in pregnant women. A study in an area of high malaria transmission in Kenya has shown that women who are protected by ITNs every night during their first four pregnancies produce 25% fewer underweight or premature babies. In addition, ITN use benefits the infant who sleeps under the net with the mother, by decreasing their exposure to malaria infection. ITNs should be provided to pregnant women as early in pregnancy as possible, and their use should be encouraged for women throughout pregnancy and during the postpartum period. Health education programmes, social marketing and lobbying to reduce the prices of ITNs and re-treatments are helping to encourage the use of ITNs by pregnant women.

### **Indoor residual spraying (IRS) with insecticides**

IRS involves applying a long-lasting (residual) insecticide to the inside walls of houses and other structures where people sleep, to kill mosquitoes when they rest on the walls. It is a highly effective malaria prevention method in settings where it is epidemiologically and logistically appropriate. IRS must be applied prior to the transmission season (either annually, or twice a year if there are continuous or multiple seasons of transmission), and is carried out by a trained cadre of workers who move through a community spraying all appropriate structures. Its full potential is realised when at least 80% of houses in targeted areas are sprayed. Indoor spraying is effective for 3–6 months, depending on the insecticide used and the type of surface on which it is sprayed. DDT can be effective for 9–12 months in some cases. Longer-lasting forms of IRS insecticides are under development. The WHO approves the following pyrethroid class of pesticides; lambda-cyhalothrin, bifenthrin, alpha-cypermethrin, deltamethrin, cyfluthrin and etofenprox.

### **Case management of malarial illness**

In areas of unstable (infrequent) *P. falciparum* malaria transmission, non-immune pregnant women exposed to malaria require prompt case management of febrile illness. Although at present there are no fully effective tools to prevent malaria among non-immune women, ITNs will decrease exposure to infective mosquito bites, and thus would be expected to be of benefit in decreasing symptomatic infections. Essential elements of the antenatal care package should therefore include malaria diagnosis, where available and needed, and treatment with antimalarial drugs that have an adequate safety and efficacy profile for use in pregnancy.

In view of the increasing evidence of the severe effects of malaria in pregnancy on both the woman and her unborn child, even when asymptomatic, all pregnant women presenting for antenatal care or delivery should be tested using an RDT. Since the sensitivities of both RDT and smear to detect low parasitaemias in pregnancy are not infallible, **both are recommended** where this is programmatically possible. Where this is not possible, RDTs are to be preferred.

All women who are found to be positive should receive an effective antimalarial drug, namely quinine in the first trimester and artemisinin-combination therapies (ACT) in the second and third trimesters. If they are found to be negative, they should receive a dose of SP as IPTp. Women should not be screened more often than monthly in the absence of signs or symptoms of malaria.

Patients with severe anaemia (haemoglobin < 7 g/dL) in a high transmission zone are in all probability infected, and should be treated with an effective antimalarial drug as well as iron/folic acid even if there are no other signs of malaria and negative smear or RDT, or if laboratory tests cannot be undertaken.

All patients with a positive biological test (RDT and/or microscopy) should be treated with an effective antimalarial drug. If you suspect malaria, but cannot examine a blood film or do an RDT, treat the mother anyway.

**Asymptomatic (placental) malaria** has the same implications in pregnant women as symptomatic malaria. Asymptomatic women should be routinely tested and treated.

In high transmission zones, many women suffer minor attacks of malaria for which they do not seek treatment. However, the placenta can still be infected. Women should be advised at each antenatal visit to come for treatment even if their symptoms are minor. **Both RDTs and smears may miss cases of placental malaria.** Because of the inability of biological tests to reliably detect placental malaria, patients with a negative biological test should receive SP as IPTp both to treat an undetected infection and to prevent further infection.

In low transmission zones, anaemia without a positive biological test and without symptoms or signs of malaria such as fever is probably due to other causes, and such patients should not automatically receive an antimalarial drug, but should be treated for the underlying cause (including treatment with iron and folate tablets).

### **RDTs versus microscopy in pregnancy**

There is indirect evidence that only 30% of cases with placental malaria show peripheral parasitaemias. Although there is little evidence, it is more likely that RDTs will detect sequestered parasites because of accumulated antigenic product.

In Thailand and Assam, studies found that RDTs missed cases of parasitaemia found on slides (2.5% of patients in Assam). This is a much lower number of cases than the number missed by smears.

**Ideally, use of both RDT and microscopy would detect most cases.** However, this is usually impractical in the field setting. RDTs are preferable to microscopy in this setting for the detection of subclinical infections.

**In cases of *P. vivax* malaria, placental malaria is difficult to detect.** However, placental *P. vivax* malaria occurs infrequently because vivax malaria does not sequester. Detection of parasites in vivax is best done by microscopy.

## **Treatment of malaria**

### **Drug safety in pregnancy**

Guidelines on the treatment of malaria in pregnancy are made difficult by the lack of evidence about the safety of ACTs in pregnancy.

The recommendation is to ask the woman if she is

pregnant, and if she is not, to treat her with ACT. This is a pragmatic recommendation based on the fact that no serious adverse effects have yet been recorded in women who were inadvertently given ACT in the first trimester, and the fact that a 7-day course of quinine is rarely adhered to.

As a change from previous recommendations, the combination of artemether and lumefantrine (AL) is now considered as safe (or as unsafe) as the other combinations of AS + AQ, AS + SP and AS + MQ.

Drug resistance of *P. falciparum* to chloroquine and the antifolates has arisen throughout malaria-endemic areas.

Combination therapy (**artemisinin-combination therapies, or ACTs**) is considered best for malaria management (artemisinin-based compounds in combination with other classes of antimalarial drugs).

ACTs are highly effective and may help to delay development of resistance. It is important to ensure wide access to these drugs through effective delivery systems and affordable cost.

The risks of ACT in the **second and third trimester** are low. During these phases of pregnancy, ACTs should be used to treat both clinical and subclinical infections, due to the serious outcomes of these infections.

Quinine should always be used in the **first trimester**. However, if the life of the woman is threatened (i.e. when the risk to the mother outweighs the theoretical risk to the fetus), an ACT should be prescribed. Malaria is less often resistant to **quinine** than it is to other drugs, and this drug may be safely used throughout pregnancy if ACTs are not available.

**ACTs in pregnancy:** the use of ACTs in pregnancy has not been widely studied, but all of the current evidence points to their relative safety, even in the first trimester. Research into the safety and pharmacokinetics of antimalarial drugs in pregnancy is ongoing.

The following ACTs (arranged in alphabetical order) are currently recommended by the WHO for the treatment of uncomplicated *P. falciparum* malaria:

- artemether (ATM) + lumefantrine (LM): combined (fixed-dose combination, FDC) tablets ATM 20 mg/LM 120 mg in blister packs.
  - **Dose:** On day 1 give 4 tablets and then repeat 4 tablets between 8 and 12 hours later. Then give 4 tablets twice daily in the morning and evening on days 2 and 3.
  - Advise the patient to take doses with food, preferably fatty food. Consider supplying dried milk powder or Plumpy'Nut® to take with tablets.
- artesunate (AS) + amodiaquine (AQ): combined (fixed-dose combination, FDC) tablets AS 100 mg/AQ 270 mg in colour-coded blister packs.
  - **Dose:** 2 tablets per day for 3 successive days.
- artesunate (AS) + mefloquine (MQ): AS = 50 mg tablets, MQ = 250 mg tablets as base.
  - **Dose:** give 4 tablets of AS on days 1, 2 and 3, and 6 tablets of MQ on day 1 **and** 2 tablets of MQ on day 2 (or 8 tablets on day 1 only).
- artesunate (AS) + sulfadoxine + pyrimethamine (SP): AS = 50 mg tablets, SP = 25 mg (S) + 500 mg (P).
  - **Dose:** give 4 tablets of SP on days 1, 2, 3 and 4 **and** 3 tablets of SP on day 1.
- dihydroartemisinin (DHA) + piperaquine (PQP): combined (fixed-dose combination, FDC) tablets DHA 40 mg/PQP 320 mg.

- **Dose:** mother weighing 50–60 kg, 1 tablet three times a day for 1 day; mother weighing 60–70 kg, 1 tablet three times a day for 1 day plus additional ½ tablet at onset of day 1.
- quinine = usually 200 mg and 300 mg tablets.
  - **Dose:** give 600 mg 8-hourly over the first 24 hours or 30 mg/kg/day in three divided doses at 8-hourly intervals.
  - In South-East Asia where quinine sensitivity appears to be reduced, add clindamycin 7–13 mg/kg every 8 hours for 5 days.

**Most pregnant women with malaria also lack folate, so give them folate tablets 5 mg daily.**

**If a pregnant woman is not immune**, that is if she comes from an area without malaria transmission, she must have regular malaria tablets throughout pregnancy, especially in the last trimester.

## Severe complicated malaria

This is usually *P. falciparum* malaria.

**Severe malaria is a complex multi-system disease, and is a medical emergency.**

Mortality approaches 100% without treatment, and death often occurs within the first few hours. Prompt initiation of antimalarial treatment in peripheral healthcare facilities and comprehensive management in hospital are necessary to prevent deaths.

Care should be provided within 15 minutes of arrival at a healthcare facility. **Triage systems** should be in place to pick up severely ill patients, referral should be rapid, and emergency facilities should be instituted in hospitals, with a high standard of medical and nursing care available 24 hours a day.

Any seriously ill or unconscious patient in a malaria endemic area must be tested for malaria by RDT (remember that parasites may not be present in the peripheral blood of a patient with cerebral malaria).

Even if a diagnostic test is not available, **the patient should be given an antimalarial drug (IV, IM or rectally, depending on the skill of the staff in the facility) before transfer to the hospital.** This can be repeated if transfer is impossible or is delayed for more than 12 hours. **A note of what has been given should be sent with the patient as soon as transfer can be arranged.**

## Clinical features of severe malaria (WHO 2013)

- impaired consciousness (including unrousable coma)
- prostration, i.e. generalised weakness so that the patient is unable to sit, stand or walk without assistance
- multiple convulsions: more than two episodes within 24 hours
- deep breathing and respiratory distress (acidotic breathing)
- acute pulmonary oedema and acute respiratory distress syndrome
- circulatory collapse or shock, systolic blood pressure < 80 mmHg in adults and < 50 mmHg in children
- acute kidney injury
- clinical jaundice plus evidence of other vital organ dysfunction
- abnormal bleeding.

**If any doubt exists about the diagnosis, it is safer to treat than not to treat before transfer.**

### **Immediate measures (in hospital)**

- Vital signs: temperature, pulse, blood pressure, and rate and depth of respiration.
- State of hydration.
- Estimation or measurement of body weight.
- Level of consciousness (AVPU or Glasgow Coma Scale scores).
  - **The depth of coma may be assessed rapidly by observing the response to standard vocal or painful stimuli (rub your knuckles on the woman's sternum; if there is no response, apply firm pressure on the thumbnail bed).**
- RDT and malaria smear (thick and thin film) for diagnosis and for continued monitoring of the progress of the disease. **Do not wait for a malaria smear result before initiating treatment, as it can take up to an hour.** If the RDT is positive, commence treatment immediately.
- Perform a lumbar puncture if the patient is unconscious, to eliminate meningitis.
- Measurement of glucose (finger prick test), haemoglobin, haematocrit and packed cell volume (PCV).
- Group and cross-match blood and **search for a suitable donor if there are no blood banking facilities.**
- Parenteral treatment (see below for details):
  - First choice: IV artesunate (2.4 mg/kg by slow IV injection at 0, 12 and 24 hours).
  - Second choice: IM artemether (loading dose of 3.2 mg/kg followed by 1.6 mg/kg every 24 hours).
  - If artemisinins are not available or the Ministry of Health has not authorised their use, commence with a loading dose of quinine 20 mg/kg (generally given in 10% dextrose to reduce the risk of hypoglycaemia) by slow infusion over 4 hours, followed by 10 mg/kg over 4 hours, every 8 hours for a minimum of 3 doses and continued until the patient is able to tolerate oral drugs. A full course of oral antimalarials must be completed once IV quinine has been discontinued. The loading dose of quinine may be omitted if the patient has definitely received a treatment dose of quinine within the previous 12 hours.

**Every effort should be made to convince the Ministry of Health to allow the use of artemisinins to treat severe malaria in hospital, as mortality may be reduced by up to 30% over the use of quinine.**

### **Additional measures where needed**

- Insert a nasogastric tube to minimise the risk of aspiration pneumonia if the patient's level of consciousness is low. This can also be used to give food to prevent hypoglycaemia if the patient is unconscious for a long period and is unable to eat.
- Monitor for hypoglycaemia by laboratory or bedside testing if available (see below for more detailed advice).
- Insert an IV cannula and restore circulating volume.
  - Fluids should be given with caution and the need for them assessed on an individual basis after ascertaining the nutritional status and degree of dehydration present (see below for more details).
- In general, patients with metabolic acidosis who have not previously received parenteral fluids are dehydrated

and should be managed accordingly (see below for more details).

- Give oxygen, especially if metabolic acidosis is suspected or shock is present.
- Treat severe anaemia with a safe blood transfusion if the patient is showing signs of decompensation.
- Give anticonvulsants (diazepam is preferred initially, then phenytoin if convulsions persist) if the patient is fitting, to prevent long-term neurological damage (see below for more details).

**Convulsions are common before or after the onset of coma. They are significantly associated with morbidity and sequelae. They may present in a very subtle way. Important signs include intermittent nystagmus, salivation, minor twitching of a single digit or a corner of the mouth, and an irregular breathing pattern.**

- Prophylactic anticonvulsants have been recommended in the past, but recent evidence suggests that **phenobarbital is harmful.**
- IV broad-spectrum antibiotics should be given routinely in an unconscious patient.

**The patient will need intensive nursing care at least until they regain consciousness. They may urgently need glucose or a blood transfusion if hypoglycaemia or haemolysis is severe.**

### **Special issues with regard to severe malaria in pregnancy**

Severe malaria is malaria with severe drowsiness, coma, vomiting, inability to walk, jaundice, fits or pulmonary oedema. These women are usually non-immune multi-gravida, or semi-immune primigravida, with *P. falciparum* malaria.

Severe malaria in pregnancy may be misdiagnosed as eclampsia. **If a pregnant woman living in a malarial area has fever, headaches or convulsions and malaria cannot be excluded, it is essential to treat the woman for both malaria and eclampsia.**

**Pregnant women with severe malaria are particularly prone to hypoglycaemia, pulmonary oedema, anaemia and coma.**

**Malaria is especially dangerous during the last trimester.**

### **Malaria drug treatment in pregnancy**

#### **Treat malaria in pregnancy urgently and early!**

Calculate the dose in mg/kg. If you cannot weigh the patient, an average pregnant woman weighs about 60 kg, a small woman weighs around 50 kg and a large woman in resource limited settings around 80 kg.

Where available, artesunate IV/IM or artemether IM are the drugs of choice in the second and third trimesters. Their use in the first trimester must balance their advantages over quinine (better tolerability and less hypoglycaemia) against the limited documentation of pregnancy outcomes. **Artemisinin and artesunate may be given rectally.**

#### **IV/IM artesunate**

**Artesunate** IV/IM: 2.4 mg/kg by direct IV injection (over 5 minutes) or IM injection at 0, 12 and 24 hours, then once daily until oral therapy is possible.

A solution for parenteral use should be prepared for either IV (10 mg/mL) or IM (20 mg/mL) use, following the

manufacturer's instructions, using the sodium bicarbonate and saline solution supplied to dilute the concentrated artesunate.

For a small pregnant woman (estimated body weight 50 kg), each dose would be 12 mL IV (10 mg/mL) or 6 mL IM (20 mg/mL).

Artesunate IM should be administered in the antero-lateral thigh, drawing back before injection to ensure that the needle is not in a vein.

### **IM artemether**

**Artemether IM:** loading dose is 3.2 mg/kg on day 0, followed by 1.6 mg/kg daily for at least two more doses; then continue until oral therapy is possible. A full course of oral therapy should be taken once IM therapy is discontinued.

An 80 mg/mL presentation is preferred to reduce the volume of the injection.

**For a small pregnant woman (estimated body weight 50 kg) each dose would be 2 mL IM (80 mg/mL).**

Artemether IM should be administered in the antero-lateral thigh, drawing back before injection to ensure that the needle is not in a vein.

Artemether is not well absorbed in shock, and in this situation an alternative treatment (parenteral or rectal artesunate, or IV quinine) should be chosen.

### **Rectal artesunate**

- It is recommended that this should be available in all rural settings, including those with trained village healthcare workers.
- It can be given at 12-hourly intervals.
- The minimum dose is 10 mg/kg. Larger doses are not harmful, but are not more effective.
- It can also be given to vomiting patients, or those unable to tolerate oral drugs.
- Rectal artesunate must always be followed by a full course of ACT when the patient is able to take oral drugs.

**At present the WHO only recommends rectal artesunate as a pre-referral treatment. Where referral is not possible, ensure that a full course of ACT is given as soon as the patient is able to take oral treatment.**

Artesunate is available as a rectal capsule: Rectocaps (Mepha), 50 mg and 200 mg.

A WHO-approved rectal capsule is to be available soon, as 100 mg and 400 mg presentation.

The dose is 10 mg/kg, and therefore an average-sized mother needs 600 mg per dose. Give three 200 mg rectal suppositories at 0, 12, 24, 36, 48 and 60 hours.

### **Follow-on treatment**

When the patient has received at least three parenteral doses of artesunate or artemether, and is able to tolerate oral intake, give a full course (3 days) of ACT orally.

### **Quinine dihydrochloride**

**Always give quinine with glucose.**

Do not confuse doses of salt and base. Quinine is usually prescribed as the salt (10 mg of quinine dihydrochloride = 8.3 mg of base).

### **Loading dose**

Infuse quinine dihydrochloride 20 mg/kg body weight (usually 1.2 grams for the average 60 kg pregnant woman) in

500 mL of IV fluids (Ringer-lactate or Hartmann's solution plus 5% or 10% glucose) over 4 to 8 hours. Do not let it go in too quickly. Quinine is usually available in 2-mL ampoules of 150 mg/mL, where 1.2 g thus corresponds to 8 mL.

Do not give quinine in 5% dextrose solutions, as there is a danger of hyponatraemia. Add 50 mL of 50% glucose to 500 mL of Ringer-lactate or Hartmann's solution to produce Ringer-lactate or Hartmann's plus 5% glucose solutions. Add 100 mL of 50% glucose to 500 mL of Ringer-lactate or Hartmann's solution to give 10% glucose solutions.

**Never give an IV bolus injection of quinine, as it is likely to cause cardiac arrest.**

- **If it is definitely known that the mother has taken an adequate dose of quinine** (1.2 grams) within the preceding 12 hours, do **not** give the loading dose. Proceed with the maintenance dose (see below).
- **If the history of treatment is not known or is unclear**, give the loading dose of quinine.

Alternatively, omit the loading dose if the patient has received three or more doses of oral quinine in the last 48 hours, or mefloquine or halofantrine within the last 3 days.

- Wait 8 hours before giving the maintenance dose.

### **Maintenance dose**

Infuse quinine dihydrochloride 10 mg/kg body weight (usually 600 mg for the average pregnant woman) in 500 mL of fluids (as above) IV over 4 hours. Repeat every 8 hours (i.e. quinine infusion for 4 hours, no quinine for 4 hours, quinine infusion for 4 hours, etc.) for 24 hours and then change to oral medication if the woman is conscious and able to swallow safely.

For follow-on oral treatment, give a **3-day course of ACT or 7 days of oral quinine**. If the combination AS + MQ is used, wait 12 hours after the last dose of quinine before giving MQ. Do not use AS + MQ if the patient developed neurological signs during the acute phase.

The dose of oral quinine dihydrochloride or quinine sulphate is 10 mg/kg body weight (usually 600 mg for the average size of pregnant woman) by mouth every 8 hours to complete 7 days of treatment. Ask the patient to swallow the tablets quickly with milk.

**Monitor blood glucose levels for hypoglycaemia every hour while the patient is receiving quinine IV.**

Quinine may increase the risk of hypoglycaemia, and it may cause haemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, which may result in the passage of haemoglobin in the urine (this is called **blackwater fever**).

Make sure that plenty of fluids are given so that the urine output is adequate. Keep a strict fluid balance chart. Monitor the volume of fluid that you give, and the urine output. Do not overload with fluid.

**If the haemoglobin level falls below 6 g/dL**, try to give blood, but observe closely for fluid overload. When the patient is improving, give iron and folate tablets.

### **Intramuscular quinine**

If you cannot place an IV line, you can give quinine IM, at a strength of not more than 60 mg/mL. Some ampoules are 60 mg/mL (usually 10-mL ampoules). Some ampoules are 300 mg/mL or 600 mg/mL. Dilute these in 0.9% saline or Ringer-lactate or Hartmann's solution to a concentration of

60 mg/mL (e.g. 600 mg of quinine in 10 mL of saline). If you do not dilute quinine, the mother may develop an injection abscess. Use the same dose as you would give IV. Give half the dose into each anterior thigh.

**When giving quinine by IM injection, regularly draw back to ensure that the needle is not in a vein, as an IV injection of quinine is likely to cause cardiac arrest.**

### Fluid replacement

If the patient is unable to drink, maintain daily fluid requirements using the nasogastric (preferred) or IV (greater risk of fluid overload) route. Do not use 0.9% saline as it is an acid solution: use Ringer-lactate or Hartmann's solution. Measure urine output (a Foley catheter should be used in unconscious patients).

Weight	Daily fluid requirement	Hourly fluid requirement
In pregnancy	50 mL/kg	2.0 mL/kg

### IV fluids

A Ringer-lactate or Hartmann's solution plus glucose mix is commonly recommended. Use a 10% glucose mix with Ringer-lactate or Hartmann's solution if hypoglycaemia is identified. Monitor carefully for fluid overload, especially when the IV route is used. Switch to the oral route as soon as possible. Fluids given should be included in the daily fluid requirement totals to avoid over-hydration.

### Antibiotics

All patients who are in shock or who remain severely ill following resuscitation should receive a presumptive treatment with broad-spectrum IV antibiotics. Unconscious patients should have a lumbar puncture to exclude meningitis. Where this is not possible a presumptive treatment with a suitable antibiotic should be given.

## Continuing hospital care of pregnant women with severe malaria

This should include the following:

- Nurse in the lateral position if the woman is more than 20 weeks' pregnant, to avoid inferior vena caval compression.
- If the patient is unconscious, nurse her in the recovery position, alternating sides frequently.
- Observe hourly pulse, blood pressure, respiratory rate and level of consciousness (using the AVPU scale: see Section 1.11).
- Frequently measure blood glucose levels (every hour if the patient has a reduced conscious level, especially when they are receiving quinine and/or where the level of consciousness does not improve).
- If the patient is conscious, regularly (4-hourly) determine blood glucose levels to exclude hypoglycaemia particularly if the patient is not eating well. This is especially important in pregnant women, particularly those receiving quinine therapy.
- A daily microscopic blood slide to determine the level of parasitaemia and to follow treatment efficacy.
- Regular haemoglobin measurement. The frequency will depend on the rate of red blood cell breakdown. This may be very rapid in cases of high parasite density.

- Blood transfusion where necessary with careful monitoring to prevent fluid overload. Packed cells should be used where possible. If overload is suspected, give a single dose of 20 mg IV.
- If the patient is unconscious or in shock, administer IV broad-spectrum antibiotics to manage septicaemia, pneumonia or meningitis, which are often associated with cerebral malaria.
- Oxygen is needed for patients in respiratory distress.
- **Blood gases** and urea and electrolytes should be measured where possible.
- Controlled IV fluids.
- Fluid balance charts: unconscious patients should be catheterised to measure urine output, facilitate correct fluid balance and detect possible renal failure.

## Management of life-threatening complications of severe malaria

### Severe anaemia (due to haemolysis)

Monitor haemoglobin levels daily.

Severe haemolytic anaemia: haemoglobin < 5 g/dL or haematocrit < 15%.

**Severe anaemia may be the presenting feature in malaria.**

**Patients with severe anaemia, especially pregnant women, should be tested for malaria.**

- Establish safe transfusion as soon as possible.
- Transfuse with screened blood only if the patient is severely symptomatic. For patients with haemoglobin < 5 g/dL or haematocrit < 15%, recheck haemoglobin levels at least every 4 hours. Transfuse if haemoglobin levels start to fall or symptoms develop.
  - Packed cells are preferred for transfusion in pregnancy. Allow red blood cells to settle at the bottom of the bag, and stop the infusion when all of the cells have been used.
  - Perform microscopy following transfusion, and repeat or extend antimalarial treatment if parasitaemia is increasing.
- **Transfusion rates** may depend on the status of the patient. Exercise caution with malnourished patients.
- **Suggested rates:** two 500-mL units over 4–6 hours giving IV 20 mg of furosemide with each 500 mL.
- If the patient shows signs of fluid overload, give additional furosemide 20 mg IV, and repeat after 1–2 hours if indicated.

Give ferrous sulphate or ferrous fumarate 60 mg by mouth *plus* folic acid 5 mg by mouth once daily upon discharge.

### Hypoglycaemia

This is defined as glucose levels of less than 2.5 mmol/litre (< 45 mg/dL).

Check for hypoglycaemia in patients who are unconscious, in shock or deteriorating, especially if they are malnourished, and in all patients receiving quinine. Often hypoglycaemia causes no symptoms until it results in coma and death. Watch for abnormal behaviour, sweating and sudden coma. Always give glucose with quinine. If the mother is drowsy, delirious or unconscious, do not assume that she has cerebral malaria; she is probably hypoglycaemic.

Treat with an IV glucose infusion over 15 minutes.

- If you give 50% glucose it irritates the veins, so dilute

50 mL of 50% glucose with 50 mL of Ringer-lactate or Hartmann's solution to make a 25% solution.

- Then give 500 mL of 5% dextrose in Ringer-lactate or Hartmann's solution over 8 hours (see above for details of how to prepare this).

**If you do not have IV glucose**, give sugar water by mouth or by nasogastric tube. Dissolve 4 level teaspoons (20 grams) in a 200 mL cup of clean water.

Retest 15 minutes after completion of infusion, and repeat the infusion if blood glucose levels remain low. Repeat until blood glucose levels recover, and then infuse with 5–10% glucose in Ringer-lactate or Hartmann's solution (according to hypoglycaemia risk) to prevent recurrence. Ensure regular feeding when oral intake can be sustained. Fluids used to treat hypoglycaemia must be included in the daily fluid requirements.

**Hypoglycaemia is a major cause of death in patients with severe malaria, especially those who are pregnant. Remember that quinine will potentiate hypoglycaemia. Patients should receive regular feeding, including by nasogastric tube, when they are unable to take oral foods.**

### Fluid balance problems

Maintain a strict fluid balance chart and monitor the amount of fluids administered and urine output to ensure that there is no fluid overload. Assess the patient's clinical status regularly.

**Note: Pregnant women with severe malaria are prone to fluid overload.**

### Acute renal failure (ARF)

This is defined as an abrupt decline in the renal regulation of water, electrolytes and acid–base balance, and continues to be an important factor contributing to the morbidity and mortality of malaria patients.

Oliguria or anuria is often associated with jaundice, anaemia and bleeding disorders.

**Note: Dehydration is a common cause of low urine output.**

- The basic principles of management are avoidance of life-threatening complications, maintenance of fluid and electrolyte balance, and nutritional support.
- The patient must be catheterised so that urine output can be accurately measured.
- Acute renal failure is suspected when the hourly urine output is < 30 mL/hour (over 4 hours). Blood concentrations of urea and creatinine are usually raised (> 2.9 mg/dL that is > 256 mmol/litre).
- Make sure that the patient is adequately hydrated, but avoid overload.
- If possible, monitor plasma electrolytes, especially serum potassium levels.

If urine output continues to be low despite adequate hydration, peripheral perfusion and normal blood pressure, give furosemide 40 mg IV.

If renal failure is established, restrict fluid to insensible loss (30 mL/hour) plus urine output. If possible, refer the mother to a tertiary care centre for management of renal failure. Consider peritoneal dialysis (if available).

### Convulsions

If there are **convulsions**, consider whether the mother has

eclampsia. Test the urine for protein and measure the blood pressure (see Section 2.5.E).

If the mother has eclampsia, treat this with magnesium sulphate. If she does not have eclampsia, prevent more convulsions with anticonvulsants.

**Note: seizure activity in cerebral malaria needs to be looked for carefully, as it may just appear as a twitching of the thumb or mouth.**

Give diazepam, 10 mg rectally or by slow IV injection over 2 minutes.

Do not exceed 10 mg per dose. Always have a bag-valve-mask of a suitable size available in case the mother stops breathing.

Alternatively, paraldehyde 0.1 mL/kg of body weight may be given by deep IM injection (usually 6 mL total dose) or 0.4 mL/kg of body weight (usually 24 mL) intra-rectally using a sterile glass syringe (a disposable plastic syringe may be used provided that the injection is given immediately after the paraldehyde is drawn up, and the syringe is never reused).

Consider preventing subsequent convulsions with phenytoin (see below).

### Phenytoin

#### Loading dose

Infuse phenytoin 1 gram (approximately 18 mg/kg body weight) in 50–100 mL of 0.9% saline over 30 minutes (the final concentration should not exceed 10 mg/mL).

**Note: Only 0.9% saline can be used to infuse phenytoin.** All other IV fluids will cause crystallisation of phenytoin.

Flush the IV line with 0.9% saline before and after infusing phenytoin.

Do not infuse phenytoin at a rate exceeding 50 mg/minute, due to the risk of irregular heartbeat, hypotension and respiratory depression. Complete administration within 1 hour of preparation.

#### Maintenance dose

Give phenytoin 100 mg IV slowly over 2 minutes or by mouth every 8 hours beginning at least 12 hours after the loading dose.

### Respiratory distress

**Rapid laboured breathing:** check for and treat secondary pneumonia (give antibiotics and oxygen) or anaemia (transfuse), or pulmonary oedema, which may occur with or without fluid overload. Check the fluid balance (reduce IV fluids), supply oxygen, nurse the patient in a semi-sitting position, and do a trial of furosemide, 40 mg IV, repeating this after 1–2 hours if indicated.

**Slower laboured breathing (acidotic)** (Kussmaul breathing): ensure appropriate fluid replacement (plus transfusion if indicated), and treat associated conditions and infections.

### Metabolic acidosis

Deep breathing with a clear chest is a sensitive and specific sign for the presence of metabolic acidosis. It is the single most important determinant of survival, and can lead to respiratory distress syndrome. Metabolic (lactic) acidosis has been identified as an important cause of death in severe malaria.

Metabolic acidosis in severe malaria has been attributed to the combined effects of several factors that reduce oxygen delivery to tissues:

- 1 increased production of lactic acid by parasites (through direct stimulation by cytokines)
- 2 decreased clearance by the liver
- 3 a marked reduction in the deformability of uninfected red blood cells, which may compromise blood flow through tissues
- 4 dehydration and hypovolaemia, which can exacerbate microvascular obstruction by reducing perfusion pressure
- 5 destruction of red blood cells and anaemia, which further compromise oxygen delivery.

### Management

- Maintain airway patency and oxygen delivery; intubate if the patient is unconscious, in severe shock, or otherwise unstable.
- Establish an IV line; replace an adequate intravascular fluid volume if the patient has tachycardia, hypotension or other signs of poor tissue perfusion, such as poor capillary refill time. **IV normal (0.9%) saline can be harmful in severe malaria, when there is frequently acidosis. Normal saline is a strongly acidotic solution and can make the acidosis much worse. Therefore use Ringer-lactate or Hartmann's solution for IV fluid replacement or in shock.**
- Monitor for cardiac arrhythmias.
- The use of sodium bicarbonate is controversial and generally should be avoided.

**Pulmonary oedema** is very dangerous. The mother may have it on admission, or it may develop after several days. Fast difficult breathing is the first sign. Frothy (bubbly) fluid may be coming from the mouth. Pulmonary oedema causes hypoxia, fits, coma and death. It can also be caused by too much fluid. Sometimes it is caused by malaria and too much IV fluid, so watch the jugular venous pressure regularly and ideally, if skilled, measure central venous pressure.

- Keep the patient upright; prop them up with pillows and lower the foot of the bed.
- Give high concentrations of oxygen using a face mask and reservoir.
- Give furosemide 40 mg IV. If there is no response (i.e. no increase in urine output), increase the dose progressively, every 4 hours, up to a maximum of 200 mg.
- If the woman might be receiving too much IV fluid, stop all drips.
- If the woman does not improve, withdraw 250 mL of blood into a transfusion bag. Give it back to her later.

### Shock

Although severe malaria alone may cause shock (algid malaria), it is uncommon and bacterial sepsis often coexists, which must be treated.

Management includes initial assessment for severe anaemia, which can also be the cause of shock due to lack of oxygen-carrying capacity in severe anaemia. The management of severe anaemia, if this is responsible, is described above.

If the patient is not severely anaemic, and particularly if they are dehydrated, give rapid fluid replacement provided that there are no signs of pulmonary oedema:

- Ringer-lactate or Hartmann's solution IV, 500 mL over 30 minutes, then reassess. If there is no improvement

in capillary refill or tachycardia, repeat the infusion once or twice more, as required.

Give IV broad-spectrum antibiotics to treat septicaemia and any associated infections.

### Abnormal bleeding

- Transfuse with fresh blood.
- Give vitamin K 10 mg IV or orally.
- Avoid IM injections and non-steroidal anti-inflammatory drugs (NSAIDs).

### Coexisting infections

Treat any associated pneumonia, dysentery or endometritis (see Sections 2.8.A, 2.8.B and 2.5.G).

### Congenital malaria

Congenital malaria is relatively rare; it occurs in up to 10% of affected pregnancies. This is because the placental barrier and maternal IgG antibodies that cross the placenta protect the fetus to some extent. All four species can cause congenital malaria, but *P. malariae* causes proportionately more than the other species.

Congenital malaria is much more common in non-immune populations, and the incidence increases during epidemics of malaria.

Fetal plasma quinine levels are about one-third of simultaneous maternal levels, and this sub-therapeutic drug level does not cure the infection in the fetus.

The newborn child can manifest with fever, irritability, feeding problems, hepatosplenomegaly, anaemia and jaundice. The diagnosis can be confirmed by a smear from cord blood or a heel prick, any time within 1 week after birth (HRP2 tests may not be relevant in the early days after birth, as the infant blood may include HRP2 from the mother). The risk of congenital malaria is higher in children born to mothers who have malaria during or shortly before delivery.

### Prevention, diagnosis and treatment of non-falciparum malaria

Other forms of malaria are found all over the world and need to be prevented, diagnosed and treated.

#### *P. vivax* and *P. ovale* malaria

*P. vivax* and *P. ovale* malaria are recurrent due to the fact that the parasites can conceal themselves as the hypnozoite form in the liver. They can emerge and cause new attacks of malaria at regular intervals for up to 30 years. Most medications (except primaquine) only act on the erythrocyte stage of the parasite and therefore do not affect the hypnozoites.

#### Prevention

Long Lasting Impregnated Bednets (LLINs) with appropriate information should be supplied to prevent initial infection (and co-infection with other parasite species), but they will not prevent recurrent attacks once the infection is established. **Indoor residual spraying** should be used.

#### Diagnosis

The following methods can be used:

- microscopy
- RDTs: **HRP2 tests such as Paracheck will only detect *P. falciparum*.** pLDH tests such as CareStart will detect

other species. At present the sensitivity and specificity of pLDH in detecting *P. vivax* and other species of malaria are not clearly defined

- **Polymerase chain reaction (PCR)** can be used to distinguish between new and recurrent infections.

### Treatment

At present, the treatment for *P. vivax* malaria (and the other non-falciparum species) is **chloroquine (CQ)**.

**This should only be used for CQ-sensitive non-falciparum malaria.**

It is available in the following formulations:

- 100 mg base tablets (chloroquine phosphate)
- 150 mg base tablets
- 50 mg base/5 mL syrup.

Chloroquine is sometimes found as a salt, but the WHO recommends use of the base product.

The regime described below is recommended by the WHO for use in settings where compliance may be difficult and dosing regimes need to be simplified.

**Dose:** 6 tablets 100 mg on days 1 and 2, then 3 tablets 100 mg on day 3 or 4 tablets 150 mg on days 1 and 2, then

2 tablets 150 mg on day 3. **Total dose** = 1500 mg base (= 2500 mg salt).

There is some evidence of resistance to chloroquine in India and Indonesia, but it is difficult to determine whether apparent failure of the treatment is due to recurrence from hypnozoites or to drug failure. There has been little evidence from efficacy studies.

**Note:** ACTs cure all types of malaria, but chloroquine is still effective (and cheaper) for treating most cases of *P. vivax*, *P. malariae* and *P. ovale*.

As mentioned above, chloroquine only kills the parasites in the red blood cells, and does not kill the pre-erythrocyte forms or the hypnozoites of the recurrent malarial *P. vivax* and *P. ovale* in the liver.

At present **primaquine** is the only drug available to tackle the hypnozoites and prevent recurrence.

### Treatment with primaquine

**Primaquine is the only drug at present available to prevent recurrent attacks of *P. vivax* and *P. ovale*.** However, it is not recommended for pregnant women, so treatment with this drug should wait until the pregnancy has ended.

## 2.8.E Acute appendicitis

### Introduction

Appendicitis should be suspected in any woman or girl with abdominal pain, whether she is pregnant or not. The diagnosis of appendicitis can be more difficult in pregnancy, due to the possibility of pregnancy-related conditions, including ectopic pregnancy, abruptio placentae, torsion of an ovarian cyst and pyelonephritis.

As pregnancy advances, the enlarging uterus displaces the appendix from its usual position, shifting the site of maximal tenderness towards the right upper quadrant (see Figure 2.8.E.1). In the third trimester, it may consequently mimic cholecystitis. The site of an incision for appendicectomy should be over the point of maximum tenderness.

### Clinical management

If appendicitis is suspected clinically, give a combination of antibiotics before surgery, and continue until the woman is post-operative and fever-free for 48 hours:

- ampicillin 2 grams IV every 6 hours
- plus gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours
- plus metronidazole 500 mg IV every 8 hours.

Morphine 10 mg IV or IM may be administered as analgesia (see Section 1.16).

Immediate surgical exploration is required, regardless of the stage of gestation. Appendicectomy should be performed even if the appendix does not look infected.

**Delaying diagnosis and treatment can result in rupture of the appendix, which may lead to generalised peritonitis. This has a high maternal mortality in pregnancy, as well as a significant risk of miscarriage or preterm labour.**

If there are **signs of peritonitis** (fever, rebound tenderness and guarding), give antibiotics above as for peritonitis but continue until the infection has fully resolved (usually following surgery) and there has been no fever for 48 hours.

**If appendicitis occurs in late pregnancy**, the infection may be walled off by the gravid uterus. As the uterus rapidly decreases in size (involutates) after delivery, the infection may spill into the peritoneal cavity. In these cases, appendicitis then presents as generalised peritonitis.

**FIGURE 2.8.E.1** The changes in position of the appendix as pregnancy advances. Adapted from McGraw-Hill Companies, Inc. Reproduced with the permission of Chris Paschalidis.

## 2.8.F Cystitis and acute pyelonephritis

### BOX 2.8.F Minimum requirements

- Microscopy and bacterial culture.
- Dipstick tests for leucocytes and nitrites.
- Antibiotics (e.g. ampicillin, gentamicin).
- Ultrasonography.

### Acute cystitis

Cystitis is a common complication of pregnancy, and is characterised by dysuria, frequency, urgency and, if severe, by haematuria. Severe cystitis can progress to pyelonephritis if not treated. The presence of loin pain and tenderness, along with fever, suggests a diagnosis of pyelonephritis.

Asymptomatic cystitis is more common in pregnancy, carries a risk of progression to pyelonephritis, and is associated with an increased risk of premature delivery.

### Diagnosis

- Use a dipstick leucocyte esterase test to detect white blood cells, and a nitrate reductase test to detect nitrites.
- Microscopy of a urine specimen (see Section 8.5) may show white blood cells in clumps, bacteria and sometimes red blood cells. Urine examination requires a clean-catch midstream specimen of urine to minimise the possibility of contamination. The results of bacterial culture, although not necessary before starting treatment, are helpful if there is treatment failure, and also for monitoring bacterial sensitivity in the population.

### Treatment with antibiotics for uncomplicated cystitis

- Amoxicillin 500 mg by mouth three times a day for 5 days or cephalexin (or alternative available cephalosporin) 500 mg three times a day for 5 days.
- Trimethoprim/sulfamethoxazole 1 tablet 160/800 mg

by mouth twice a day for 3 days. **This drug is best avoided in pregnancy** unless there is no alternative. It must be completely avoided in the first trimester. This antibiotic is a folate antagonist and therefore promotes congenital abnormalities, and in the third trimester it may cause haemolysis in the neonate.

- If treatment fails, check urine culture and sensitivity (if available), and treat with an antibiotic appropriate for the organism.

### Acute pyelonephritis

Acute pyelonephritis is an acute infection of the upper urinary tract, mainly of the renal pelvis, which may also involve the renal parenchyma. It can precipitate premature labour.

- If shock is present or suspected, initiate immediate ABC treatment.
- Check urine culture and sensitivity (if available), and treat with an antibiotic appropriate for the organism.
- If urine culture is unavailable, treat with antibiotics until the woman has been fever-free for 48 hours:
  - ampicillin 2 grams IV every 6 hours
  - *plus* gentamicin 80 mg IM/IV every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours.
- Once the woman has been fever-free for 48 hours, give amoxicillin/ampicillin 500 mg by mouth three times a day to complete 14 days of treatment.
- If there is no clinical response within 72 hours, review the results and antibiotic coverage.

Alternative and/or second line treatment is with IV cephalosporins, e.g. cefuroxime 750 mg to 1.5 g 8-hourly.

- Perform a renal ultrasound scan. If any significant malformation of the kidneys or renal tract is noted, refer the patient for specialist advice.

## 2.8.G Tuberculosis in pregnancy

### BOX 2.8.G Minimum standards

- Mantoux test/purified protein derivative.
- Sputum for acid-fast bacilli for stain and culture.
- Chest X-ray.
- Anti-tuberculosis therapy.

### Introduction

Tuberculosis (TB) is generally becoming less common during pregnancy and in the fetus, even in high endemic countries, but remains a leading infectious cause of death during pregnancy and delivery, especially among women living with HIV. It is estimated that more than half a million women of child-bearing age die from TB (including HIV-related TB) each year, but the current epidemiology of TB in pregnancy is a reflection of the general incidence of disease. The infection has been associated with an increased risk of spontaneous abortion, perinatal mortality,

small-for-gestational age and low birth weight in some studies. Poor outcome is attributable to delays in diagnosis or treatment, increasing the frequency of severe forms of extra-pulmonary disease.

### Clinical findings

Signs and symptoms of TB are usually the same in both pregnant and non-pregnant woman. They include prolonged fever (especially at night), cough, weight loss, fatigue and breathing difficulty. Extra-pulmonary disease will present with organ-specific signs and symptoms such as lymphadenopathy, abdominal pain or mass, back pain, vaginal bleeding, pelvic inflammatory disease symptoms or infertility.

### Diagnosis

Any woman who presents to an antenatal clinic with chronic respiratory symptoms, or has had close contact with a TB index case, or unexplained illness, should be screened

for TB. This includes a tuberculin skin test, sputum for acid-fast bacilli (AFB) stain and culture for mycobacterium TB. A chest X-ray may have harmful effects on the fetus in the first trimester of pregnancy, but may be done with an abdominal lead shield. If clinically indicated a Chest X-ray is recommended as the risk to the fetus is very small and the mother's health a priority.

Additional newer tests, namely interferon gamma release assay (IGRA) or polymerase chain reaction (PCR) identification (if available), may complement diagnosis.

Extra-pulmonary TB is much more difficult to diagnose during pregnancy. After delivery, the placenta should be sent for histopathology, AFB stain and AFB culture to contribute to a diagnosis. The neonate should be evaluated thoroughly and treated accordingly.

### Antituberculous treatment during pregnancy

During pregnancy, tuberculosis represents a greater hazard to the pregnant woman and her fetus than does its treatment. Therefore treatment should be commenced as soon as possible after a diagnosis has been made. Treatment for new patients with pulmonary TB is the same in pregnancy as it is for all other adults (see WHO guidelines 4th edition 2010 for full details: [www.who.int/tb/publications/2010/9789241547833/en/](http://www.who.int/tb/publications/2010/9789241547833/en/)).

In summary, new patients with pulmonary TB should be treated with a regime containing isoniazid (H) and rifampicin (R) for 6 months (see Table 2.8.G.1 for doses). There is an initial 2-month intensive phase of HRZE and then a 4-month continuation phase of just HR.

The optimal dosing frequency is daily throughout the 6-month course. However, provided directly observed treatment is practiced and the patient is not living with HIV infection or in a high risk setting for HIV the last 4 months of treatment can be given three times a week.

Isoniazid, ethambutol and rifampin are relatively safe for

the fetus. In some countries, the routine use of pyrazinamide is discouraged because of inadequate teratogenicity data, but the WHO continues to recommend it as first-line therapy. The benefits of ethambutol and rifampin for therapy of tuberculosis disease in the mother outweigh the risk to the infant.

The use of these first-line antituberculous drugs in pregnancy is considered safe for the mother and the baby by the British Thoracic Society, International Union Against Tuberculosis and Lung Disease, and the World Health Organization.

The effects of other second-line drugs on the fetus are unknown, and their use during pregnancy must be undertaken only after a careful risk and benefit analysis.

Fixed-dose combinations (FDCs) are recommended in both children and adults, but drugs can be given separately as well. Tablets are the preferred formulation, even in children, as they prevent the emergence of resistance and improve compliance.

The WHO-recommended two-, three- and four-drug FDC schemes are simplified for clinical use according to body weight, and ensure that the doses remain within the therapeutic margins, and that underlying liver and renal impairment is considered (see Tables 2.8.G.1 and 2).

### Drugs that are contraindicated during pregnancy

These include the following:

- streptomycin (which interferes with development of the ear and may cause congenital deafness)
- kanamycin, amikacin and capreomycin
- fluoroquinolones (ciprofloxacin, levofloxacin, ofloxacin and sparfloxacin)
- other second-line drugs (cycloserine, ethionamide and clofazimine).

**TB treatment during pregnancy is the same for pregnant women as it is for non-pregnant women.**

**TABLE 2.8.G.1** Commonly used drugs for the treatment of TB in pregnancy

Drug	Daily dose (mg/kg/when given daily)	Daily dose when given three times weekly	Potential adverse reactions
Isoniazid (H) tablet, 100 mg, 300 mg	5 mg/kg (4–6 mg/kg) Maximum 300 mg	10 mg/kg (8–12 mg/kg) Maximum 900 mg	Mild hepatic enzyme elevation, hepatitis, peripheral neuritis, hypersensitivity
Rifampin (R) tablet, 150 mg, 300 mg, 450 mg	10 mg/kg (8–12 mg/kg) Maximum 600 mg	10 mg/kg (8–12 mg/kg) Maximum 600 mg	Orange discoloration of urine and other body fluids, vomiting, hepatitis
Pyrazinamide (Z) tablet, 500 mg	25 mg/kg (20–30 mg/kg)	35 mg/kg (30–40 mg/kg)	Hepatotoxicity, hyperuricaemia
Ethambutol (E) tablet, 100 mg, 400 mg	15 mg/kg (15–20 mg/kg)	30 mg/kg (25–35 mg/kg)	Optic neuritis, decreased visual acuity, gastrointestinal disturbance, hypersensitivity
Four-drug FDC tablet, R 150 mg + H 75 mg + Z 400 mg + E 275 mg	Dosage recommendations are more straightforward, and adjustment of dosage is done according to patient weight category		
Three-drug FDC tablet, R 150 mg + H 75 mg + Z 400 mg			
Two-drug FDC tablet, R 300 mg + H 150 mg			
Two-drug FDC tablet, H 150 mg + E 400 mg			

H = isoniazid, R = rifampicin, Z = pyrazinamide, E = ethambutol, S = streptomycin, FDC = fixed drug combination.

- A **three- to four-drug regimen** of isoniazid, rifampin and pyrazinamide with or without ethambutol is recommended for uncomplicated pulmonary TB (see Table 2.8.G.1).
- If pyrazinamide treatment is included in the initial drug regimen, after an **initial 2 months of three to four drugs**, therapy is continued with **two drugs** (isoniazid and rifampin) to complete **at least 6 months of therapy**.
- If pyrazinamide is not used, the two-drug period should be extended to at least 9 months.
- Prompt initiation of therapy is mandatory to protect the mother and the fetus.

**Streptomycin should not be used in pregnancy, as it crosses the placenta and can cause auditory nerve impairment and nephrotoxicity in the fetus.**

Vitamin K should be administered at birth to the infant of a mother taking rifampicin because of the risk of postnatal haemorrhage.

Pyridoxine (vitamin B<sub>6</sub>) 10 mg daily is recommended for pregnant or breastfeeding women who are taking isoniazid-containing regimens.

Extra-pulmonary TB in pregnant women requires the same regimens as uncomplicated pulmonary TB. Some forms (e.g. meningitis, bone, joint) require a longer duration (9–12 months) of TB drugs.

If a woman has suspected resistant TB, attempts must be made to confirm drug resistance by appropriate cultures and therapy based on susceptibility results. Regimens are complicated and depend on susceptibilities, previous drug therapy, local susceptibility data, availability of second-line drugs and tolerability. **An expert in infectious disease must be consulted in such cases.** Pregnant women with resistant TB have a less favourable prognosis. They may sometimes require treatment with second-line drugs, including cycloserine, ofloxacin, amikacin, kanamycin, capreomycin and ethionamide. The safety of these drugs is not well established in pregnancy.

### Breastfeeding and TB

The low concentrations of anti-TB drugs in breast milk do not produce toxicity in the nursing newborn. Therefore breastfeeding should not be discouraged for an HIV-seronegative woman who is planning to take or is taking anti-TB drugs. Anti-TB treatment is the best way to prevent transmission of tubercle bacilli to the baby. Mother and baby should stay together and the baby should continue to breastfeed. After active TB in the baby is ruled out, the baby should be given 6 months of isoniazid preventive therapy, followed by BCG vaccination (for advice on breastfeeding and HIV, see Section 6.2.D). Breastfed infants do not require pyridoxine supplementation unless they are receiving isoniazid.

### Treatment of latent TB infection

In most pregnant women, treatment of latent TB infection (LTBI) – that is, treatment of asymptomatic pregnant women with a positive tuberculin test or IGRA result and normal chest X-ray – should be delayed until 2 or 3 months after delivery, even though no harmful effects of isoniazid (INH, the standard treatment regimen for LTBI) on the fetus have been documented.

However, in the following situations where there is a high risk of progressing to active disease, treatment for LTBI with isoniazid (INH), 300 mg daily should begin during pregnancy.

Treatment of LTBI should be started **during the first trimester** of pregnancy for:

- pregnant women who have HIV infection or behavioural risk factors for HIV infection, but who refuse HIV testing
- pregnant women who have been in recent close contact with an individual with smear-positive pulmonary TB.

Treatment of LTBI should be started **after the first trimester** of pregnancy for pregnant women who have had a documented tuberculin skin test conversion in the past 2 years.

Treatment of LTBI, if indicated, should be started 2 to 3 months after delivery for all other pregnant women, including those with radiographic evidence of old healed TB. The recommended duration of LTBI therapy is 9 months. If a woman who is taking isoniazid and/or rifampin for treatment of LTBI becomes pregnant, treatment should be interrupted and started again 2 or 3 months after delivery, unless one or more of the above risk factors are present.

### Perinatal TB

Women who have only pulmonary TB are not likely to infect the fetus, but can infect their infant after delivery. Although protection of the infant from exposure and infection is of paramount importance, continuous close contact between infant and mother should be encouraged. Congenital TB is rare, but *in-utero* infections can occur after maternal bacteraemia. If a newborn infant has suspected congenital TB, a full evaluation should be done and treatment initiated based on individual circumstances and specific recommendations. Management of the newborn infant is based on categorisation of the maternal (or household contact) infection as follows:

- If the mother has completed TB chemotherapy during pregnancy, or has inactive disease, her infant should be given BCG at birth.
- If the mother has active disease or still requires treatment, the infant should be given isoniazid 10 mg/kg once daily for 3 to 6 months.
- Once the mother and infant are on appropriate treatment, the infant may breastfeed unless the mother has multidrug-resistant TB. A tuberculin test and chest X-ray are then performed on the neonate. If these are negative, BCG is given. If they are positive, full investigations for TB are undertaken. If no evidence of disease is detected, isoniazid is continued for another 3 to 4 months. If TB is suspected, full treatment is given at standard doses.

### Monitoring

All pregnant women with TB must be carefully followed up monthly. At each visit, the patient needs to be checked for compliance, response to therapy, adverse effects and adjustment for any clinical event.

### Directly observed treatment

**Directly observed treatment: short-course (DOTS)** remains an important WHO strategy for reducing the TB burden worldwide. In DOTS, healthcare workers observe patients as they take their medicine. DOTS is practised even for children, and parents can be asked to supervise treatment in the communities where DOTS is used. This is especially true for HIV-infected children, patients with multi-drug-resistant (MDR) TB or those with complicated TB, and has been shown to be successful.

The WHO has developed a new six-point **Stop TB Strategy**, which builds on the successes of DOTS. One of these is to 'pursue high-quality DOTS expansion and enhancement' through the following steps.

- 1 Secure political commitment, with adequate and sustained financing.
- 2 Ensure early case detection and diagnosis through quality-assured bacteriology.
- 3 Provide standardised treatment with supervision and patient support.
- 4 Ensure effective drug supply and management.
- 5 Monitor and evaluate performance and impact.

## 2.8.H Syphilis in pregnancy and the newborn infant

### Introduction

Syphilis is a dangerous bacterial infection caused by *Treponema pallidum* which, when it occurs in pregnancy, can cause early fetal death, stillbirth, preterm birth, neonatal death or congenital infection. Mother-to-child transmission is a major problem, especially in resource-limited countries.

In a recent analysis, it was estimated that in 2008 worldwide there were between 1.2 and 1.6 million pregnant women with active syphilis, of whom 39% were living in Africa. In the absence of screening and treatment this would have resulted globally in 707 000 adverse pregnancy outcomes, including 286 000 stillbirths or early fetal deaths, 122 000 neonatal deaths, 82 000 preterm or low-birth-weight babies and 218 000 infected newborn infants. Additional mortality after the first month of life was estimated to be 10% by 1 year of age.

The cost of diagnosis and treatment per individual is US\$2.

All countries must ensure that all pregnant women have access to antenatal care that includes diagnostic screening and treatment for syphilis.

### Clinical features

Infection is either congenital (through *in-utero* transfer) or acquired (through sexual transmission or blood transfusion). The average time between acquired infection and the appearance of symptoms and signs is 21 days, but this period can range from 10 to 90 days.

Acquired syphilis has early and late phases. The early phase has primary, secondary, early latent (hidden and < 1 year), late latent (hidden > 1 year) and tertiary stages.

The early stages are more infectious and respond best to penicillin treatment.

The symptoms and signs can resemble those of many other diseases.

### Primary stage

The chancre is firm, round, painless and usually single, but may be multiple at the location where syphilis entered the body. Chancres may not be visible in the vagina or anus. The chancre lasts for 3 to 6 weeks, and heals whether or not it is treated. If untreated, the infection progresses to the secondary stage.

### Secondary stage

A non-itchy skin rash and/or mucous membrane lesions (sores in the mouth, vagina or anus) occur. This stage typically starts with the development of a rash on one or more areas of the body. The characteristic rash is rough red or reddish brown spots on the palms of the hands and the

soles of the feet. However, rashes with a different appearance may occur on other parts of the body, sometimes resembling rashes caused by other diseases. Sometimes the rashes are barely visible. Large raised grey or white lesions, known as condylomata lata, may develop in warm moist areas such as the mouth, underarm or groin region. In addition, there may be fever, swollen lymph glands, sore throat, patchy hair loss, headaches, weight loss, muscle aches and fatigue. The symptoms will resolve with or without treatment, but if not treated the infection will progress to the latent and possibly late stages of disease.

### Latent (hidden) and late stages

Without treatment, syphilis infection can persist without showing any signs or symptoms. **Early latent syphilis** is latent syphilis where infection occurred within the past 12 months. **Late latent syphilis** is latent syphilis where infection occurred more than 1 year ago.

**Late stages (tertiary syphilis)** develop in around 15% of people who have not been treated, and can appear 10–20 years after infection was first acquired. In the late stages of syphilis, the disease may damage the internal organs, including the brain, nerves, eyes, heart, blood vessels, liver, bones and joints. Symptoms of the late stages of syphilis include difficulty coordinating muscle movements, paralysis, numbness, gradual blindness and dementia.

When it invades the nervous system, at any stage of infection, syphilis causes headache, altered behaviour, and movement disorders that occur in Parkinson's and Huntington's disease.

HIV infection modifies the symptoms and signs described above, including hypopigmented skin rashes. There is also a greater likelihood of neurological involvement.

Where disease is prevalent, most cases are asymptomatic. At least 50% of women with acute syphilis have adverse pregnancy outcomes. The more recent the maternal infection, the more likely it is that the fetus and infant will be infected.

Congenital syphilis is divided into early (becoming apparent in the first 2 years of life) and late (becoming apparent after the first 2 years of life) types. At birth the following can be present: low birth weight, hepato-splenomegaly, pallor, jaundice and purpura, blisters or peeling of palms and soles. There can be difficulties in feeding and rhinorrhea. If not treated immediately, the newborn baby may remain asymptomatic but more commonly develops serious problems within a few weeks affecting many body systems. Untreated babies may become developmentally delayed, have seizures or die.

Late congenital syphilis can present with the following: blunted upper incisor teeth known as Hutchinson's teeth,

inflammation of the cornea known as interstitial keratitis, deafness from auditory nerve disease, frontal bone bossing, a saddle nose (collapse of the bony part of nose), defects of the hard palate, swollen knees, saber like shins, short maxillae and protruding mandible. A frequently-found group of symptoms is Hutchinson's triad, which consists of Hutchinson's teeth (notched incisors), keratitis and deafness and occurs in 63% of cases.

Treatment (with penicillin) before the development of these late symptoms is essential.

Congenital syphilis may occur if the expectant mother has syphilis, but the risk is minimal if she has been given penicillin during pregnancy. Congenital syphilis does not cause congenital malformations as infection of the fetus in early pregnancy is lethal.

Treatment with penicillin is extremely effective (98% success rate) in preventing mother-to-child transmission.

### Diagnosis

There are two types of blood tests available, namely non-treponemal tests and treponemal tests.

**Non-treponemal tests** (e.g. VDRL and RPR) are simple, inexpensive, and are often used for screening. Ideally, women with a reactive non-treponemal test should receive a treponemal test to confirm a syphilis diagnosis.

Their sensitivity increases from primary to secondary syphilis, and their specificity is high in the absence of another chronic condition.

The on-site RPR card test is quick and simple to use, allowing immediate treatment to be given. A simple strip of paper impregnated with treponemal antigen is used to test a finger-prick sample of blood.

**Treponemal tests** such as the *Treponema pallidum* haemagglutination assay (TPHA) and Rapid Syphilis Test have higher sensitivity and specificity and measure antibodies that are specific for syphilis. Treponemal antibodies appear earlier than non-treponemal antibodies and usually remain detectable for life, even after successful treatment, and therefore do not correlate with disease activity.

All pregnant women should be screened for syphilis at their first antenatal visit with an on-site RPR or other rapid test and to prevent congenital infection, preferably before 16 weeks' gestation and again in the third trimester.

All women who were not screened or tested during pregnancy should be screened at or immediately after delivery.

All infants born to mothers who have positive non-treponemal and treponemal test results should be evaluated for congenital syphilis.

Advise women who test positive that their partner(s) must also be investigated and treated if positive.

Test all women with a history of adverse pregnancy outcome (e.g. abortion, stillbirth, syphilitic infant) for syphilis.

Screen all women with syphilis for other sexually transmitted and HIV infections.

### Treatment of pregnant women with syphilis

#### Early syphilis (primary, secondary or latent syphilis of not more than 2 years' duration)

Give benzathine benzylpenicillin, 2.4 million IU intramuscularly (check that it is not injected into a vein), in a single

session. Because of the high volume, this is usually given as two injections at separate sites.

Alternatively, give procaine benzylpenicillin 1.2 million IU intramuscularly (check that it is not injected into a vein) daily for 10 consecutive days.

If the patient is allergic to penicillin, give ceftriaxone 500 mg IM/IV daily for 10 days. Erythromycin does not cross the placenta to treat the fetus.

#### Late latent syphilis (infection of more than 2 years' duration)

Give benzathine benzylpenicillin, 2.4 million IU intramuscularly (check that it is not injected into a vein), once weekly for 3 consecutive weeks.

Alternatively, give procaine benzylpenicillin, 1.2 million IU intramuscularly (check that it is not injected into a vein), once daily for 20 consecutive days.

If the patient is allergic to penicillin, give ceftriaxone 500 mg IM/IV daily for 14 days or (although this is less effective) erythromycin, 500 mg orally, four times a day for 30 days.

#### Treatment of congenital syphilis

All asymptomatic newborn infants born to seropositive mothers should be treated with a single IM dose of benzathine benzylpenicillin, 50 000 IU/kg, whether or not their mothers were treated during pregnancy. Routine CSF examination is not required.

Newborn infants with any signs of congenital syphilis should receive:

- aqueous benzylpenicillin, 100 000–150 000 IU/kg/day administered as 50 000 IU/kg/dose IV every 12 hours, during the first 7 days of life, and every 8 hours thereafter for a total of 10 days
- or
- procaine benzylpenicillin, 50 000 IU/kg by IM injection, as a single daily dose for 10 days (ensure that it is not injected into a vein).

Early congenital syphilis generally responds well to penicillin. Recovery may be slow in seriously ill children with extensive skin, mucous membrane, bone or visceral involvement.

For older infants up to 2 years of age with confirmed congenital syphilis the treatment is the same as above.

If the patient is allergic to penicillin (this is unusual), give ceftriaxone 80 mg/kg IM/IV once daily for 10 days or give erythromycin, 7.5–12.5 mg/kg orally, four times a day for 14 days but erythromycin is less effective.

For infants older than 2 years, give aqueous benzylpenicillin, 200 000–300 000 IU/kg/day by IM/IV administered as 50 000 IU/kg/dose every 4–6 hours for 10–14 days.

An alternative regimen for penicillin-allergic patients after the first month of life is to give erythromycin, 7.5–12.5 mg/kg orally, four times a day for 30 days.

#### Jarisch–Herxheimer reaction

After starting penicillin treatment in some patients, the death of the bacteria results in the release of mediators that produce the adverse symptoms and signs such as myalgias, fever, headache and tachycardia, sometimes with exacerbation of whatever current syphilitic lesions are manifested (e.g. rash, chancre).

This reaction develops within several hours after

beginning antibiotic treatment, and usually clears within 24 hours after its onset. It is very rare in newborn infants.

Management consists of symptomatic treatment (e.g. antipyretics, analgesics) and observation. In pregnancy, treatment may induce early labour or cause fetal distress. Patients should be informed of the possibility of this reaction

before undergoing antibiotic therapy. However, this risk should not preclude or delay therapy for syphilis. Women are advised to seek obstetric care after treatment if they notice any fever, uterine contractions, or a decrease in fetal movement.

## 2.8.1 Varicella zoster (chickenpox) in pregnancy

### Introduction

Pregnant women and newborn infants are at risk of severe disease from varicella, involving serious effects on organs such as the lungs.

Varicella is transmitted from respiratory aerosols and skin lesions in chickenpox itself, and from the skin lesions but not aerosols in shingles (which is not infectious until the skin lesions appear).

In chickenpox, patients are infectious for 48 hours prior to emergence of the rash and until all of the skin lesions are crusted over.

The incubation period is 10–21 days.

Non-immune patients are those without a history of chickenpox or shingles or a completed vaccination profile. Immune status can be checked with blood varicella IgG measurement (if available).

### Clinical features in pregnancy

#### ***Congenital varicella syndrome (CVS)***

In the first or early second trimester infection may result in stillbirth, or the neonate may be born with a group of physical abnormalities known as congenital varicella syndrome (CVS). This is rare, occurring in 1–2.8% of women infected with chickenpox in the first 20 weeks of gestation (the period of maximum risk is between 12 and 20 weeks' gestation). There may be dermatomal scarring, limb hypoplasia, ocular abnormalities, low birth weight and early death. Survivors may have long-term developmental problems. An infant with CVS has a 30% risk of mortality in the first few months of life, and a 15% risk of developing herpes zoster between 2 months and 3 years of life.

#### ***Varicella pneumonia***

Pregnant women with chickenpox may be more likely than non-pregnant women to develop severe pneumonitis. The risk is greatest in the third trimester, especially if lung disease is already present, or if the patient is a smoker or is immunocompromised (e.g. due to HIV infection).

Symptoms start as a non-productive cough, which can rapidly progress to respiratory failure within 36–48 hours. The cough becomes increasingly productive, with tachypnoea, dyspnoea, cyanosis and chest pain.

#### ***Perinatal infection***

If a neonate is exposed (mother has a rash) around the time of birth (from 5 days before to 2 days after delivery), there is a 17–30% risk of dangerous perinatal infection. This is characterised by skin lesions, disseminated intravascular

coagulation, pneumonitis and hepatitis, and it has a mortality of up to 30%.

### Management

#### ***Maternal contact with varicella during pregnancy***

If the patient is immune (see above for definition), no treatment or isolation is required.

If she is non-immune and an IgG test is not available and affordable, then if she has had a significant contact with chicken pox or shingles then give varicella zoster immunoglobulin (VZIG) (see below for details) within 4 days of contact if possible (maximum of 10 days after contact). Avoid contact with other pregnant women. The patient should be counselled regarding the signs of infection so that she can be treated early if it occurs.

Significant exposure to chicken pox occurs after very limited contact with an infected person (any face to face contact and as little as 15 minutes in the same room as an infectious patient). The risk of contracting chicken pox from exposure to shingles is very low if the infection is not in an exposed area.

#### ***Chickenpox during pregnancy***

If this is **mild**, give oral aciclovir (see below for dose regimen) for 7 days, starting within 24 hours of the appearance of vesicles, and avoid contact with other pregnant women. In mild cases, aciclovir leads to little improvement. It is most important in women at risk of severe disease (immuno-compromised, HIV infected, history of respiratory disease or smoking).

If it is **severe**, give IV aciclovir for 7 days. High-dependency care should be provided if available, as appropriate.

#### ***Prevention of neonatal chickenpox if the mother is infected from 7 days before to 7 days after birth***

Give VZIG to the neonate as soon as possible after delivery. Isolate the mother and infant.

In addition, give IV aciclovir to the neonate if the onset of maternal symptoms was between 4 days before, and 2 days after the birth.

#### ***Infant in contact with chickenpox other than from mother, or from mother who develops chickenpox more than 7 days after the birth***

If the mother is immune and the infant is full term at birth, no prophylaxis is needed. Mild illness may occur.

If the mother is not immune and the infant is less than 4 weeks of age, and full term at birth, give varicella zoster immunoglobulin (VZIG) (if available).

If the infant is preterm, and regardless of maternal immunity, give VZIG.

Regardless of whether VZIG is given, monitor the baby for signs of infection to enable early treatment should infection occur.

Shingles is very rare in infants and, if present, suspect HIV infection.

### Doses of VZIG and aciclovir

#### *In pregnancy*

**Aciclovir** is of no benefit if commenced more than 24 hours after the appearance of chickenpox vesicles.

- Oral route: 800 mg five times daily for 7 days (mildly ill cases only).
- IV route: 10 mg/kg/dose every 8 hours for 7 days.

Side effects include nausea, vomiting, diarrhoea, headache and nephrotoxicity. Reduce the dose or dosage interval in patients with impaired renal function.

**Varicella zoster immunoglobulin (VZIG):** 1 gram IM. Anaphylaxis is rare, but ensure that adrenaline is available.

#### *In the neonate*

**Aciclovir** 10–20 mg/kg IV every 8 hours for at least 7 days. Side effects are as described above.

**Varicella zoster immunoglobulin (VZIG):** 250 mg by deep IM injection.

## 2.9

# Mental health problems associated with pregnancy and the postnatal period

### BOX 2.9.1 Minimum standards

- Screening tools for depression, such as the Edinburgh Postnatal Depression Scale (EPDS).
- Selective serotonin reuptake inhibitor (SSRI) antidepressant drugs.
- Ideally, an inpatient hospital facility for mothers and babies when the mother has puerperal psychosis.
- Antipsychotic drugs.

### Introduction

Childbirth poses a risk to a woman's mental health. This applies to all women and girls who become pregnant in all countries, irrespective of their social and cultural background. However, the background will influence how a mother presents and how quickly she receives appropriate care.

Much of the research about pregnancy-related mental illness and its effects on the new baby has been done in high-income countries where it has been possible to develop specialised services. However, there is evidence that mental health problems in mothers are as common in low- and middle-income countries. A number of risk factors that have been suggested as underlying maternal depression are listed in Box 2.9.2.

Perinatal psychiatric services have developed in many high-income countries, and involve liaison between psychiatric and obstetric services. The specialty covers women with pre-existing mental health problems who want to have a family, as well as mental illness that is first diagnosed antenatally and postnatally. Maintaining the mental health of a pregnant woman benefits the family, and in some cases can prevent problems from developing postnatally. The onset of depression and anxiety in pregnancy or postnatally can be especially worrying for a woman and her family because it is contrary to their expectations that this will be a happy time. The woman may not want to admit how she is feeling,

### BOX 2.9.2 Risk factors for development of maternal depression in low- and middle-income countries

- Poverty and high levels of economic stress
- Low levels of social support
- Domestic violence
- Chronic maternal illness
- Maternal anaemia
- Lack of awareness among primary healthcare workers of depression as an illness
- Social stigma associated with a family member being diagnosed with a mental illness
- Families with four or more children, especially when the children are under 7 years of age
- Having a preterm infant or an infant with a low birth weight
- Having a child with a developmental disability
- Having an unplanned or unwanted infant
- Having a female child in a culture where there is a strong preference for male children
- Lack of participation in family financial decisions, control of resources and reproductive health

Adapted from Wachs, Black and Engle (2009).

being ashamed both of her inability to feel joy about her newborn baby and of her perceived inability to cope, and fearing that she will be judged harshly for these feelings. This is especially important in countries and cultures where women and girls are not valued and their main role is perceived to be the production of healthy babies.

Mild antenatal and postnatal depression can be managed with minimal resources and does not require medication. Recognition of the condition and practical help from family and friends can be enough to prevent depression affecting the care of the baby. Reassurance from

healthcare professionals can help the mother and her family to realise that she is not on her own in her feelings. To a depressed new mother it can feel as if every other mother is better than her, and to know that this is not the case can be extremely helpful. If antidepressants are available they may, in selected cases, speed up recovery (see below).

However, there are serious psychiatric conditions associated with childbirth that can necessitate prompt psychiatric treatment and admission of the mother to a psychiatric hospital, preferably with her baby. The most serious of these conditions, puerperal psychosis, has been described as the only true psychiatric emergency. Usually rare, this condition is more common in women who have had a manic episode and have been diagnosed with bipolar affective disorder. A history of a previous episode of puerperal psychosis considerably increases the risk of having another episode following subsequent pregnancies. Knowing that a woman is at risk provides an opportunity for prevention – either of the illness itself, or of the repercussions of the illness if it has not been possible to prevent it.

### Antepartum psychiatric disorders

There is evidence that psychiatric symptoms occur as frequently antenatally as postnatally, with an estimated prevalence of 10–15%. The symptoms are often of mild depression and anxiety. Careful enquiry may reveal that the symptoms were present before conception. The development of a serious psychiatric condition in the antenatal period is no more common than at other times, but if a diagnosis is made during pregnancy, the decision to start medication has to balance the severity of the mother's illness against the adverse effects of medication on the fetus.

Women with mild symptoms usually present early in pregnancy, and may improve as the pregnancy progresses. Hyperemesis can make the first trimester miserable and lead women to express thoughts of rejecting the pregnancy. Sometimes this is mistaken for evidence of depression. The third trimester can be a time of anxiety about labour and the impending birth, especially for first-time mothers or those who have had previous complicated deliveries. The factors that make women and girls more vulnerable are listed in Box 2.9.3.

Supportive counselling is often sufficient to improve the mental health of most women, but if antidepressants are indicated, there needs to be a discussion about the risks and benefits before they are prescribed. The selective serotonin reuptake inhibitors (SSRIs) fluoxetine and sertraline seem to have the best safety profile, but new information is emerging as more women take antidepressants in pregnancy and clinicians continually evaluate the safety profile of this class of drugs. There is increasing evidence that the SSRI antidepressants, especially paroxetine, are associated with an increased risk of cardiac abnormalities in the baby if taken during embryogenesis. However, the risk is still relatively low (4%), and has to be balanced against the risks to the pregnancy if the depression is left untreated. If SSRIs are not available, tricyclic antidepressants can be effective, but prescribers must be wary of patients with suicidal ideation, as the tricyclic antidepressants are more dangerous than SSRIs when taken in overdose.

A woman with an established diagnosis of bipolar disorder may be taking a mood stabiliser such as **lithium, sodium valproate or carbamazepine**, and **these are**

**associated with increased fetal malformations**, so consideration needs to be given to stopping them prior to conception. In women in whom relapse has occurred when stopping lithium, the balance between risks and benefits is probably in favour of continuing the drug. This is less likely to be the case for sodium valproate or carbamazepine.

#### BOX 2.9.3 Factors that increase the risk of antenatal depression and/or anxiety

- Previous obstetric loss
- Previous fertility problems
- Anxiety about the viability of the pregnancy
- Social and interpersonal adversity
- Feelings of ambivalence about the pregnancy
- Previous depression and/or anxiety associated with pregnancy

### Postpartum psychiatric disorders

Psychiatric disorders that present postnatally are traditionally classified into three types as shown in Box 2.9.4. Other conditions can also present at this time, and it has been suggested that the term **postnatal common mental disorders** is more useful for distinguishing the milder depressive, anxiety and obsessional disorders from the more severe depressive disorders and puerperal psychosis.

#### BOX 2.9.4 Postpartum-onset psychiatric disorders

##### Maternity blues

##### Postnatal depression

- Mild
- Moderate
- Severe

##### Puerperal psychosis

##### Anxiety and obsessive-compulsive disorders

### Maternity blues

This is generally a mild and self-limiting condition that affects over 50% of women, usually between day 3 and day 10 postnatally, but most commonly on day 5. A hormonal cause has been postulated for this transient condition, which is marked by variability of mood, feelings of confusion, irritability, insomnia and a feeling of not being able to cope. It is generally self-limiting, although if it is longer-lasting or more severe than usual, it can herald problems later in the postnatal period. Reassurance is usually sufficient to help the woman through this period, which usually last about 48 hours.

### Postnatal depression

It is estimated that around 10% of women develop symptoms of depression postnatally. The majority of these symptoms will be relatively mild and overlap with the process of adjusting to having a baby, particularly (although not exclusively) following the birth of a first child. In most cases a diagnosis will not be made until about 6 weeks after the onset of the depression.

Symptoms are not dissimilar to those that occur in non-puerperal depression, but sleep and appetite are

often disrupted because of the baby's presence, so different questions may need to be asked in order to elicit a diagnosis. The mother may not recognise that she is depressed and so does not share how she is feeling. The commonly experienced anhedonia (inability to feel pleasure) is particularly difficult at this time, when the mother (and those around her) feels that she should be happy. This can lead her to conclude that she is a poor mother. Meanwhile others, particularly in western cultures, may state that there is a problem with bonding, which can exacerbate her guilt and low mood. Obsessional symptoms and irritability are also often reported.

The Edinburgh Postnatal Depression Scale (EPDS) is a screening tool (see Appendix) which has been translated into a number of languages and used across diverse cultural settings. It requires no psychiatric training to administer, and so can be used by healthcare workers to identify mothers who may be depressed.

Two recent studies in Ethiopia showed the EPDS to be less effective in rural areas than in urban ones. For rural Ethiopia the self-reporting questionnaire (SRQ) was considered to be superior. In urban areas the Kessler Psychological Distress Scale (which is used to assess psychological distress in various situations) and the EPDS were reported to be equally effective screening tools, but it was suggested that the Kessler Psychological Distress Scale may be more effective in detecting postnatal mental health disorders in this setting.

When the depression is mild, relatively simple interventions can be very effective, including listening to the mother's concerns, reassuring her that her feelings do not mean she is a bad mother, and giving practical help with the baby, allowing her to rest as much as possible. Antidepressants are not usually indicated in mild depression.

In cases of moderate depression with persistent low mood, reduced sleep and appetite, poor concentration, feelings of not being able to cope, and lack of improvement when practical help and support are given, antidepressants are likely to be needed. If available, sertraline or paroxetine are the SSRIs with the lowest relative infant dose (i.e. the amount passing to the infant through breast milk), so are the safest ones for breastfeeding mothers.

- **Sertraline:** starting dose is 50 mg, with a maximum dose of 200 mg daily.
- **Paroxetine:** starting dose is 20 mg, with a maximum dose of 60 mg daily.

The most commonly reported side effect for both of these drugs is nausea, which wears off after 2 to 3 weeks – the same time that it takes for the therapeutic effects to begin to appear – so the mother needs to be warned about this.

Imipramine and amitriptyline also appear to be safe in breastfeeding mothers.

- **Imipramine:** starting dose is 25 mg three times daily, increasing to a maximum total daily dose of 200 mg.
- **Amitriptyline:** starting dose is 25 to 100 mg total daily dose, given in three doses during the day or (usually more acceptably, because of its sedative effects) once at night. The maintenance dose is a total daily dose of 75 to 150 mg/day. Rarely a total daily dose of up to 300 mg may be used.

Side effects include sedation, postural hypotension, dry mouth, blurred vision, constipation, urinary retention

and increased body temperature. In overdose imipramine and amitriptyline are cardiotoxic, and this has to be considered when prescribing for a mother who may be experiencing suicidal thoughts. However, if these are the only drugs available, this risk needs to be weighed against the ongoing suicide risk if the mother is not given antidepressants.

Severe postnatal depression affects about 3% of women and can merge with puerperal psychosis. It tends to occur early postnatally, and it is likely to be obvious that the mother is unwell. Sleep is evasive, even when the baby sleeps well through the night. Appetite will be markedly reduced, with marked weight loss. Most mothers, even when very depressed, will use all their energies on the baby and neglect themselves. Depressive delusions can develop, with the mother believing that the baby would be better off without her, and this leads to a significant suicide risk. The risk of the mother taking the baby with her in a suicide attempt, although rare, has to be considered, though again this should be managed by closely monitoring the mother while keeping her baby with her. Separating the mother from the baby can increase the woman's sense of desperation and feelings of failure as a mother.

Admission of the mother and baby to a suitable hospital setting (if available) is the ideal way to manage a woman with severe delusional postnatal depression. **Electroconvulsive treatment (ECT), but only if given under general anaesthesia and safely**, is indicated, often fairly early after the onset of symptoms, as this can treat the mother quickly and reduce the amount of time she is unwell. Antidepressants should be given (see above for doses; the SSRI group is likely to be the best and safest option if available), and also antipsychotics if these are needed.

Once improved, the mother is likely to benefit from the supportive measures described for milder types of postnatal depression. It is not only possible but desirable to continue breastfeeding, whether or not the mother is being treated with antidepressants. If antipsychotics are also required, breastfeeding can continue. Adequate sleep for the mother can be achieved by her expressing breast milk and other family members giving this to the baby from a cup and spoon whenever the baby wakes during the night.

### Puerperal psychosis

This is the most severe postpartum mood disorder, and symptoms can appear rapidly. The usual incidence is 1 in 500 deliveries. It is a great shock to the mother and her family when it develops with no prior warning. However, a previous diagnosis of bipolar disorder or puerperal psychosis increases the risk to as much as 1 in 2. This presents the clinician with an opportunity to identify women at risk antenatally, consider the options for prevention, and develop a plan of management for the puerperium should the mother become unwell.

Characteristically, the woman may have been mentally healthy during her pregnancy, which may have given her and her family hope that all would be well in the puerperium. Typically there is a sudden onset of symptoms, most commonly in the first 2 weeks following childbirth. Sometimes the symptoms appear to come on overnight. The symptoms vary, but tend to progress rapidly over the first few days, and characteristically include the following:

- perplexity and confusion
- overactivity

- insomnia
- marked behavioural changes.

These common presenting features are often accompanied by a fear that something will happen to the mother or the baby, or sometimes a belief that the baby is not her own. The woman is usually easily distracted, with grossly impaired concentration, and is unable to finish one task before trying to start another, in a markedly disorganised way. This significantly interferes with her ability to look after her baby. Pointing this out often causes her even more distress. This can reinforce delusional beliefs that the baby is not her own, or that others are going to take her baby away, especially if she is separated from the baby because of her illness. A strong affective component is often present, usually hypomania or labile emotions, although this can develop into a more typically depressive picture.

During the acute phase there is a risk of harm to the mother or child, mainly due to the mother's chaotic behaviour which may unintentionally lead to neglect of the infant, rather than to any deliberately harmful actions on her part. Rarely, a mother may describe delusional beliefs involving the baby that could lead to direct harm, but this is very unusual. Although these risks to the child obviously have to be borne in mind, it is important to note that most mothers do not want to harm their babies. This risk should be managed wherever possible by keeping the mother and baby together and supervising them very closely. Even when the mother is very unwell and unable to manage much of the baby's care herself, both mother and baby benefit from being in close proximity. The mother can then be encouraged to take over more of the baby's care as her mental state improves, re-establishing the mother-child bond.

Women or girls with puerperal psychosis will frequently need medication, and the type of drug will depend on the predominant symptoms. In settings where the choice of medication is limited, the older antipsychotics can be just as effective as more modern drugs, and, with monitoring, breastfeeding can be continued, although it should be remembered that the disorganised behaviour of the mother can make breastfeeding difficult. It is therefore very important to supervise this.

**Chlorpromazine** is an inexpensive and generally widely available 'typical' antipsychotic drug which is very effective but tends to have been superseded in well-resourced countries by the 'atypical' antipsychotics with their more acceptable side-effect profile. Nevertheless, chlorpromazine is efficacious and the dose can be titrated up quite rapidly from 50 mg four times daily to as high as 1000 mg daily. Side effects include sedation (which can be beneficial in the acute stages of illness), dry mouth, nausea and parkinsonism (mask-like face, slowing and stiffness of gait, and tremor), although the inherent anticholinergic properties of chlorpromazine mean that this is not so common as with some of the other typical antipsychotic drugs (e.g. haloperidol).

**Haloperidol** is given at a dose of 0.5–3 mg two to three times daily, with a maximum daily dose of 30 mg orally. It is also often used in emergency situations as an IM injection of 5 mg or 10 mg, with a maximum daily dose of 18 mg IM.

The atypical antipsychotic drugs include **risperidone**, for which the starting dose is 1 mg twice daily, with a maximum daily dose of 6 mg, and **olanzapine**, for which the starting dose is 10 mg, with a maximum daily dose

of 20 mg. Although these drugs have a low incidence of parkinsonism, they are associated with weight gain and an increased risk of type 2 diabetes.

If a woman on an atypical antipsychotic wishes to conceive, she may want to switch to a typical drug, as there is longer-term evidence for their safety. However, this introduces a risk of relapse, and she may not want to take that risk. Also if a woman has conceived while on an atypical antipsychotic, the balance is probably in favour of continuing it, although, if possible, the dose could be reduced.

In mothers who present with puerperal psychosis, the prognosis is generally good if treatment is available, but they may remain vulnerable for several months even when the psychotic symptoms remit. As the psychotic symptoms improve and insight develops, the mother may experience a period of depressed mood as she adjusts to what has happened. However, recovery is usually complete by 6 months, although there is a risk of relapse at other times, particularly in a subsequent pregnancy.

In a woman with a pre-existing diagnosis of bipolar disorder, the management of labour is important for reducing the risk of a puerperal psychosis. Where possible, sleep deprivation should be minimised in order to reduce the risk of the illness developing. The importance of letting the mother sleep when she can following childbirth should be emphasised to the family, and the father should be asked to undertake as much care as possible during the night.

The effectiveness of using prophylactic antipsychotic drugs has yet to be established. The trigger for puerperal psychosis appears to be biological, but so far the condition has proved difficult to prevent, even when treatment is continued through pregnancy. It is therefore essential to have a plan in place for what to do if the mother becomes unwell, and this can also reduce stress for the family.

### Anxiety disorders and obsessive-compulsive disorders

Women and girls with a history of anxiety disorders and obsessive-compulsive disorders may relapse postnatally.

Anxiety can range from mild concerns about the health of the baby to extreme anxiety that the baby may be seriously unwell, with constant vigilance and fear of a sudden infant death. The mother may seek and receive much reassurance from family and healthcare workers, yet remain concerned.

Mothers may experience obsessional thoughts or images of their babies being harmed, and sometimes the thought is that they will be the person to harm the baby. This can cause great distress, as the mother may fear that she will act on these thoughts, and so will avoid caring for her baby and allow her family to do so instead, which will reinforce her belief that she is a bad mother. Careful diagnostic exploration to identify obsessional rather than psychotic symptoms is essential in such cases.

Non-delusional, non-psychotic obsessions have the following characteristics:

- They come into the mind fully formed.
- They are recognised as the mother's own thoughts and not placed there by someone else.
- They are not voices telling her to harm her child.
- They are repetitive and intrusive.
- They are difficult to push away.

This analysis should be followed by an explanation of the

nature of these thoughts. The mother will need encouragement to continue to care for her baby despite these abnormal thoughts, and to dispel the belief that she is a bad mother. These intrusive thoughts can lead to immense guilt and feelings of incompetence. Therefore allowing the mother to express her concerns and be reassured can be very therapeutic. Antidepressants may be indicated, even in the absence of other biological symptoms of depression.

**Benzodiazepines such as diazepam must not be used regularly in pregnancy. When taken later in pregnancy they can cause withdrawal symptoms, hypotonia and agitation in the newborn.**

### **Effect of maternal mental health disorders on the infant**

For the majority of women experiencing symptoms of depression and anxiety during pregnancy or in the early postnatal period, their ability to care for their baby is not significantly compromised. However, there are many studies describing the adverse effects of maternal depression on early childhood development, and chronic depression does have deleterious effects on the whole family. This evidence needs to be taken seriously from a public health point of view to highlight the problem and aid development of services. However, it is also important to remember that for an individual mother the thought that she may be regarded as causing harm to her baby will reinforce the guilt that she is already feeling, and delay recovery. Several of the factors listed in Box 2.9.2, while predisposing to maternal depression, are also going to disadvantage the child, so addressing these where possible will benefit both mother and child.

Baby's date of birth: \_\_\_\_\_ Phone number: \_\_\_\_\_

#### Instructions

As you have recently had a baby, we would like to know how you are feeling now. Please choose the answer that comes closest to how you have felt IN THE PAST WEEK, not just how you feel today.

Here is an example, already completed.

I have felt happy:

- Yes, all of the time
- Yes, most of the time (*This would mean: 'I have felt happy most of the time' during the past week*)
- No, not very often
- No, not at all

#### In the past 7 days:

##### Question 1

In the past week I have been able to laugh and see the funny side of things:

- As much as I always could
- Not quite so much now
- Definitely not so much now
- Not at all

##### Question 2

In the past week I have looked forward with enjoyment to things:

- As much as I ever did
- Rather less than I used to
- Definitely less than I used to
- Hardly at all

##### Question 3\*

In the past week I have blamed myself unnecessarily when things went wrong:

- Yes, most of the time
- Yes, some of the time
- Not very often
- No, never

##### Question 4

In the past week I have been anxious or worried for no good reason:

- No, not at all
- Hardly ever
- Yes, sometimes
- Yes, very often

##### Question 5\*

In the last week I have felt scared or panicky for no very good reason:

- Yes, quite a lot
- Yes, sometimes
- No, not much
- No, not at all

##### Question 6\*

In the past week things have been getting on top of me:

- Yes, most of the time I haven't been able to cope at all
- Yes, sometimes I haven't been coping as well as usual
- No, most of the time I have coped quite well
- No, I have been coping as well as ever

##### Question 7\*

In the past week I have been so unhappy that I have difficulty sleeping:

- Yes, most of the time
- Yes, sometimes
- Not very often
- No, not at all

##### Question 8\*

In the past week I have felt sad or miserable:

- Yes, most of the time
- Yes, quite often
- Not very often
- No, not at all

##### Question 9\*

In the past week I have been so unhappy that I have been crying:

- Yes, most of the time
- Yes, quite often
- Only occasionally
- No, never

##### Question 10\*

In the past week the thought of harming myself has occurred to me:

- Yes, quite often
- Sometimes
- Hardly ever
- Never

Source: Cox JL, Holden JM and Sagovsky R (1987) Detection of postnatal depression: development of the 10-item Edinburgh Postnatal Depression Scale. *British Journal of Psychiatry*, **150**, 782–6.

### **Instructions for using the Edinburgh Postnatal Depression Scale**

- 1 The mother is asked to check the response that comes closest to how she has been feeling in the previous 7 days.
- 2 All of the items must be completed.
- 3 Care should be taken to avoid the possibility of the mother discussing her answers with others. Answers must come from the mother or pregnant woman.
- 4 The mother should complete the scale herself, unless she has limited English or has difficulty with reading.

Mothers who score above 13 are likely to be suffering from a depressive illness of varying severity. The EPDS score should not override clinical judgement. A careful clinical assessment should be undertaken to confirm the diagnosis.

The scale indicates how the mother has felt during the previous week. In doubtful cases it may be useful to repeat the tool after 2 weeks. The scale will not detect mothers with anxiety neuroses, phobias or personality disorders.

#### **Scoring**

**Questions 1, 2 and 4 (without an asterisk)** are scored 0, 1, 2 or 3, with the top box scored as 0 and the bottom box scored as 3.

**Questions 3, 5, 6, 7, 8, 9 and 10 (marked with an asterisk)** are reverse scored, with the top box scored as 3 and the bottom box scored as 0.

The maximum possible score is 30.

Possible depression is indicated by a score of  $\geq 10$ .

**Always look at item 10 (suicidal thoughts).**

## **2.10 Female genital cutting**

### **Introduction**

#### **What is female genital cutting?**

Female genital cutting (FGC), also known as female circumcision or female genital mutilation, refers to all procedures involving partial or total removal of the external female genitalia, or other injury to the female organs for non-therapeutic reasons. It ranges from very simple to radical, and may be carried out between birth and puberty, or can be performed just before marriage or childbirth.

FGC varies across cultures, ethnic groups and tribal affiliations; there is also some variation in the types of cutting undertaken within cultures, ethnicity and tribes. The World Health Organization has estimated that 130 million women worldwide have undergone FGC. There are an estimated 2 million infants, girls and women at risk each year.

The European Parliamentary Committee on Women's Rights and Gender Equality states that around 500 000 women and girls living in Europe have been subjected to FGC.

A practice of performing a symbolic form of infibulation to accompany the usual ceremonies has been recently adopted in Somalia. The procedure consists of applying to the clitoris a small needle (sterile insulin needle) to obtain a drop of blood. The practice is called 'Sunna' and is not yet widespread in the country. It is performed only by enlightened women in that society, but hopefully it will attract others to adopt this approach while awaiting a time when all forms of this practice end.

#### **Who performs FGC?**

FGC is commonly performed by traditional medicine practitioners, including traditional birth attendants, local women or men, or female family members. Such individuals do not have formal medical training, and usually perform cutting without anaesthesia or asepsis with crude instruments such as kitchen knives or razor blades. It is not uncommon

for those who perform FGC to cut or damage more of the genital area than they intended to. Increasingly, doctors are also undertaking these procedures.

The health problems associated with FGC are life-threatening haemorrhage, sometimes death during or shortly after the procedure (from haemorrhage or infection), death during pregnancy, the need for assistance during childbirth due to interference with normal delivery, and the spread of HIV/AIDS and hepatitis due to the frequent use of unclean and unsterile instruments. There are also links to mental illness in the victims and to intimate partner violence.

### **Prevalence of FGC**

FGC is practised in about 28 countries in Africa, Asia and the Middle East. A recent interview by Integrated Regional Information Networks (IRIN) in 2012 confirmed that FGC is still being practised in Pakistan. It is estimated that at least 50–60% of Bohra women undergo FGC; this is usually a symbolic snipping of the clitoris.

**TABLE 2.10.1** Estimated prevalence of FGC by country

Country	Estimated prevalence of FGC in girls and women aged 15–49 years (%)	Year
Benin	16.8	2001
Cameroon	1.4	2004
Chad	44.9	2004
Central African Republic	25.7	2005
Djibouti	93.1	2006
Egypt	95.8	2005
Ethiopia	74.7	2005
Eritrea	95.0	1995

Country	Estimated prevalence of FGC in girls and women aged 15–49 years (%)	Year
Guinea Bissau	44.5	2005
Ghana	3.8	2005
Guinea	95.6	2005
Gambia	78.3	2005
Ivory Coast	41.7	2005
Liberia	45.0	
Mali	91.6	2001
Mauritania	71.3	2001
Nigeria	19.0	2003
Niger	2.2	2006
Sierra Leone	90.0	2003
Senegal	28.2	2005
Somalia	97.9	2005
Sudan, northern (approximately 80% of total population in survey)	90.0	2000
Kenya	32.2	2003
Togo	5.8	2005
United Republic of Tanzania	14.6	2004
Uganda	0.6	2006
Yemen	22.6	1997
Burkina-Faso	72.5	2005

Data taken from OHCHR, UNAIDS, UNDP, UNECA, UNESCO, UNFPA, UNHCR, UNICEF, UNIFEM and WHO (2008) *Eliminating Female Genital Cutting: an interagency statement*. [www.un.org/womenwatch/daw/csw/csw52/statements\\_missions/Interagency\\_Statement\\_on\\_Eliminating\\_FGM.pdf](http://www.un.org/womenwatch/daw/csw/csw52/statements_missions/Interagency_Statement_on_Eliminating_FGM.pdf)

### Types of female genital cutting

The WHO has classified FGC into four types.

- **type 1:** excision of the prepuce, with or without excision of the clitoris, entirely or in part
- **type 2:** excision of the clitoris with partial or total excision of the labia minora
- **type 3:** excision of part or all of the external genitalia and stitching/narrowing of the vaginal opening (also known as infibulation). This type is most common in countries in the Horn of Africa, namely Sudan, Eritrea, Djibouti, Ethiopia and Somalia
- **type 4:** unclassified – includes pricking or incising of the clitoris or labia, cauterisation by burning of the clitoris, or introduction of corrosive substances or herbs into the vagina; sometimes the clitoris is buried rather than excised.

Around 90% of FGC is of types 1, 2 and 4, and 10% is of type 3 (infibulation). The type often varies depending on ethnicity.

The age at which FGC is undertaken varies between countries. In Ethiopia, Eritrea and Yemen most girls will have been mutilated in infancy. In Egypt, 90% are mutilated between 5 and 15 years of age.

FIGURE 2.10.3 Area of tissue removed in type 2 female genital cutting.

FIGURE 2.10.4 Appearance of genitalia after type 2 female genital cutting.

FIGURE 2.10.5 Appearance of genitalia after type 3 female genital cutting.

## Implications and complications of FGC

FGC is dangerous to girls' and women's health and psychological well-being. It can cause urological, gynaecological and obstetric problems. Around 10% of girls and women are estimated to die from the short-term complications of FGC, such as haemorrhage, shock and infection. Another 25% die in the long term as a result of recurrent urinary and vaginal infections and complications during childbirth, such as severe bleeding and obstructed labour.

### Short-term complications

These include the following:

- haemorrhage and anaemia
- severe pain (it is almost always the case that no local anaesthetic is given)
- shock (due to haemorrhage and/or pain)
- death from shock (due to haemorrhage and/or pain)
- difficulty passing urine or faeces
- urinary tract infection
- urethral meatus injuries, prolonged micturition, and dysuria
- injury to adjacent tissues
- damage to other organs
- fractures or dislocation due to restraint during the procedure
- infection due to tetanus, and bloodborne viruses such as HIV, and hepatitis B and C
- vulval abscess.

### Long-term complications

These include the following:

- chronic pain
- chronic pelvic infection
- haematocolpos (obstruction to menstrual flow, leading to dangerous swelling of the vagina)
- keloid scarring
- decreased quality of sexual life, including pain on intercourse
- complications in pregnancy and childbirth, including obstructed labour (see below)
- psychological damage, including fear and anxiety during labour and delivery, as well as post-traumatic stress disorder and depression
- psychosexual effects; fear of and anxiety about sexual intercourse, difficulties with penetration, marital breakdown and divorce.

### Complications during childbirth

Women who have undergone FGC are more likely to experience difficulties during childbirth, and their babies are more likely to die. A WHO study conducted in 2006 in six African countries showed an increased risk of possible obstetric complications in women who had been subjected to FGC compared with women who had not undergone this procedure. The same study showed an increased incidence of maternal death, Caesarean section, postpartum haemorrhage and neonatal resuscitation, as well as prolonged hospital stays, in women who had undergone FGC.

## Management during pregnancy, labour and the postnatal period

### Antenatal period

All women and girls who have been subjected to FGC

should be identified at antenatal booking or the gynaecological clinic by asking questions such as 'Have you been closed?' or 'Did you have the cut or operation as a child?' Most women will then assume that you know about FGC, and further questions can be asked, such as 'Do you have any problems with passing urine or menstruation?' or 'How long does it take to pass urine?' Once the issue is raised, the woman may then feel comfortable discussing it further with the midwife or doctor.

### Reversal of FGC (de-infibulation)

Reversal (de-infibulation) is best undertaken at 17–18 weeks' gestation (mid-trimester) by a specialist midwife or surgeon, to enable easy access to the vaginal orifice and urethra during labour. Performing reversal in the second trimester ensures complete healing prior to labour. Reversal is not recommended in the first trimester, as the procedure may be wrongly blamed for fetal loss.

Antenatal reversal is essential to assist in vaginal examinations using a speculum, and in urinary catheterisation. It may also prevent recurrent urinary tract infection. Local anaesthesia is encouraged for reversal, but general anaesthesia may be necessary if the woman suffers from flashbacks to childhood trauma.

Post-reversal care during the antenatal period should include adequate pain relief and promotion of personal hygiene. Some re-education may be necessary, as some women will have forgotten, or may never have known, what normal micturition or menstruation is like.

### Labour

The aim is a normal delivery, with Caesarean section only for the usual obstetric indications. The woman should receive standard care in labour.

If the woman has not been seen antenatally, or if she has chosen not to have reversal undertaken, an individual assessment should be made on admission in labour, regarding the need for reversal and/or episiotomy to facilitate delivery.

If she has sustained FGC type 3 (infibulation), a midline incision should be made to expose the introitus and urethra, after infiltration with 1% lignocaine. Infibulated women should have a midline incision and medio-lateral episiotomy **only if necessary**.

Adequate **pain relief** is very important, especially as flashbacks may occur.

**Bladder care** is very important during labour, to avoid damage to the bladder and the urethra (catheterisation is not usually necessary; encourage frequent voiding).

### Care following delivery

If suturing is needed, it should occur promptly. **Re-infibulation of FGC type 3 must not be carried out at this time.**

If a midline incision has been made to open a type 2 or 3 FGC to enable delivery, then each side of the incision is over sewn separately on either side. In this way the FGC is 'reversed' and haemostasis achieved.

### Postnatal period

**Immediate care** following delivery should include the following:

- adequate pain relief.
- perineal care
- re-education. Some women will have forgotten or will

never have known what normal micturition or menstruation is like.

Following discharge from the healthcare facility, continued support for the woman should be provided. If reversal is performed in labour, there should be a post-reversal check 4 to 6 weeks later.

If the woman has delivered a baby girl, support and information should be given, encouraging her not to inflict or allow others to inflict the same procedure on her daughter.

### Safeguarding children who are at risk of FGC

- The safety and welfare of the child is paramount.
- All agencies must act in the best interests of the rights of the child as stated in the UN Convention on the Rights of the Child (1989).
- In some countries, FGC is illegal.

### Laws and FGC

The following countries in Africa have issued laws against FGC, although this does not mean that the prevalence of FGC has been significantly reduced:

- Benin (2003)
- Burkina Faso (1996)
- Central Africa Republic (1966)
- Chad (2003)
- Cote d'Ivoire (1998)
- Djibouti (1994)
- Egypt (Ministerial Decree) (1996)
- Ethiopia (2004)
- Ghana (1994)
- Guinea (1965)
- Kenya (2001)
- Niger (2003)
- Senegal (1999)
- Tanzania (1998)
- Togo (1998)
- Nigeria (multiple states) (1999–2002).

It is acknowledged that some families see FGC as an act of love rather than of cruelty. However, FGC causes significant harm in both the short and long term, and constitutes physical and emotional abuse of children.

All decisions or plans for the child(ren) should be based on good-quality assessments. They should be sensitive to issues of race, culture, gender, religion and sexuality, and should avoid stigmatising the child or the practising community as far as possible.

Accessible, acceptable and sensitive involvement with the health, education, police, children's social care and voluntary-sector services may be needed.

All agencies should work in partnership with members of local communities, to empower individuals and groups to develop support networks and education programmes.

### Appropriate care for women and girls who have been subjected to FGC

- Provide access to information, support and services.
- Provide care pathways and guidelines for professionals.
- Ensure that information is accurate and up to date.
- Empower women and girls and encourage them to speak out and seek help.
- Engage and mobilise all concerned, and develop an understanding of cultural diversity.
- Be open and supporting, sensitive and non-judgemental.
- Encourage alternative rites to FGC. This is a strategy that retains all of the rites of passage or initiation that the girls would traditionally undergo, except for the genital cutting. The girls are still encouraged to learn essential domestic duties that would be useful when they get married.

### Conclusion

FGC is a violation of human rights. It is essential to empower women and girls, to encourage women to have a voice, and to raise awareness of the dangers of FGC. Engagement with all concerned local communities is crucial, including community and religious leaders.

As has been expressed so beautifully by Uche Umeh, 'When culture kills, when culture silences, when culture is complicit then culture must be changed.'

It is essential to work with all professionals. We all have a duty and a responsibility to safeguard girls who are at risk of FGC, as the welfare of children is paramount.

## 2.11 Domestic/intimate partner violence and pregnancy

### Introduction

Everyone has a fundamental right to be, and remain, safe from harm. **Domestic violence**, also described as **intimate partner violence**, is defined as 'any incident of threatening behaviour, violence or abuse (psychological, physical, sexual, financial or emotional) between adults who are, or have been, intimate partner or family members, regardless

of gender or sexuality'. Family members are defined as mother, father, son, daughter, brother, sister and grandparents, whether directly related, in-laws or step-family.

The main characteristic of domestic violence is that the behaviour is intentional and is calculated to exercise power and control within a relationship.

Domestic violence is reported in up to one in five

pregnancies, often beginning or getting worse at this time. The risk of moderate to severe violence appears to be greatest in the postpartum period.

Injuries to the abdomen, genitals and breasts are most frequent in pregnancy, but can be multiple, affecting any part of the woman's body.

Women and girls who suffer domestic violence are at increased risk of miscarriage, premature labour, placental abruption, low-birth-weight infants, fetal injury and intrauterine fetal death. As a result of violence, women are five times more likely to attempt suicide.

The impact of domestic violence can be devastating, and creates long-term consequences for women and girls, such as anxiety and mistrust. The impact on children must also be considered, as domestic violence and child abuse are often linked to the same perpetrator.

### Recognising domestic violence in pregnancy

Studies show that around 30% of women will suffer from domestic violence in their lifetime. The first incident of violence commonly occurs during pregnancy. For some of these women, the pregnancy might be unwanted, due to abuse, rape, or as a result of not having access to or not being able to negotiate contraceptive use.

Domestic violence in pregnancy may be suspected on the basis of the type of injury, as well as the mental health and emotional status of the woman.

Women who are being abused may book late, and be poor attendees at antenatal clinics. They may attend repeatedly with trivial symptoms, and appear reluctant to be discharged home. The partner may be constantly present, not allowing private discussion. The woman may seem reluctant to speak in front of her partner, or to appear to contradict him.

Abusive partners often seek to minimise the evidence of their violence (e.g. by targeting areas that are normally clothed). As with child abuse, the stated mechanism of injury often does not fit with the apparent injury. There may be untended injuries of different ages, or the late presentation of injuries.

Multiple injuries and bruising (especially to the face, arms, breasts and abdomen), loss of consciousness, and drunkenness are significant but non-specific markers of domestic violence.

A history of behavioural problems, or abuse of children in the family, may be suggestive of domestic violence.

### Diagnosing domestic violence

Routinely ask mothers whether they have been subjected to violence. Questions such as the following may allow the woman to disclose that she is being subjected to violence:

- I have noticed you have a number of bruises. Did someone hit you?
- You seemed frightened by your partner. Has he ever hurt you?
- You mention that your partner loses his temper with the children. Does he ever do that with you?
- How does your partner act when he is drinking alcohol or on drugs?

Other strategies such as the use of questionnaires in the women's toilets/rest room may help those women whose partner is constantly by their side (see Appendix).

Community midwives and traditional birth attendants visiting women at home may have the privacy to discuss such sensitive issues.

The provision of interpreters is essential. **Family members should not act as interpreters in this situation, as free dialogue will probably not occur.**

A system for caring for and protecting mothers subject to violence should be advocated for by all healthcare professionals undertaking maternal and child healthcare. Multi-agency working is crucial, and should include liaison with police, social services and the judicial system.

All professionals must take any available steps to seek a safe haven and to protect and support women who are experiencing domestic violence. The impact of domestic violence on the unborn child should be acknowledged, as well as the potential impact on existing children. It is very important to perform a risk assessment on women. Access to information and support must be easily and readily available to pregnant women.

It is equally crucial to empower and counsel women to make their own choices. Underlying issues such as finance and housing should be addressed, and the woman should be directed to the appropriate agency or support group, or to a legal adviser.

## Appendix

### How do I know if I am experiencing abuse?

If you answer yes to one or more of the following questions, you may be in an abusive relationship.

- Has your partner tried to keep you from seeing your friends or family?
- Has your partner prevented you from continuing or starting a college course, or from going to work?
- Does your partner constantly check up on you or follow you?
- Does your partner accuse you unjustly of flirting or of having affairs?
- Does your partner constantly belittle or humiliate you, or regularly criticise or insult you in front of other people?
- Are you ever scared of your partner?
- Have you ever changed your behaviour because you're afraid of what your partner might do or say to you?
- Has your partner ever deliberately destroyed any of your possessions?
- Has your partner ever hurt or threatened you or your children?
- Has your partner ever kept you short of money so that you were unable to buy food and other necessary items for yourself and your children?
- Has your partner ever forced you to do something that you really didn't want to do, including sexually?

Wellbeing Foundation Africa. *Eliminating Domestic Violence*. [www.wbfafrica.org/resources/cat\\_view/1-resources/6-eliminating-domestic-violence.html](http://www.wbfafrica.org/resources/cat_view/1-resources/6-eliminating-domestic-violence.html)

## 2.12 Post-operative care

### Basic nursing issues

The patient should be discharged to the ward or recovery area with clear orders for the following:

- **Monitor ABC.**
- If the patient is unconscious (P or U on the AVPU scale) they should not be left alone until they are responding to voice. Put them in the recovery position and undertake airway opening as required.
- Check vital signs (temperature, pulse, respiratory rate, blood pressure and capillary refill time) every 15 minutes for the first hour, hourly for the next 4 hours, and then 2-hourly. Observations should be more frequent if there is a change in observation from a normal to abnormal value.
- Monitor SaO<sub>2</sub> (normal value is > 93%) after a general anaesthetic. Give **oxygen** as required until SaO<sub>2</sub> is > 93% in air or the patient's colour is normal. Remember that cyanosis may not be present if the patient is severely anaemic.
- Observe the mother closely until the effect of the anaesthetic has worn off.
- Control pain: if it is severe, the patient will need IV morphine.
- Record the rate and type of IV fluid (if the patient has ketosis, ensure that there is an adequate amount of glucose in the drip).
- Record urine output, surgical and nasogastric drainage, and vomiting.
- Record input versus output, and calculate the difference every 12 hours.
- Document other medications.
- Perform laboratory investigations.

The patient's progress should be monitored, and documentation should include at least the following:

- a comment on medical and nursing observations
- a specific comment on the wound or operation site
- any complications
- any changes made in treatment.

### Prevention of complications

- Provide adequate pain control.
- Encourage early mobilisation:
  - deep breathing and coughing
  - active daily exercise
  - joint range of motion
  - muscular strengthening
  - availability of walking aids such as canes, crutches and walkers, as well as instructions for their use.
- Ensure adequate nutrition.
- Consider thromboprophylaxis in those at high risk of thrombo-embolic disease (DVT/PE) (see Section 2.5.H: 'Pulmonary embolism').
- Prevent skin breakdown and pressure sores:
  - turn the patient frequently
  - keep urine and faeces off the skin.

### Pain management (see Section 1.15)

Manage pain wherever the patient is seen (emergency department, operating theatre or on the ward), and anticipate their needs for pain management after surgery and discharge. Do not delay the treatment of pain unnecessarily.

In the first 12–24 hours after a major surgical procedure, such as Caesarean section, powerful opiate analgesia (usually morphine IV) will be needed (see Section 1.15 for details). Thereafter, the pain should be less severe, and regular codeine, non-steroidal anti-inflammatory drugs (NSAIDs), aspirin or paracetamol should be sufficient.

### Wound care

Dressings protect the wound and absorb exudates. Usually the dressing applied in theatre can remain in place for 48 hours unless there is excessive or purulent exudate, when a new dressing should be applied as a sterile procedure after cleansing with sterile 0.9% saline. Swabbing a wound can be harmful as it damages the newly granulating tissue. It is also painful.

After 48 hours, provided that the wound is intact, it can be cleaned under a shower.

Removal of sutures should usually occur after 7 days. Use one hand to hold the knot with forceps, place the stitch cutter or scissors under the knot next to the skin, and cut the stitch where it emerges from the skin. Remove the suture by pulling on the knot, which prevents a potentially contaminated stitch being pulled through the wound. Observe the wound every 4–6 hours, without touching it, for evidence of dehiscence.

### Monitoring

All patients should be assessed at a frequency that is determined by the severity of their condition. Even those who are not seriously ill must be regularly assessed.

Vital signs (temperature, pulse, respiratory rate, blood pressure, urine output and fluid inputs) should be recorded on a standard form or graph at least 4-hourly for 24 hours after the immediate post-operative recovery phase.

Do not forget anti-tetanus coverage when appropriate.

Progress notes need not be lengthy, but must comment on the patient's condition and note any changes in the management plan. They should always be signed by the person writing the note.

Notes can be organised in the 'SOAP' format as follows:

- **Subjective:** how the patient feels.
- **Objective:** findings on physical examination, vital signs and laboratory results.
- **Assessment:** what the healthcare worker thinks.
- **Plan:** management plan (this may also include directives which can be written in a specific location as 'orders').

### Specific post-operative issues

#### *Post salpingectomy for ruptured ectopic pregnancy*

- Counsel patient regarding operative findings and likely

future fertility (if the other tube is normal in appearance then fertility is around 70%).

- Counsel patient regarding risk of recurrence (1 in 10 or more) and the need for early ultrasound in any subsequent pregnancy. If evidence of pelvic inflammatory disease intraoperatively, treat patient and partner unless clear history of recent treatment.
- Offer child spacing/family planning advice. The intrauterine contraceptive device (IUCD) is associated with ectopic pregnancy if the patient becomes pregnant while using it. If another contraceptive is available and acceptable/suitable then this should be used in preference.

### Post Caesarean section

#### Monitoring

- 1 Regularly (at least 2- to 4-hourly initially) monitor vital signs, including temperature, heart rate, respiratory rate, blood pressure, urine output, AVPU and SaO<sub>2</sub>.
- 2 Regularly palpate the uterine fundus to ensure that the uterus remains contracted.
- 3 Regularly check for excessive vaginal blood loss.

#### Fluids and nutrition

- 1 If uncomplicated, give liquids and solids after 4–8 hours.
- 2 Bowel function should be normal after 12 hours.
- 3 Remove the IV cannula when the patient is stable and eating and drinking.
- 4 If there is infection, obstructed labour or uterine rupture, wait until bowel sounds appear before giving oral fluids.

#### Urine output

- 1 Keep a fluid balance chart and ensure that adequate urine output is occurring.
- 2 Remove the urinary catheter after 8 hours if the urine is clear; if not wait, until it is.
- 3 Wait 48 hours before removing the urinary catheter if there is a history of severe pre-eclampsia, uterine rupture, prolonged or obstructed labour, massive perineal oedema, or puerperal sepsis with pelvic peritonitis.
- 4 If the bladder was damaged, leave the catheter in for 7 days and until the urine is clear. If the patient is not receiving antibiotics, give nitrofurantoin 100mg or cefalexin 500 mg or amoxicillin 500 mg orally once daily until the catheter is removed.

#### Anaemia

- 1 If the mother is significantly anaemic (haemoglobin level < 6–7 g/dL), transfusion may aid recovery from the operation. If possible, consider giving 500 mL of fresh cross-matched blood from a relative or other donor. The need for blood transfusion is dependent on the starting Hb and how well the patient is tolerating the anaemia.

#### Wound care

- 1 Check the dressing without disturbing it every 6 hours for the first 48 hours. Look for bleeding or infection.
- 2 Change the dressing after 48 hours.
- 3 If blood is leaking, replace the dressing with a new one if it is more than half soaked.

#### Postpartum vaginal haemorrhage

- 1 Massage the uterus to expel blood and blood clots. The presence of blood clots will inhibit effective uterine contractions;

- 2 Give oxytocin 10 units IM and then infuse 40 units in 500 mL of IV fluids (Ringer-lactate or Hartmann's solution) over 4 hours. If bleeding is heavy, give misoprostol orally, 3 × 200 microgram tablets, or rectally, 4 × 200 microgram tablets (see Section 2.5.D.iv for further management of postpartum haemorrhage).

#### Infection

- 1 If there are signs of infection or the mother currently has fever, give ampicillin 2 grams IV every 6 hours, *plus* gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours, *plus* metronidazole 500 mg IV every 8 hours. If fever is still present 72 hours after initiating antibiotics, re-evaluate and revise the diagnosis.
- 2 Infection of the uterus is a major cause of maternal death. Delayed or inadequate treatment of endometritis may result in pelvic abscess, peritonitis, septic shock, deep vein thrombosis, pulmonary embolism, chronic pelvic infection with recurrent pelvic pain and dyspareunia, tubal blockage and infertility.
- 3 If retained placental fragments are suspected as a cause of infection, perform a digital exploration of the uterus to remove clots and large pieces. Use ovum forceps or a large curette if required.
- 4 If there is no improvement with conservative measures and there are signs of general peritonitis (fever, rebound tenderness and abdominal pain), perform a laparotomy to drain the pus.
- 5 If the uterus is necrotic and septic, perform a hysterectomy (subtotal is preferable, if the cervix is not necrotic).

#### General measures

- 1 Ensure that the mother cannot fall out of bed when recovering from a general anaesthetic or if she is very unwell with a reduced conscious level.
- 2 Ensure pain control.
- 3 Encourage early mobility and deep breathing exercises.
- 4 The patient should wear knee-length well-fitting anti-embolism stockings until she is fully ambulant.

#### At the time of discharge from hospital

- 1 Discuss the implications of Caesarean section for future pregnancy management.
- 2 Discuss the timing of future activities such as sexual intercourse and heavy lifting.
- 3 Provide details of warning signs as to when the mother should contact a trained healthcare worker for advice.

#### Wound abscess

- If there is **pus or fluid**, open and drain the wound. Remove infected skin or subcutaneous sutures and debride the wound. Do not remove fascial sutures unless deep infection is evident or suspected.
- If there is an **abscess without cellulitis**, antibiotics are not required.
- Place a damp sterile normal saline dressing in the wound and change the dressing every 24 hours.
- Advise the patient on good hygiene and the need to wear clean pads or cloths that are changed frequently.
- **If the infection is superficial and does not involve deep tissues, monitor for development of an abscess and give antibiotics for 5 days or until fever free for 48 hours:**

- Flucloxacillin/cloxacillin 250–500mg by mouth four times a day for 5 days.
- **If the infection is deep, involves muscles and is causing necrosis (necrotising fasciitis), give antibiotics until the necrotic tissue has been removed and the patient has been fever-free for 48 hours:**
  - Flucloxacillin/cloxacillin 500mg–1 gram IV 6 hourly plus penicillin G 2million units IV every 6 hours, plus metronidazole 500mg IV every 8 hours.

**Necrotising fasciitis requires urgent wide surgical debridement. Perform secondary closure 2 to 4 weeks later, depending on the resolution of infection.**

It is important to inform the mother on discharge that she is at risk of uterine rupture during her next pregnancy. Offer child spacing/family planning advice.

### Other complications

#### Peritonitis

##### Signs and symptoms

These include severe generalised abdominal pain, nausea and vomiting, fever, absent bowel sounds, rigid abdominal wall and shock.

##### Treatment

- 1 Call a surgeon and an anaesthetist.
- 2 Provide nasogastric suction.
- 3 Treat shock if present, but always place a wide-bore IV line and infuse fluids.
- 4 Give antibiotics until the patient has been fever-free for 48 hours:
  - ampicillin 2 grams IV every 6 hours, *plus* gentamicin 80mg IV/IM every 8 hours or 5mg/kg body weight IV/IM once every 24 hours, *plus* metronidazole 500mg IV every 8 hours.
- 5 If necessary, perform laparotomy for peritoneal washout.

#### Pelvic abscess

Give antibiotics before draining the abscess, and continue until the patient has been fever-free for 48 hours:

- ampicillin 2 grams IV every 6 hours, *plus* gentamicin 80mg IV/IM every 8 hours or 5mg/kg body weight IV/

IM once every 24 hours, *plus* metronidazole 500mg IV every 8 hours.

If the abscess is fluctuant in the pouch of Douglas (*cul-de-sac*), perform culdocentesis. If the **spiking fever continues**, perform a laparotomy.

### Care of the patient after spinal anaesthesia

#### Observations

##### Standard post-anaesthetic observations

Sensation should return within 4 hours. If after 4 hours the patient remains numb and/or cannot move her legs, contact the anaesthetist urgently.

#### Analgesia

Severe pain may return suddenly when the effects of the spinal block have worn off. Give analgesia when the patient first experiences pain.

#### Fasting

Fasting is not needed unless it is a surgical requirement (e.g. after abdominal operations).

#### Posture

The patient does not have to lie flat. Allow them to sit up as soon as they are able to do so.

#### Mobilising

If not contraindicated by the surgery, the patient can get out of bed 2 hours after the return of normal sensation, but **only with assistance**. Before getting the patient out of bed, sit her up slowly. If she feels faint, dizzy or sick then lie her down, take her blood pressure and inform the anaesthetist.

#### Potential complications

- **Postural hypotension:** lie the patient on the bed, give or increase IV fluids and inform the anaesthetist.
- **Urinary retention:** encourage the patient to pass urine when sensation returns. If the patient has not passed urine and she has a palpable bladder, she may need a catheter.

## 2.13 Obstetric procedures

### The importance of basic and comprehensive Emergency Obstetric and Neonatal Care in resource-limited settings

The availability of Emergency Obstetric and Neonatal Care (EmONC) indicates how well any healthcare system can respond to the obstetric and newborn complications that are the main causes of maternal and newborn deaths. The Averting Maternal Death and Disability Program (AMDD)

and the United Nations have defined nine essential EmONC services that directly treat these complications. These are termed signal functions.

The functional status of an EmONC facility depends on the 24-hour availability of these life-saving signal functions and whether they have been performed recently. To qualify as a basic EmONC (or BEmONC) facility, health centres and hospitals must have performed the following seven signal functions within the past 3 months:

- 1 administered IM or IV antibiotics
- 2 administered IM or IV anticonvulsants
- 3 administered IM or IV uterotonic drugs
- 4 performed manual removal of the placenta
- 5 performed removal of retained products of conception (manual vacuum aspiration)
- 6 performed assisted vaginal delivery (with vacuum extractor or forceps)
- 7 performed neonatal resuscitation with a bag and mask.

To qualify as a comprehensive EmONC (or CEmONC) facility, health centres and hospitals must have performed all seven basic services listed above plus the following two additional signal functions within the past 3 months:

- 1 blood transfusion
- 2 Caesarean section.

In order for these EmONC systems to work adequately, there must be effective coordination of the supplies of essential emergency drugs, medical and surgical supplies and equipment to every facility providing this care. Essential drugs must include oxytocin, magnesium sulphate, misoprostol, antibiotics and antihypertensive drugs. Essential supplies include sutures and urinary catheters. Essential equipment includes manual vacuum aspirators, vacuum delivery kits and self-inflating bag-and-mask ventilators for newborn resuscitation.

## Urethral catheterisation

### Method

Use an appropriate size of catheter, which is one that is smaller in diameter than the external urethral meatus (to minimise the risk of subsequent urethral stricture formation). Usually this will be size 10–14 French gauge.

Using sterile precautions (gloves, etc.), wash the area with gauze swabs soaked with antiseptic (although sterile water or 0.9% saline can be just as effective), and clean from anterior to posterior with downward movements (to avoid faecal contamination). Sterile lubricant should be used to aid passage of the catheter. Use a syringe of sterile water or 0.9% saline to inflate the balloon if it is a Foley catheter, with the woman lying on her back or in the left lateral tilt position if she is more than 20 weeks' pregnant. The catheter is inserted far enough (urethra length is around 4 cm) for urine to be seen in the tube. Attach a catheter bag (if

FIGURE 2.13.1 Normal female external genitalia showing urethra.

available). Secure the catheter to the thigh with tape to prevent traction damage to the bladder.

The balloon must be deflated before the catheter is removed.

## Ventouse (vacuum) delivery

### Introduction

The ventouse creates a vacuum in a cup attached to the fetal head to assist delivery. This technique is also called vacuum-assisted vaginal delivery or vacuum extraction (VE).

The advantages of the ventouse over forceps are that less training is needed, there is less risk of excessive traction, there are clear-cut rules on its use (e.g. the number of contractions during which traction is allowed), if the baby needs to rotate in order to be delivered this can occur spontaneously, and it can cause less injury to the mother.

The disadvantages are that it cannot be used for pre-term delivery, face presentation, breech or after-coming head of breech, and if the mother is unable to provide expulsive efforts the ventouse is generally not effective. The equipment is more complex than forceps and more difficult to sterilise and maintain, and there can be more trauma to the baby (e.g. cephalhaematoma).

A number of different types of cups are available.

The original (Malmström) metal cup (see Figure 2.13.2) has the chain within a pipe leading to the cup. It may be difficult to sterilise the tube adequately.

FIGURE 2.13.2 The Malmström cup.

The Bird metal cup (see Figure 2.13.3) has two configurations:

- 1 The 5 cm **anterior metal cup** is used for occipito-anterior positions. The smaller 4 cm cup is reserved for the small fetus (e.g. a second twin, and particularly if the cervix is no longer fully dilated).
- 2 The **posterior metal cup** is used for occipito-posterior positions, particularly those with significant deflexion. This is often also the cup of choice for the deep transverse arrest, as the abnormal angle of the baby's head to the vertical, which is often marked, makes correct placement with the anterior cup highly unlikely.

The plastic cup (50 or 60mm internal diameter) comes in two main forms:

- a silastic/silicon soft cup (see Figure 2.13.4) is the safest of all for the fetus, but has a slightly higher failure rate, especially with occipito-posterior positions
- the easy-to-use Kiwi OmniCup (see Figure 2.13.5), which is reusable but relatively expensive ([www.youtube.com/watch?v=TgAcCi9rJhw](http://www.youtube.com/watch?v=TgAcCi9rJhw)).

**FIGURE 2.13.3** The two types of Bird metal cup. (a) Anterior cup. (b) Posterior cup.

**FIGURE 2.13.4** A soft plastic cup.

The application of negative pressure to the cup, including a vacuum gauge to show how much pressure is being applied, is shown in Figure 2.13.6.

#### Indications for an assisted delivery using the vacuum extractor

- Delay in the second stage of labour.
- Fetal distress in the second stage.
- Maternal conditions that require a short second stage (e.g. eclampsia, heart disease).
- Maternal exhaustion.

#### Contraindications

- Face presentation.
- Gestation less than 34 weeks.
- Breech presentation.
- Signs of obstructed labour.

**FIGURE 2.13.5** The Kiwi OmniCup.

**FIGURE 2.13.6** A simple vacuum extractor attached to a Bird anterior metal cup. This is Bird's modification of Malmström's extractor.

#### Prerequisites

- Full dilatation of the cervix and engagement of the head (head at least at 0 station and no more than 1/5 above the symphysis pubis).
- The position of the fetal head in relation to the pelvis must be known.
- A fetus greater than 36 weeks' gestation, or with great care if between 34 and 36 weeks.
- Cooperation of the mother is helpful so that she can enhance contractions and traction by bearing down.
- Uterine contractions must be present.
- Ensure that a healthcare worker who is able to undertake neonatal resuscitation is present in case this is required.
- Ensure that the equipment is working, in particular that the vacuum reaches the correct value by testing the cup on the palm of the hand of the operator (covered by a sterile glove).

### Basic rules

- If the patient is mobile, ask them to empty their bladder. If not, catheterise them. If the patient is catheterised, ensure that any within-catheter balloon is deflated.
- No additional anaesthetic is required (perineal infiltration with lidocaine will suffice if an episiotomy is planned).
- Lithotomy is the commonest position used, but delivery may be possible in a dorsal, lateral or squatting position. The mother should be in a 45-degree sitting position to aid expulsion.
- The delivery should be clearly achievable after three pulls, with evidence of descent with each pull.
- The head, not just the scalp, should descend with each pull.
- The cup should be reapplied no more than twice provided that it has been in the right position and the direction of pull is correct (and after one detachment an experienced operator, if available, should be summoned).
- If failure with the ventouse occurs despite good traction, do not try the forceps but proceed to Caesarean section (provided that it is safe, and available within a reasonable time).

### Methods

**First check your equipment. Attach the cup to the suction, and ensure the suction is working by testing it. This can be done by briefly holding the cup against your hand while suction is applied.**

- 1 Examine the mother carefully using a sterile procedure and gloves and ideally an obstetric cream such as Hibitane. Estimate the size of the baby by abdominal examination, and ensure that the head is fully engaged (no more than 1/5 of the head should be palpable). The membranes should have ruptured.
- 2 Determine the position of the vertex and the amount of caput by vaginal examination. Identify the posterior fontanelle.
- 3 Describe the attitude of the presenting part as 'flexed' or 'deflexed'. In a flexed attitude only the posterior fontanelle can be felt, whereas any situation in which the anterior fontanelle can be felt or the posterior fontanelle cannot be found should be described as deflexed.
- 4 With two fingers press on the perineum posteriorly to widen the vaginal opening (see Figure 2.13.7).

**FIGURE 2.13.7** Inserting a Malmström cup.

**FIGURE 2.13.8** Placing the cup.

**FIGURE 2.13.9** Correct and incorrect positions for the cup.

- 5 Insert the cup, avoiding the urethra. Apply the largest cup that will fit, with the centre of the cup over the flexion point, 2–3 cm anterior to the posterior fontanelle (see Figures 2.13.8 and 2.13.9). This placement will promote flexion, descent and autorotation with traction. Suction is applied to draw the fetal scalp into the cup.
- 6 Ensure that no maternal tissue is caught under the edge of the cup.
- 7 Place the middle of the cup 1–2 cm anterior to the baby's posterior fontanelle/posterior to the anterior fontanelle. This will flex the head during its passage through the pelvis.
  - If you put it more towards the front it will tend to extend the head, so that it will be less easy to pull out. The distance 'Y' when the head is deflexed (bent backwards) is much longer than the distance 'X' when it is flexed (bent forward).
  - If you put the cup to one side, the head will bend to one side.
- 8 Connect the cup to the pump (see Figure 2.13.6), and check for leaks prior to commencing the delivery.
  - First increase the pressure to 0.2 kg/cm<sup>2</sup>, and then, after checking again that there is no maternal tissue caught under the cup, increase the pressure to 0.8 kg/cm<sup>2</sup>, but never any higher than this.
  - Common problems include suction bottles not tightly screwed in or tubing loosely attached to the metal cup.
  - The metal cup should have a meshed bottom plate, which functions to maintain a clear space between

FIGURE 2.13.10 Delivery with the Bird anterior metal cup.

the scalp and the cup so that an effective vacuum can be applied.

- 9 Only perform an episiotomy when the head stretches the perineum (to avoid blood loss), and only if the perineum is interfering with the delivery.
- 10 Check the application. Ensure that there is no maternal soft tissue (cervix or vagina) within the rim.
- 11 During a contraction, encourage the patient to push, and aid her expulsive efforts by applying traction to the cup/fetal head (method described below).

#### Delivery with the anterior metal or plastic cup

The metal or plastic cup is lightly lubricated with sterile delivery cream (e.g. chlorhexidine cream) and then inserted sideways into the vagina. To orientate the cup correctly, direct the chain towards the occiput, which will result in the vacuum pipe lying centrally. Take the pressure up to  $0.2 \text{ kg/cm}^2$ . Check that no maternal tissue is caught under the cup and then increase the pressure directly to  $0.8 \text{ kg/cm}^2$ , but never any higher than this. Begin traction with the next contraction after this pressure has been achieved.

Traction should be along the pelvic axis for the duration of the contraction (initially down, then progressively forwards, and finally upwards as the head delivers) and always perpendicular to the cup (see Figure 2.13.10).

**Always pull in the direction of the birth canal.**

FIGURE 2.13.11 How to ensure that the vacuum cup is securely on the infant's head as you pull.

FIGURE 2.13.12 Guiding the cup with the fingers to detect any slippage while pulling.

FIGURE 2.13.13 Cup slipping off with sideways traction.

- 1 Pull downwards towards the floor until the head is below the ischial spines.
- 2 Pull outwards until the head is stretching the perineum.
- 3 Finally pull upwards until the baby is delivered.

During traction keep one finger or thumb on the edge of the cup and another finger on the scalp so that the earliest sign of detachment or slippage is detected (see Figures 2.13.11 and 2.13.12).

With each contraction apply traction in a line perpendicular to the plane of the cup rim to help to prevent the cup slipping off (see Figure 2.13.13). Place a finger on the scalp next to the cup during traction to assess potential slippage and descent of the vertex (see Figure 2.13.12). **Slight** side-to-side movements may help to edge the head down the pelvic wall, but side-to-side movements must be small to keep the traction line perpendicular and prevent the cup from detaching.

As the head crowns, the angle of traction changes through an arc of over 90 degrees.

If the perineum is stretching as normal, it is simply supported with the hand that was on the cup. An episiotomy must only be undertaken if perineal resistance is preventing delivery.

Occasionally, an edge of the cup might lift off at the introitus (this is more likely to happen if there is caput present). If this occurs, one has to be careful not to catch maternal tissue under the cup as it reattaches. Therefore this should be rechecked before final delivery of the head.

Once the head has delivered, release the vacuum and take off the cup and complete the delivery normally.

### Delivery with the posterior metal cup

For a deflexed head in an occipito-posterior position, the 'OP' cup or if this is not available a plastic cup, ideally a Kiwi OmniCup, should be used. It is applied as far back on the head as possible, again ideally in the midline over the occiput. To allow good placement of the cup, it sometimes helps to try to flex the head, with two fingers of the left hand pressing on the sinciput, while the right hand inserts the cup behind the head. Once correctly placed, the vacuum can be started and taken directly to the required level. (Because the cup lies parallel to the vagina it is unlikely to catch any maternal tissue.) The first pull will be in the direction required to flex the head. With flexion of the head, the presenting diameter immediately becomes less. Thereafter, traction will be along the pelvic axis. The delivery may be completed simply by a standard spontaneous rotation of the baby with maternal effort and gentle assistance. **It is essential not to try to twist the cup to rotate the baby. This will cause trauma, especially spiral tears of the scalp, with the rotational deliveries.**

Overall, occipito-posterior deliveries are the most likely to cause problems. The most difficult ones are those where the head is markedly deflexed or where there is excessive caput. Another difficulty sometimes encountered is that the suction pipe tends to kink once the head flexes, making the cup more likely to detach. If the cup detaches at this point (after flexion and rotation), put it back on again or perform a lift-out forceps.

Between contractions, check the **fetal heart rate** and **secure application of the cup**.

#### Note the following:

- Never use the cup to actively rotate the baby's head. Rotation of the baby's head will occur naturally with traction, if it is going to rotate.
- Do not continue to pull between contractions and expulsive efforts.
- With progress, and in the absence of fetal distress, continue the 'guiding' pulls to achieve delivery. Descent must be seen with each pull, and delivery should be clearly achievable following three pulls.

### Causes and management of failure to deliver with the ventouse

#### Vacuum extraction has failed if:

- the head does not advance with each pull
- the fetus is not delivered or delivery is not imminent after three pulls
- the cup slips off the head twice at the proper direction of pull with a maximum negative pressure.

Every application should be considered a trial of vacuum extraction. Do not persist if there is no descent with every pull.

Generally delivery is achieved with three pulls. As a minimum, it should be clear after three pulls that the delivery is **definitely** going to be achieved imminently by the vaginal route.

#### Failures occur for the following reasons.

- 1 Inadequate initial assessment of the case:
  - The head being too high: a classic mistake is to assume that because caput can be felt below the ischial spines, the head must be engaged.
  - Misdiagnosis of the position and attitude of the head: attention to simple detail will minimise this.
- 2 Anterior or lateral placements will increase the failure rate.
  - If the cup placement is found to be incorrect, it may be appropriate to begin again with correct placement (i.e. midline over the flexion point).
- 3 Failures due to traction in the wrong direction.
  - Gentle sustained traction in the correct direction is what is needed, and sideways movements will be ineffective and increase scalp trauma and cup detachments.
- 4 Excessive caput.
  - Rarely, even with metal cups, adequate traction is not possible because of excessive caput.
  - In these cases, consideration must be given to delivery by Caesarean section unless the head is well down, in which case forceps can be used.
- 5 Poor maternal effort.
  - Maternal effort can contribute substantially to success.
  - Adequate encouragement and instruction should be given to the mother.
  - This may be a reason for preferring forceps to ventouse if the patient is under general anaesthetic.
- 6 The incidence of cephalo-pelvic disproportion (CPD) (true failure) is low. However, in settings where the majority of women deliver at home or in community clinics, it must be remembered that the patient is likely to have been fully dilated for some time before arrival in the hospital, if she has been referred for failure to progress in the second stage. CPD is likely to be relatively more common in this group.

FIGURE 2.13.14 The EgAr device.

One of the main problems with using a ventouse in resource-limited settings is difficulty with the availability of reliable suction. Although this is integral to the Kiwi, these are expensive and usually disposable. A new technique to provide negative pressure for a plastic or metal cup (the EgAr device) has been developed in Gambia by a senior midwife and is described here.

The main components are two valves from out-of-use aneroid blood pressure machines, a 100-mL bladder syringe, a four-way open tap from a urine bag, a urine bag control valve, and a vacuum gauge (see Figure 2.13.14).

The blood pressure system valves are attached to the outflow control unit of a urine bag, which is then attached to the syringe. The valves are arranged in such a way that when the plunger of the syringe is pulled, air is withdrawn into the syringe through the first valve (i.e. valve A). When the plunger is pushed back, the air in the syringe is expelled through the second valve (i.e. valve B). Since the valves (when closed) allow air to flow in only one direction, the syringe can function both to create vacuum pressure by pulling the plunger, and also as an air pump when the plunger is pushed back.

A standard conventional vacuum delivery cup (either the metal or silicon type) is attached to the syringe through one of the blood pressure valves, using the tube from the blood pressure machine. Both valves are closed to ensure that air flows into the syringe only through the first valve (A) when the plunger is pulled, and is expelled only through the second valve (B) when the plunger is pushed back. The vacuum cup is attached to the fetal head and a few pulls (three or four) on the plunger create a negative pressure measured on the vacuum gauge attached to the fourth outlet of the four-way tap (D) sufficient to deliver the baby without the need for continuous pumping. Vacuum pressure is released when the baby is born through the valve (C) from the urine bag near to where the cup is attached.

If vacuum extraction fails, use vacuum extraction in combination with symphysiotomy (see below) or perform Caesarean section.

### Vacuum extraction and symphysiotomy

Vacuum extraction may be used in combination with symphysiotomy in the following circumstances:

- the head is at least at -2 station or no more than 2/5 palpable above the symphysis pubis
- Caesarean section is not feasible or immediately available
- the provider is experienced and proficient in performing symphysiotomy
- vacuum extraction alone has failed or is expected to fail
- there is no major degree of disproportion.

### Complications of vacuum extraction

Complications usually result from not observing the conditions of application, or from continuing efforts beyond the time limits stated above.

#### Fetal complications

- Localised scalp oedema (artificial caput or chignon) under the vacuum cup is harmless and disappears within a few hours.
- Cephalhaematoma (see Figure 2.13.15) requires observation, and will usually clear in 3 to 4 weeks.
- Scalp abrasions (common and harmless) and lacerations

#### Under the periosteum of the skull

#### Under the galea

**FIGURE 2.13.15** Fetal scalp bleeding complications of ventouse (vacuum extraction).

may occur. Clean and examine lacerations to determine whether sutures are necessary. Necrosis is extremely rare.

- Sub-galeal haemorrhage is more serious.

There have been reports of transmission of herpes viral infections from the mother to the fetal scalp following the use of a metal cup. It is theoretically possible that hepatitis or HIV infection may also be transmitted in this way. There is a lower risk of scalp injury using the flexible/plastic cups. Therefore for straightforward ventouse deliveries use the flexible cup when possible, bearing in mind that where rotation is needed as part of the delivery the metal cup is more successful. The metal cup can also deliver a stronger traction force.

### Maternal complications

Tears of the genital tract may occur. Examine the woman carefully and repair any tears to the cervix or vagina, or undertake episiotomy repair.

### Special indications for delivery with the ventouse

With the exception of second twin deliveries (where the cervix is in effect recently parous), vacuum extraction before full dilatation is generally only possible in multiparous women in which the cervix is soft and easily stretchable. This is definitely not always the case even with multiparous women, and great caution must be taken before proceeding to any vaginal delivery before full dilatation. Complications of such deliveries include cervical tears which can extend upward to involve the uterus, and therefore may require laparotomy for repair or even hysterectomy as for a ruptured uterus.

If the operator is uncertain about the degree of engagement, degree of cervical dilatation or the position of the head, a more experienced practitioner should assist (if available).

### Forceps delivery after failure to deliver with the ventouse

There is no place for an attempt at forceps delivery if there

has been no descent with the ventouse despite adequate traction. However, if traction has been inadequate (due to caput, leaking equipment or no maternal assistance), it may be justified to change to forceps. The most experienced operator should make this decision.

**The ventouse is the instrument of first choice for operative vaginal delivery provided conditions for its use are safe and suitable.**

## Forceps delivery

### Introduction

Forceps are particularly helpful in the delivery of the after-coming head of a breech, delivery of a mento-anterior face presentation, and delivery before 34 weeks (although this is controversial).

### Conditions for possible use of forceps

These include the following:

- vertex presentation
- face presentation with chin anterior
- entrapped after-coming head in breech delivery; some operators will routinely control the delivery of the head here by using forceps, provided that the cervix is fully dilated.

**At the very minimum, the sagittal suture should be in the midline and straight, guaranteeing an occiput-anterior or occiput-posterior position.**

### Outlet forceps

In resource-limited settings, forceps at the outlet can be helpful for delay in the second stage when the baby's head is near the outlet, but for all other situations the ventouse is preferred if suitable. The conditions for the use of outlet forceps are as follows:

- the fetal scalp is visible without separating the labia
- the fetal skull has reached the pelvic floor
- the sagittal suture is in the antero-posterior diameter or right or left occiput-anterior or occiput-posterior position (rotation does not exceed 45 degrees)
- the fetal head is at or on the perineum.

The blade on the mother's left always goes in first, and the right blade fits on top of it.

**FIGURE 2.13.16** Outlet forceps.

### Procedure

- Ensure that the head is engaged in the pelvis. Abdominal palpation must be undertaken, particularly in the case of face presentation.
- Urinary catheterisation is required.

**FIGURE 2.13.17** Applying outlet forceps.

- Pudendal block and perineal infiltration with 1% lignocaine is required.
- An episiotomy is usually required.
- Identify the position of the head. Occipito-transverse or occipito-posterior positions are indications for ventouse, and if the head is deflexed, for using the OP ventouse cup or Kiwi OmniCup.
- Ensure that the pair of forceps match. Assemble them and check. It may be useful to check the maximum diameter between the blades, which must be at least 9 cm.
- Lubricate the blades of the forceps with disinfectant cream (e.g. Hibitane).
- Wearing sterile gloves, insert two fingers of the right hand into the vagina on the side of the fetal head. Slide the left blade gently between the head and fingers to rest on the side of the head (see Figure 2.13.18).

A biparietal bimalar application is the only safe option.

**FIGURE 2.13.18** Applying the left blade of the forceps.

Repeat the same manoeuvre on the other side, using the left hand and the right blade of the forceps (see Figure 2.13.19).

**FIGURE 2.13.19** Applying the right blade of the forceps.

- Depress the handles and lock the forceps.
- Difficulty in locking usually indicates that the application is incorrect. In this case, remove the blades and recheck the position of the head. Reapply only if the head is in the appropriate position for the use of forceps.
- After locking check that the sagittal suture lies vertically in the midline between the shanks of the forceps. Also ensure that no more than two fingers can be placed laterally into the fenestrations of the blades. Note: these checks do not ensure correct placement but do help detect some instances of mal-placement.
- After locking, apply steady traction inferiorly and posteriorly with each contraction (see Figures 2.13.20 and 2.13.21). There should be both traction and pressure on top of the joined forceps.

**FIGURE 2.13.20** Locking the handles.

**FIGURE 2.13.21** The correct way of applying traction with downward pressure.

#### **Between contractions check the fetal heart rate and correct application of forceps.**

- When the head crowns, make an adequate **episiotomy**.
- Lift the head slowly out of the vagina between contractions.
- The head should descend with each pull. Only two or three pulls should be necessary.
- Ensure that the head rather than the blades of the forceps are descending with each pull by feeling the fingers on the fetal head moving down. It is very harmful to the fetus if the blades slide down the side of the fetal head.

#### **Failure of forceps**

- The fetal head does not advance with each pull.
- The fetus is not delivered after three pulls.

Every application should be considered a trial of forceps. Do not persist if there is no descent with every pull.

#### **If forceps delivery fails, consider a symphysiotomy or perform a Caesarean section.**

- After repairing any episiotomy, ensure that swab and instrument counts are correct.
- Do a rectal examination to check the integrity of the rectal sphincter and the mucosa for tears.

#### **Complications of forceps use**

##### **Fetal complications**

- Injury to facial nerves requires observation. This injury is usually self-limiting.
- Lacerations of the face and scalp may occur. Clean and examine any lacerations to determine whether sutures are necessary.
- Fractures of the face and skull require close monitoring.

##### **Maternal complications**

Tears of the genital tract may occur. Examine the woman carefully and repair any cervical or vaginal tears and undertake episiotomy repair.

#### **Caesarean section**

The WHO suggests that systems should be in place to ensure that Caesarean section is performed in a minimum of 5% of all expected births.

##### **Indications**

- Obstructed labour.
- Obstetric haemorrhage (especially if ongoing or the mother or fetus is unstable).
- Severe maternal illness where urgent delivery is indicated and is not achievable rapidly by vaginal delivery (e.g. eclampsia where delivery is advised within 12 hours).
- Fetal distress.
- Malpresentation.
- Major placenta praevia.

##### **Pre-operative considerations**

- Check for fetal life by listening to the fetal heart rate.
- Examine for fetal presentation and to ensure vaginal delivery is not achievable.
- Avoid performing a Caesarean section if there is no maternal indication and the fetus is dead.
- Obtain informed consent from the mother.

**Take a blood sample for haemoglobin or haematocrit, blood grouping and cross-matching if indicated. More than 2 × 500 mL units may be needed if antepartum bleeding or massive haemorrhage is anticipated.**

- Transfer the patient to the operating theatre in the left lateral position with a wedge under the right buttock.
- Give antacid immediately prior to general anaesthetic (30 mL of 0.3% sodium citrate (preferable non-particulate) or 300 mg of magnesium trisilicate). This neutralises the stomach acid and minimises damage to the lungs if aspiration occurs.
- Start an IV infusion with a crystalloid such as Ringer-lactate or Hartmann's solution.
- Spinal or general anaesthesia with rapid sequence induction, or ketamine, or local infiltration may be used, depending on local circumstances.

**(For choice of anaesthesia, see Section 1.24.)**

In theatre, the operating table must be kept in the left lateral tilt position or a pillow placed under the woman's right lower back to reduce aorto-caval compression until after delivery.

### **Urinary catheterisation**

The woman must be catheterised and her bladder emptied before starting the procedure, both to avoid injury to the bladder and to monitor urine output.

Remove the catheter after 8 hours if the urine is clear; if not, wait until it is.

Wait 48 hours before removing the catheter if there is:

- uterine rupture
- prolonged or obstructed labour
- gross perineal oedema
- puerperal sepsis with pelvic peritonitis.

If the bladder was damaged, leave the catheter in for 7 days. The urine should be clear of blood and remain so after 48 hours. If the woman is not receiving antibiotics, give nitrofurantoin 100 mg (or cefalexin 500 mg or amoxicillin 500 mg) orally once daily until the catheter has been removed.

### **Skin preparation**

The presence of a large amount of pubic hair around the site of skin incision can interfere with healing. A suitable proportion of this should be shaved off **immediately before the skin is disinfected and the incision is made. There must not be a gap between shaving and operation.**

Tincture of chlorhexidine, iodophor and tincture of iodine are the recommended antiseptic products for preparing the patient's operative site. Apply three times to the incision site using disinfected ring forceps and a cotton or gauze swab. Do not contaminate the glove by touching unprepared skin. Begin at the proposed incision site and work outwards in a circular motion away from the incision site. At the edge of the sterile field discard the swab.

The use of alcohol or hexachlorophene as a single agent is not recommended unless the patient's skin is sensitive to the recommended antiseptic products. Impregnated adhesive film as skin preparation is not recommended.

All patients should be given a prophylactic antibiotic, ampicillin 2 grams IV, before the skin incision, and ideally thromboprophylaxis post-operatively (compression stockings, mobilisation, and 5000 units of heparin

subcutaneously 12-hourly until the patient is discharged from hospital).

### **Prevention of exposure of staff to HIV and hepatitis**

In many operations, micro-holes develop in gloves (not due to needlestick injuries). These micro-holes will of course be more prevalent if gloves are reused, as in some resource-limited settings. If there is a significant risk of HIV or hepatitis, double gloves or special thick gloves should be used. A clear plastic facial shield reduces exposure to blood.

### **Opening the abdomen**

Abdominal and uterine scars are two separate issues. Classical section is a vertical uterine scar, usually but not always associated with a vertical abdominal scar. A vertical abdominal scar may be present with either a classical or lower segment uterine scar.

### **Skin incision**

The choice of skin incision depends on the following:

- the gestational age of the fetus
- the indication for section
- the presence of previous scars
- the operator's surgical experience.

A low transverse incision is preferred to the vertical incision, as there is less likelihood of wound dehiscence and hernia. There are two possibilities, namely the Pfannenstiel incision and the Joel-Cohen incision.

### **The Joel-Cohen incision**

The Joel-Cohen technique includes straight transverse incision through the skin only, 3 cm below the level of the anterior superior iliac spines (higher than the Pfannenstiel incision; see below). The subcutaneous tissues are opened only in the middle 3 cm. The fascia is incised transversely in the midline and then extended laterally with a blunt finger. Finger dissection is used to separate the rectus muscles vertically and laterally and open the peritoneum. All of the layers of the abdominal wall are stretched manually to the extent of the skin incision. The bladder is reflected inferiorly. The myometrium is incised transversely in the midline, but not to breach the amniotic sac, then opened and extended laterally with finger dissection. Interrupted sutures are used for the closure of the myometrium.

### **The Pfannenstiel incision**

This consists of a curved skin incision, two finger-breadths above the symphysis pubis, transverse incision of the sheath, blunt separation of the rectus muscles, and incision of the parietal peritoneum in the midline.

### **The low vertical incision**

The incision is made from the base of the umbilicus to the pubic hair line. This is preferred if better exposure is needed or local anaesthesia is used. It allows easier access to the upper abdomen, is indicated if the lower uterine segment is difficult to access due to adhesions from previous Caesarean sections, if the lie of the fetus is transverse with the back down, and if there are fetal malformations, large fibroids over the lower segment, a vascular lower segment due to placenta praevia, or carcinoma of the cervix.

### **Compared with Pfannenstiel-based Caesarean**

**section, Joel-Cohen-based Caesarean section has been shown to be associated with a reduction in blood loss, operating time, time to oral intake, fever, duration of post-operative pain, analgesic injections, and time from skin incision to birth of the baby.**

The surgeon must ensure that the access to the uterus is adequate to deliver the fetus without difficulty, and in the presence of scarring a Pfannenstiel incision may give better exposure.

### Length of incision

A minimum length of 15 cm is indicated (which accommodates an open Allis forceps).

Excision of the previous scar is not essential for better healing and cosmetic results unless there is keloid scarring.

### General measures

- Handle tissue gently.
- Prevent bleeding.
- Eradicate dead space.
- Minimise the amount of desensitised tissue and foreign material in the wound.

### Practical points

- Extend incision of the fascia, peritoneum and myometrium digitally or with scissors rather than with a scalpel.
- Transfer sharp instruments into a basin/tray.
- Retract tissue with instruments, reposition suture needles with forceps and remove the needle before the final tying of sutures.

### Make the skin incision to the level of the fascia.

If the Caesarean section is performed under local anaesthesia, make a vertical incision that is about 4 cm longer than when general/spinal anaesthesia is used. A **Pfannenstiel incision** takes longer, retraction is poorer and it requires more local anaesthetic.

#### Make a 2–3 cm vertical incision in the fascia.

- Hold the fascial edge with forceps and lengthen the incision from side to side using scissors.
- Use fingers or scissors to separate the rectus muscles (abdominal wall muscles).
- Use scissors to make an opening in the peritoneum near the umbilicus. Use scissors to lengthen the incision up and down in order to see the entire uterus. Use scissors to separate the layers and open the lower part of the peritoneum, taking care to avoid bladder injury.
- Place a bladder retractor over the pubic bone.
- Use forceps to pick up the loose peritoneum covering the anterior surface of the lower uterine segment, and incise with scissors.
- Extend the incision by placing the scissors between the uterus and the loose serosa. Cut transversely about 3 cm on each side.
- Use two fingers to push the bladder downwards off the lower uterine segment. Replace the bladder retractor over the pubic bone and bladder.

### Opening the uterus

- Use a scalpel to make a 3 cm transverse incision in the lower segment of the uterus. It should be about 1 cm below the level where the vesico-uterine peritoneal fold was incised to bring the bladder down.

- Widen the incision by placing a finger at each edge and gently pulling upwards and laterally at the same time.
- If the **lower uterine segment is thick and narrow**, extend the incision in a crescent shape, using scissors instead of fingers to avoid extension into the uterine vessels.
- **It is important to make the uterine incision large enough to deliver the head and body of the baby without tearing the incision.**

### Uterine incision

A **high vertical uterine incision** is indicated if any of the following are present:

- an inaccessible lower segment due to dense adhesions from previous Caesarean section
- transverse lie (with the baby's back down) for which a lower uterine segment incision cannot be safely performed
- fetal malformations (e.g. conjoined twins)
- large fibroids over the lower segment
- a highly vascular lower segment due to placenta praevia
- carcinoma of the cervix.

A **lower transverse incision** is commonly used because:

- less dissection of the bladder is needed
- entry into the uterus is easier
- there is less blood loss
- there is a lower incidence of uterine rupture with subsequent pregnancies.

Lower vertical incision (De Lee's incision) can be useful if the lower uterine segment is poorly formed and thickened, in which case a transverse incision would be unwise.

If a lower transverse incision has been attempted and found to be inadequate, it can be extended upwards in a J-shaped incision to avoid blood vessels and enable adequate access.

**FIGURE 2.13.22** Enlarging the uterine incision.

### Delivery of the baby and placenta

- To deliver the baby, place one hand inside the uterine cavity between the uterus and the baby's head.
- With the fingers, grasp and flex the head.

- Gently lift the baby's head through the incision (see Figure 2.13.23), taking care not to extend the incision down towards the cervix.

**FIGURE 2.13.23** Delivering the baby's head.

- With the other hand, gently press on the abdomen over the top of the uterus to help to deliver the head.
- If the **baby's head is deep down in the pelvis or vagina**, ask an assistant (wearing sterile gloves) to reach into the vagina (which must be sterilised as described above) and push the baby's head up into the uterus. Then lift and deliver the head (see Figure 2.13.24).

**FIGURE 2.13.24** Delivering the deeply engaged head abdominally with assistance via the vagina.

### Method of delivery of fetus

The head delivers into the wound in a transverse direction, so gentle rotation with lateral flexion of the neck is required. In the following circumstances this can be difficult or impossible:

- Caesarean section in the second stage of labour following failed forceps/ventouse, when the head is very low

- occipito-posterior position
- impacted breech
- transverse lie
- prematurity and oligohydramnios where the lower segment is poorly formed and thick.

Manoeuvres that may help include the following:

- an assistant can disengage and push the presenting part upwards from the vagina
- modified lithotomy position with a combined abdomino-vaginal approach
- application of forceps when the head is free
- grasping a foot and delivering by the breech in the presence of transverse lie
- uterine relaxation.

### Other practical points

- If there is posterior placenta praevia, open the uterus and reach in below the placenta, separating it upwards until the membranes are reached, and then deliver the baby. If the placenta is anterior, as soon as you cut into it there will be haemorrhage from the fetus. **It is vital that the cord is clamped as quickly as possible.**
- **In all cases of fetal distress, quick delivery is required.**
- Suction the baby's mouth and nose when delivered, especially if there is meconium-stained liquor.
- Deliver the shoulders and body.
- Give oxytocin 5 units IV to aid delivery of the placenta, and then infuse 40 units in 500 mL of IV fluids (Ringer-lactate or Hartmann's solution) over 4 hours if there is a risk of haemorrhage.
- Clamp and cut the umbilical cord.
- Hand the baby to an assistant for initial care.
- Give a single dose of a prophylactic antibiotic after the cord has been clamped and cut, but only if not given prior to incision: ampicillin 2 grams IV or cefotaxime 1 gram IV.
- Keep gentle traction on the cord and massage the uterus through the abdomen.
- Deliver the placenta and membranes.

### Delivery of the placenta

Spontaneous delivery after oxytocin has been given on delivery of the baby, and with controlled cord traction, is preferred to manual removal. Manual delivery of the placenta may be necessary, and routine checking of the cavity is essential to ensure that no retained placental fragments or membranes are present, as this cannot always be ensured by inspection of the placenta.

### Closing the uterine incision

#### General principles

- Meticulous handling with re-approximation of tissues. Avoid strangulating tissue with tight knots.
- Haemostasis: isolate and ligate major bleeding vessels.
- Grasp minimal tissue while cauterising.

### Exteriorisation of the uterus

This may be necessary in order to visualise the lower segment for suturing, and it may thereby reduce blood loss. It may cause vagal stimulation leading to bradycardia, and may be uncomfortable if performed under spinal or epidural anaesthesia. It is important to inform the anaesthetist of the need to exteriorise.

### Suturing of the uterus

Sutures of polyglycolic acid suture are preferred to catgut. Use of thick suture causes more foreign body and tissue reaction, but if too thin it will cut through the myometrium. Usually the uterus is closed in two layers.

- Grasp the corners of the uterine incision with clamps.
- Grasp the bottom edge of the incision with clamps. Make sure that it is separate from the bladder.
- Look carefully for any extensions of the uterine incision.
- Repair the incision and any extensions with a continuous locking stitch using a robust absorbable suture such as No. 1 or 0 chromic catgut, polyglycolic acid or Vicryl (see Figure 2.13.25).
- A routine second layer of sutures is usually undertaken for the uterine incision, as it may help to reduce the risk of haemorrhage and subsequent uterine rupture through the scar.
- If there is any **persisting bleeding from the incision site**, close with figure-of-eight sutures.

FIGURE 2.13.25 Closing the uterine incision.

Peritoneal closure of parietal and visceral peritoneum is safe. Healing and strength of the wounds are not affected. The duration of surgery is reduced and there is less tendency to form intra-abdominal adhesions.

### Rectus sheath

Standard single-layer closure with a synthetic delayed absorbable suture is recommended. Place each suture 1 cm from the wound edge to allow healing. In vertical incisions, mass closure using synthetic permanent suture is appropriate, but the stitch should not be locking, as this increases post-operative pain and wound hernias.

### Subcutaneous tissue and skin closure

Closure of Camper's fascia with continuous suture reduces the rate of wound disruption. The routine use of closed suction drainage in non-obese patients is not recommended.

Subcuticular or interrupted skin suturing may be undertaken. The type of suture material used for subcuticular suturing does not affect the outcome. Interrupted mattress sutures are recommended in obese patients and in cases where delayed healing is anticipated. Placement of clips has similar results.

**If a Couvelaire uterus (swollen and discoloured by blood) is seen at Caesarean section, as a result of major placental abruption, close it in the normal manner and monitor closely for 48 hours after delivery.**

- **Closing the abdomen.** Look carefully at the uterine incision before closing the abdomen. Make sure that there

is no bleeding and the uterus is firm. Use a sponge to remove any clots inside the abdomen.

- Examine carefully for any injuries to the bladder, and repair these.
- If there are **signs of infection**, pack the subcutaneous tissue with gauze and insert loose 0 catgut (or polyglycolic) sutures. Delay closure of the skin until the infection has cleared.
- If there are **no signs of infection**, close the skin with vertical mattress sutures of 3-0 nylon (or silk) and apply a sterile dressing.
- Gently push on the abdomen over the uterus to remove clots from the uterus and vagina. Swab out the vagina to remove any clots. Any bleeding subsequently noted will therefore be recognised as fresh loss.
- Ensure that there are no instruments or swabs left in the abdomen. One way of achieving this is to have a black or white board in the operating theatre on which is documented every swab or instrument used during the operation, and to ensure that these are available when the abdomen is closed.

### Types of needle and suture material

In resource-limited settings it is often only possible to find two types of suture material for a Caesarean section, for example:

- 1 chromic catgut which can be used on a round-bodied needle for the uterus
- 2 polyglycolic acid which can be used on a round-bodied needle for the uterus and on a cutting/round-bodied needle for the rectus sheath and the skin.

### Complications of Caesarean section

In cases of previous Caesarean section, other abdominopelvic operations or pelvic sepsis, bowel may be adherent to the undersurface of the peritoneum. Extra care must then be taken when opening the peritoneum, dividing it transversely under direct vision when possible.

In such cases, the peritoneum should be opened with a knife or scissors rather than with the fingers.

Bladder may be adherent to the lower segment, and care must be taken to push the bladder well down in order to avoid trauma to the bladder or ureters. Emptying the bladder pre-operatively reduces the likelihood of bladder damage.

Fibroids may obstruct access to the lower segment. A decision has to be made as to whether to make the uterine incision above, below or around the fibroids, or to cut through them. Alternatively, a classical (midline) uterine incision may be necessary, with its attendant greater risk of scar rupture in future pregnancies.

In cases of placenta praevia, the placenta is encountered on making the lower segment incision. This may lead to excessive bleeding.

The placenta may be morbidly adherent to a previous Caesarean section scar (placenta accreta). It is important not to traumatise the uterine wall by delivering the placenta piecemeal. It may be necessary to leave the adherent fragment *in situ*, and monitor carefully for bleeding and signs of infection. Postpartum hysterectomy may be required in this situation.

Caesarean section at full dilatation may be complicated by difficulty in dis-impacting the fetal head. An assistant should push firmly but gently from the vagina using sterile

gloves and obstetric chlorhexidine cream on their fingers. Once the head is dis-impacted, fundal pressure is required.

Excessive bleeding at Caesarean section is most commonly due to uterine atony, lateral extension of the lower segment incision, or a combination of these two factors (see Section 2.5.D.iv on postpartum haemorrhage).

Where a trial of forceps has taken place prior to Caesarean section, care must be taken to identify and suture any vaginal tears, which may bleed heavily.

### Uncontrolled bleeding

#### Primary haemorrhage

The cause of the haemorrhage, whether due to atony or trauma, should be determined. Help should be sought from senior colleagues (if available). The anaesthetist must be informed about the haemorrhage, and blood should already be cross-matched (at least 4 to 6 units). In cases of vertical extension into the vagina, suturing should be attempted from the lowest part of the tear before suturing the transverse incision. Massage the uterus to expel blood and blood clots. The presence of blood clots will inhibit effective uterine contractions.

#### Broad ligament haematomas

The leaves of the broad ligament need to be opened and the ureters should be identified before suturing the bleeding point.

#### Atonic uterus

If the uterus is atonic, massage it, continue to infuse oxytocin, and give:

- ergometrine 200–500 micrograms IM (must not be used if the patient has hypertension), if the mother is fully conscious
- *and/or* misoprostol 400–600 micrograms sublingually or orally or 800 micrograms rectally if the mother is drowsy or unconscious.

These drugs can be given together or sequentially.

Transfuse as necessary.

Have an assistant apply firm pressure with a fist over the aorta to reduce the bleeding until the source of bleeding can be found and stopped.

**If bleeding is not controlled, see Section 2.5.D.iv for details of the many methods of treatment that can be adopted. They include a hysterectomy.**

#### Breech delivery at Caesarean section

The fetal back should always be upwards during breech delivery. Gentle rotation of the fetal trunk may be required, being careful to grasp the bony pelvis and legs, thereby avoiding traumatising the fetal abdomen.

The baby is delivered as if performing a breech extraction vaginally. In summary, place the fingers of each hand into the groin of the baby and lift out the buttocks and legs.

Deliver the arms by the Løvset's manoeuvre; legs and the body up to the shoulders, then deliver the arms.

Flex the head and deliver using the Mauriceau–Smellie–Veit manoeuvre.

Complete the delivery as for a vaginal delivery.

#### Transverse lie delivery at Caesarean section

Assess the position of the fetus, including the position of the head, before opening the uterus. If the membranes are

intact and there is liquor around the fetus, try to convert the transverse lie to a longitudinal lie.

- If **the back is up** (near the top of the uterus), reach into the uterus and find the baby's ankles.
- Grasp the ankles and pull gently through the incision to deliver the legs and complete the delivery as for a breech baby.
- If **the back is down**, a high vertical uterine incision may be preferred, but this is too late if only discovered once inside the uterus.
- Following the incision, reach into the uterus and find the feet. Pull them through the incision and complete the delivery as for a breech baby.
- To repair the vertical incision, three layers of suture will be needed.

#### Placenta praevia

If a low anterior placenta is encountered, find an edge of the placenta and move the placenta laterally or incise through it and deliver the fetus.

- An ultrasound scan prior to the operation will help the operator to judge whether it will be possible to manually displace the placenta in order to access the amniotic cavity.
- After delivery of the baby, **if the placenta cannot be detached manually**, the diagnosis is placenta accreta, occasionally seen at the site of a previous Caesarean scar.
- There are two approaches to this problem. The **placenta can be left *in situ* to degenerate spontaneously, or a hysterectomy may be performed**. If the former approach is followed, a careful watch will need to be kept for any signs of infection in the postnatal period, and prophylactic antibiotics will be required.
- Women with placenta praevia are at high risk of postpartum haemorrhage.
  - If there is bleeding at the placental site, under-run the bleeding sites with chromic catgut (or polyglycolic/Vicryl) sutures before closing the wound.
  - It may also be helpful to compress the lower segment vessels by packing the uterus or inserting a condom-catheter.
  - Watch for bleeding in the immediate postpartum period and take appropriate action.

#### Post-operative care

- Bowel function should be normal after 12 hours.
- If progress is uncomplicated, give liquids immediately and solids when the patient is passing gas per rectum.
- If there is infection, obstructed labour or uterine rupture, wait until bowel sounds reappear before giving oral fluids.
- Keep a dressing on the wound for 24 hours to ensure re-epithelialisation.
- If blood is leaking, reinforce the dressing or replace it with a new one if it is more than half soaked.

#### If bleeding occurs:

- Massage the uterus to expel blood and blood clots. The presence of blood clots will inhibit effective uterine contractions:
  - Give oxytocin 5 units IV slowly or 10 units IM and then infuse 40 units in 500 mL of IV fluids (Ringer-lactate or Hartmann's solution) over 4 hours

- or ergometrine 500 micrograms IM or misoprostol 400 micrograms sublingually or orally **provided that the mother is fully conscious**
- or misoprostol 800 micrograms rectally **if the mother is drowsy or unconscious.**

These drugs can be given together or sequentially.

- **If there are signs of infection or the mother has a fever**, give a combination of antibiotics until she has been fever-free for 48 hours:
  - Ampicillin 2 grams IV every 6 hours
  - *plus* gentamicin 80mg IV/IM every 8 hours or 5mg/kg body weight IV/IM once every 24 hours
  - *plus* metronidazole 500mg IV every 8 hours.
- Give appropriate analgesic drugs.

Discharge the mother home when her temperature has been normal for at least 24 hours, and she is mobilising and able to eat and drink normally.

## Symphysiotomy

### Background

Symphysiotomy is performed for the management of cephalo–pelvic disproportion in selected situations in resource-limited countries or ill-equipped obstetric units. It may be required for the delivery of the trapped after-coming head with a breech delivery, or for shoulder dystocia. Symphysiotomy results in a temporary increase in pelvic diameter (up to 2 cm) by surgically dividing the cartilage of the symphysis under local anaesthesia. Symphysiotomy in combination with vacuum extraction is a life-saving procedure in areas where Caesarean section is not immediately available.

Symphysiotomy leaves no uterine scar, so the risk of ruptured uterus in subsequent pregnancies is not increased.

Caesarean section can have high morbidity and mortality rates in resource-limited healthcare facilities. Mortalities of up to 5% and uterine scar rupture in 7% of subsequent pregnancies have been reported. Symphysiotomy has a very low maternal mortality, with 3 deaths reported in a series of 1752 symphysiotomies. These deaths were unrelated to the procedure.

However, symphysiotomy has risks of complications, which include urethral and bladder injury, infection, pain and long-term difficulty in walking. Therefore it should only be performed when there is no safe alternative.

Symptoms following symphysiotomy include pain in the symphysis pubis and groin, hip or thigh pain, backache and stress incontinence.

FIGURE 2.13.26 Site of the symphysiotomy incision.

**The majority of mothers (73%) will have an uncomplicated vaginal delivery in a subsequent pregnancy.**

### Indications for symphysiotomy

- Trapped after-coming head in breech delivery, in the presence of full cervical dilatation.
- Shoulder dystocia, where all other methods have failed.
- A live fetus with vertex presentation **and** presumed cephalo–pelvic disproportion (i.e. prolonged second stage, no head descent after adequate augmentation, and failure or anticipated failure of vacuum extraction alone).
- At least one-third of the fetal head should have entered the pelvic brim.
- The cervix should be fully dilated, and the head should be at –2 station or no more than 3/5 above the symphysis pubis, with no overriding of the head above the symphysis.

### Technique

FIGURE 2.13.27 Legs abducted no more than 45 degrees from vertical.

Ask two assistants to support the woman's legs with her thighs and knees flexed. The thighs should be abducted no more than 45 degrees from the midline, **not** the lithotomy position.

**Abduction of the thighs more than 45 degrees from the midline may cause tearing of the urethra and bladder.**

- Infiltrate the anterior, superior and inferior aspects of the symphysis with 1% lignocaine solution.
  - Aspirate (pull back on the plunger) to make sure that no vessel has been penetrated. **If blood is returned in the syringe with aspiration**, remove the needle. Recheck the position carefully and try again. Never inject if blood is aspirated.
- **Infiltrate the local anaesthetic and wait for it to take effect.**
- Insert a firm sterile urinary catheter to identify the urethra.
- Apply antiseptic solution to the suprapubic skin.
- Wearing sterile gloves:
  - Place the index and middle fingers of the left hand into the vagina.

**FIGURE 2.13.28** The position for holding the woman's legs for symphysiotomy.

- Using the index finger, push and hold the catheter, and with it the urethra, away from the midline to the patient's right side.
- The middle finger lies centrally under the symphysis to guide the incision.
- With the other hand, use a firm-bladed scalpel to make a vertical incision over the symphysis.
- Cut down through the cartilage joining the two pubic bones until the pressure of the scalpel blade is felt on the finger in the vagina.
  - The symphysis pubis is incised in the midline at the junction of the upper and middle thirds. The point of the scalpel will be felt impinging on the vagina by the underlying finger of the left hand.
  - The upper third of the uncut symphysis is used as a fulcrum against which the scalpel is levered to incise the lower two-thirds of the symphysis.
  - The scalpel is then removed and rotated through 180 degrees, and the remaining upper third of the symphysis is cut.
- Once the symphysis has been divided, the pubic bones will separate.
  - 1 The symphysis should open as wide as the operator's thumb. A large episiotomy is required to relieve tension on the anterior vaginal wall. Usually a vacuum extractor will be used to pull the fetus downward at this point.
  - 2 Delivery of the head and trunk of the baby occurs in a downward direction, taking care to avoid the temptation to lift the baby up until it is completely delivered.
  - 3 After delivery of the baby and placenta, the symphysis is compressed between the thumb above and the index

**FIGURE 2.13.29** Sagittal view of symphysiotomy.

**FIGURE 2.13.30** The symphysiotomy incision.

**FIGURE 2.13.31** Cutting through the cartilage.

- and middle fingers below for several minutes in order to express blood clots and promote haemostasis.
- 4 There is no need to close the incision unless there is bleeding.
- 5 Reinsert the urinary catheter.

**Post-procedure care**

- If there are signs of infection or the mother has a fever, give a combination of antibiotics until she has been fever-free for 48 hours:

- Ampicillin 2 grams IV every 6 hours
- *plus* gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours
- *plus* metronidazole 500 mg IV every 8 hours.
- Give appropriate analgesia.
- Apply a binder or sheet or elastic strapping across the front of the pelvis from one iliac crest to the other to hold the pelvis together to aid pelvic healing and reduce pain. Nurse the woman on her side to allow gravity to aid pelvic healing.
- Leave the urinary catheter in for at least 5 days.
- Encourage oral fluids to ensure a good urinary output.
- Encourage bed rest for 7 days after discharge from hospital.
- Encourage the mother to begin walking with assistance when she is ready to do so.
- If **long-term walking difficulties and pain** occur (2% of cases), treat them with physiotherapy.

### Induction of labour for intrauterine death in the second or third trimester

See Section 2.6.B.

### Destructive operations

#### Background

Destructive procedures are undertaken when a vaginal delivery must occur because:

- skilled staff are not available to carry out what may be a difficult or dangerous Caesarean section
- in neglected obstructed labour there is a risk of overwhelming infection following Caesarean section
- of the implications of a uterine scar for future pregnancies
- the patient does not give consent to Caesarean section.

#### Reasons for fetal death in obstructed labour

- Strong and continuous contractions (sometimes made worse by inappropriate use of oxytocic drugs or other non-prescription uterotonic drugs) interfere with placental exchange.
- Excessive moulding of the head, in cephalic presentation, can lead to intracranial haemorrhage. In breech presentation the head may be trapped by an incompletely dilated cervix, or may not enter the pelvis because of disproportion.
- Prolapsed cord.
- Ascending infection, amnionitis and intrauterine infection due to prolonged ruptured membranes and labour, and/or unsterile vaginal examinations.
- Ruptured uterus.

### Destructive operations

**Before a destructive procedure is undertaken the fetus must be dead.**

**Ensure that the mother is adequately resuscitated.**

Ruptured uterus must be excluded.

**Ensure adequate analgesia or anaesthesia.**

The procedure can be performed under general or regional anaesthesia, or sedation and analgesia with morphine, midazolam and/or ketamine.

### General issues relating to destructive procedures

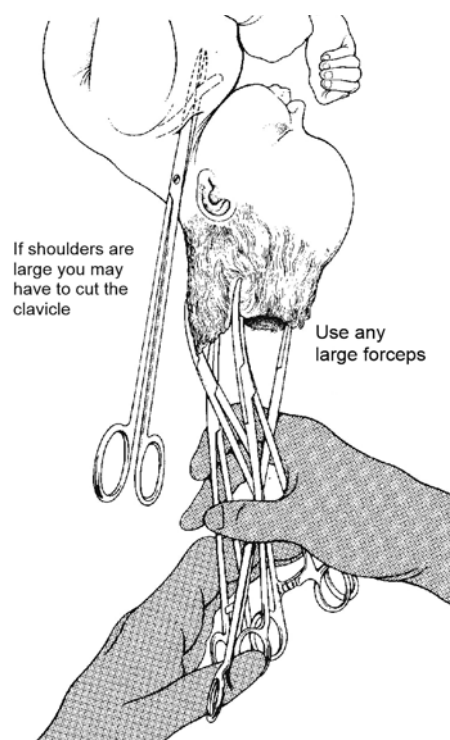

- The operator must be competent at destructive deliveries.
- Destructive operations are most safely done at full dilatation, but may be performed when the cervix is 7 cm or more dilated. If there is hydrocephaly, it is best to drain the CSF at diagnosis without waiting for full dilatation, as the hydrocephalic head may cause uterine rupture.
- The bladder must be catheterised.
- Post-delivery care includes continuous catheterisation of the bladder, IV antibiotics and IV fluids.

### Craniotomy

Craniotomy is used for the delivery of a dead fetus with cephalic presentation when labour is obstructed. Usually the head is impacted in the pelvic brim. If the head is mobile, craniotomy may be difficult and Caesarean section may be safer (if circumstances are suitable).

The head may need to be dis-impacted from the pelvis to facilitate urinary catheterisation.

A 3 cm incision is made on the posterior aspect of the skull using Mayo scissors. The index finger of the left hand is inserted into the incision and the suture and fontanelle are identified. The scissors are then pushed through the fontanelle into the cavity of the skull. Thereafter the brain is evacuated and Kocher's forceps are clamped on to the edges of the parietal bones. A weight is attached to the Kocher's forceps with a length of bandage. The mother's legs are taken out of the lithotomy stirrups and placed on two stools for support. Delivery will take place within a period ranging from a few minutes to several hours. This method can be used when the cervix is at least 8 cm dilated.

**FIGURE 2.13.32** Craniotomy. This baby's skull has been opened and the brain removed. These are not vulsellum forceps, but you can use such forceps.

FIGURE 2.13.33 X-shaped fetal skull incision.

FIGURE 2.13.34 Perforating the skull: a life-saving operation. Your assistant is pushing the baby's head into the mother's pelvis. You have made an X-shaped incision in the skin of the baby's scalp. You have found a suture line, and are pressing a strong pair of scissors into it.

**Breech presentation with an entrapped head and dead fetus**

- Make an incision through the skin at the base of the neck.
- Insert a craniotome (or large pointed scissors or a heavy scalpel) through the incision and tunnel subcutaneously to reach the occiput.
- Perforate the occiput and open the gap as wide as possible.
- Apply traction on the trunk to collapse the skull as the head descends.

**Craniocentesis (skull puncture) for hydrocephalus and obstructed labour and dead fetus**

FIGURE 2.13.35 Hydrocephaly. A child with one abnormality often has several others as well.

**Craniocentesis with a fully dilated cervix**

- Pass a large-bore spinal needle through the dilated cervix and the sagittal suture line or fontanelles of the fetal skull (see Figure 2.13.36).
- Aspirate the cerebrospinal fluid until the fetal skull has collapsed. Then allow normal delivery to proceed.

**Craniocentesis with a closed cervix**

- Palpate for the location of the fetal head.
- Apply antiseptic solution to the suprapubic skin.
- Pass a large-bore spinal needle through the abdominal and uterine walls and through the hydrocephalic skull.

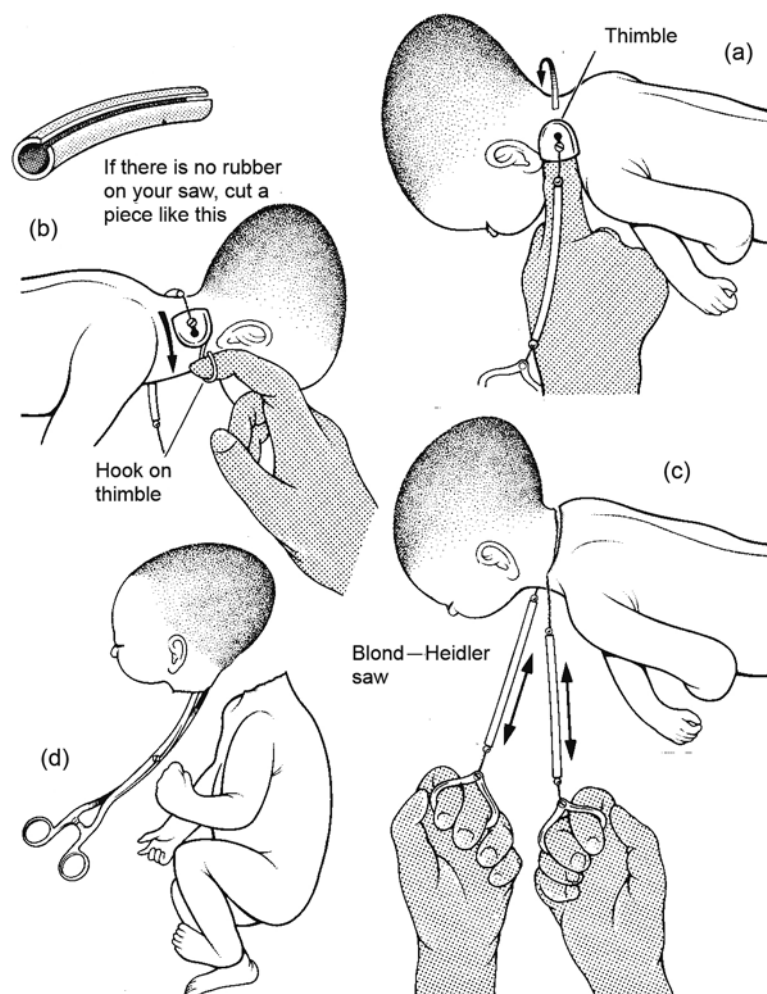

FIGURE 2.13.36 Draining a hydrocephalus. (a) Draining the vertex. (b) Draining the occiput. (c) Draining through a meningo-myelocele. (d) Draining through the mother's abdomen.

**FIGURE 2.13.37** Decapitation of dead fetus. (a) Fix the saw to the thimble and push it over the neck. (b) Remove the thimble and fix the handles to each end of the saw. (c) Saw to and fro. (d) Grasp the stump of the neck.

- Aspirate the cerebrospinal fluid until the fetal skull has collapsed. Then allow vaginal delivery to proceed.

**Craniocentesis in breech where the hydrocephalic head is stuck and the fetus is dead**

- When the rest of the body has been delivered, insert a large-bore spinal needle through the dilated cervix and foramen magnum.
- Aspirate the cerebrospinal fluid and deliver the after-coming head as in breech delivery.

This can be managed similarly, by craniotomy with perforation of the head through the occiput. Where there is hydrocephalus and accompanying spina bifida, CSF can be withdrawn by exposing the spinal canal and passing a catheter into the canal and up into the cranium. Alternatively, the hydrocephalic head can be decompressed trans-abdominally using a spinal needle.

**Decapitation**

This procedure is summarised in Figure 2.13.37.

In cases of neglected obstructed labour with shoulder presentation and a dead fetus, decapitation is the treatment of choice. The lower uterine segment is very vulnerable. If

the fetus is small, the neck can easily be severed with stout scissors. However, for the larger fetus, where the neck is not easily accessible, the Blond–Heidler decapitation tool is probably the safest instrument. If possible, an arm of the fetus is brought down in order to facilitate access and exposure of the neck. The saw is threaded around the fetal neck, and by keeping the handles at the ends of the saw close together, injury to the vagina is prevented and the neck can be severed with a few firm strokes. Delivery of the trunk is straightforward, and the after-coming head is delivered by grasping the stump with a heavy volsellum.

**Cleidotomy**

Cleidotomy is indicated where the impacted shoulders prevent delivery of the dead fetus. The most accessible clavicle is divided first using stout scissors.

**Evisceration**

This is sometimes necessary for an abdominal tumour or very large fetus following craniotomy. An incision is made in the abdomen or thorax. The viscera are then extracted digitally. Once the bulk of the fetus has been reduced the fetus can be extracted easily.

**TABLE 2.13.1** Possible situations of fetal death and the relevant procedures

Clinical situation	Procedure
<i>Cephalic presentation:</i>	
Head < 60% above the pelvic brim	Craniotomy
Head free or > 60% palpable	Caesarean section
Hydrocephalus	Perforation before full dilatation
Obstruction due to abdominal tumour	Embryotomy if the abdomen is accessible, otherwise Caesarean section
Impacted shoulders	Cleidotomy
<i>Breech presentation:</i>	
Obstruction due to after-coming head	Perforation of the head
Obstruction due to abdominal tumour	Embryotomy
Impacted shoulders	Cleidotomy
<i>Transverse or oblique lie:</i>	
Shoulder presentation or arm prolapse	Decapitation
Access to fetal neck difficult	Caesarean section
Ruptured uterus	Laparotomy – repair/hysterectomy
Gross disproportion	Caesarean section

### Complications of destructive operations

Instruments or sharp pieces of bone may cause a vesico-vaginal fistula. The vagina, cervix and perineum must therefore be carefully examined after the procedure.

### Alternative to destructive operations

Symphysiotomy with episiotomy may avert the need for destructive operations if the fetus is still alive.

Caesarean section may be preferred, if available, especially if the operator is inexperienced in performing destructive procedures. However, caesarean section will create a risk for scar rupture during a subsequent pregnancy and in low resource settings this could result in maternal and fetal death.

### Post-procedure care

- After delivery, examine and repair any tears to the cervix or vagina, or undertake episiotomy repair.
- Leave a self-retaining catheter in place until bladder injury has been excluded.
- Ensure adequate fluid intake and urinary output.

### Episiotomy

Episiotomy should be considered in the case of:

- complicated vaginal delivery (e.g. breech, shoulder dystocia, forceps, vacuum delivery)
- scarring from female genital cutting
- fetal distress
- delay in the second stage
- previous third- or fourth-degree tears
- where significant perineal trauma is anticipated if it is not performed.

### Procedure

- Apply antiseptic solution to the perineal area.
- Use local infiltration with 1% lignocaine. Make sure that there are no known allergies to lignocaine or related drugs.
- Infiltrate beneath the vaginal mucosa, beneath the skin of the perineum and deeply into the perineal muscle (see Figure 2.13.38) using 5–10 mL of 1% lignocaine solution.
- **Aspirate (pull back on the plunger) to be sure that no vessel has been penetrated. If blood is returned in the syringe with aspiration, remove the needle. Recheck the position carefully and try again. Never inject if blood is aspirated.**
- After local anaesthetic infiltration, wait for 2 minutes and then pinch the incision site with forceps. **If the mother feels the pinch, wait a further 2 minutes and then retest.**

**FIGURE 2.13.38** Infiltration of the perineum with local anaesthetic.

Do not perform an episiotomy until the perineum is thinned out and 3–4 cm of the baby's head are visible during a contraction.

**Performing an episiotomy will cause bleeding, so it must not be done too early.**

- 1 Wearing disinfected gloves, place two fingers between the baby's head and the perineum.
- 2 Use scissors to cut the perineum about 3–4 cm in the medio-lateral direction (see Figure 2.13.39). It is essential that the episiotomy cut is not made where, if it runs into a tear, it involves the anal sphincter. That is, it must be at an angle away from the anus, as shown in Figure 2.13.39.
- 3 Control the baby's head and shoulders as they deliver, ensuring that the shoulders have rotated to the midline to prevent an extension of the episiotomy.
- 4 Carefully examine for extensions and tears, and repair them (see below).

### Repair of episiotomy

**It is important that absorbable sutures or Vicryl are used for closure.** Polyglycolic sutures are preferred to chromic catgut because of their tensile strength, non-allergenic properties and lower risk of infection and episiotomy breakdown. However, chromic catgut is an acceptable alternative.

Apply antiseptic solution to the area around the episiotomy.

- If the episiotomy is extended (torn) through the anal sphincter or rectal mucosa, which should not happen if the original cut has been away from the vertical

**FIGURE 2.13.39** Using two fingers to protect the baby's head while making the incision.

(see above), manage as third- or fourth-degree tears, respectively.

- **Close the vaginal mucosa using continuous 2-0 suture.**
- Start the repair about 1 cm above the apex (top) of the episiotomy. Continue the suture to the level of the vaginal opening.
- At the opening of the vagina, bring together the cut edges of the vaginal opening.
- Bring the needle under the vaginal opening and out through the incision and tie.
- Close the perineal muscle using a continuous 2-0 suture.
- Close the skin using a subcuticular or interrupted 2-0 suture.

#### Complications of episiotomy

- 1 **Haematoma.** If this occurs, open and drain it. If there are **no signs of infection and bleeding has stopped**, reclose the episiotomy.
- 2 **If there are signs of infection**, open and drain the wound. Remove infected sutures and debride the wound:
  - If the **infection is mild**, antibiotics are not required.
  - If the **infection is severe but does not involve deep tissues**, give a combination of antibiotics:
    - Ampicillin 500 mg orally four times a day for 5 days
    - *plus* metronidazole 400 mg orally three times a day for 5 days.
  - If the **infection is deep and involves muscles**, give a combination of antibiotics until the necrotic tissue has been removed and the mother has been fever-free for 48 hours:
    - penicillin G, 2 million units IV every 6 hours
    - *plus* gentamicin 80 mg IV/IM every 8 hours or 5 mg/kg body weight IV/IM once every 24 hours
    - *plus* metronidazole 500 mg IV every 8 hours.
  - When **the mother has been fever-free for 48 hours**, give:
    - ampicillin 500 mg orally four times a day for 5 days
    - *plus* metronidazole 400 mg orally three times a day for 5 days.

**Necrotic tissue requires wide surgical debridement.** Perform secondary closure in 2 to 4 weeks (depending on resolution of the infection).

#### Repair of cervical tears

- If the mother is bleeding heavily it may be best to resuscitate and then pack the tear with sterile gauze. Bimanual compression may be required. Ensure that whoever repairs this is experienced. This might need referral to another hospital.
  - Repair only when the mother is stable and most of the bleeding has stopped, unless there is heavy ongoing blood loss despite compression in which case repair needs to be undertaken urgently while resuscitation continues
  - Apply antiseptic solution to the vagina and cervix.
- Anaesthesia is not required for most cervical tears.
  - For tears that are high and extensive, give morphine 10 mg IV slowly over 5 minutes (provided that shock is not present), or use ketamine.
- Ask an assistant to massage the uterus and provide fundal pressure.
- Gently grasp the cervix with ring or sponge forceps.
  - Apply the forceps on both sides of the tear and gently use the forceps to pull each part of the cervix down in turn so that the entire cervix is examined.
  - There may be several tears.
- One way of finding a high tear is to insert a suture as high as possible and then use it to provide traction to work up to the apex to obtain haemostasis, and then to work downward towards the introitus.
- Close the cervical tears with a continuous polyglycolic/Vicryl suture starting at the apex (upper edge of tear), which is often the source of bleeding (see Figure 2.13.40).
- **If a long section of the rim of the cervix is tattered and bleeding**, under-run it with a continuous polyglycolic/Vicryl suture. Often if the bleeding is persistent but mild, compressing the ragged edges with a sterile pack is the most effective way of halting the bleeding, if no specific delineated tear is identified.
- **If the apex is difficult to reach and ligate**, it may be possible to grasp it with artery or ring forceps. Leave the forceps in place for 4 hours.
  - Do not persist in attempts to ligate the bleeding points, as this may increase the bleeding.
  - After 4 hours, open the forceps partially but do not remove.
  - After another 4 hours, remove the forceps completely.
- A laparotomy may be required to repair a cervical tear that has extended beyond the vaginal vault.

**FIGURE 2.13.40** Repair of a cervical tear.

## Manual removal of the placenta

If the placenta does not separate within 1 hour of delivery, or immediately if there is heavy bleeding:

- start an IV infusion
- ensure that the bladder is emptied either by the mother or by catheterisation
- give a slow IV injection of ketamine (1–2 mg/kg or 50–100 mg) or morphine (10 mg), ideally in the presence of an anaesthetist
- give a single dose of prophylactic antibiotics:
  - ampicillin 2 grams IV *plus* metronidazole 500 mg IV
  - or cefotaxime 1 gram IV *plus* metronidazole 500 mg IV.
- Ensure full aseptic drapes.
- Hold the umbilical cord with a clamp. Pull the cord gently until it is taut.
- Wearing sterile gloves (ideally covering the forearms) insert a hand into the vagina and follow the cord up into the uterus until you reach the edge of the placenta (see Figure 2.13.41). If the cervix is closed, gentle pressure with one or two fingers will usually relax it and make it open.
- Let go of the cord with the other hand and move the hand up over the abdomen in order to support the fundus of the uterus and to provide counter-traction during removal to prevent inversion of the uterus (see Figure 2.13.42).

**If uterine inversion occurs, reposition the uterus immediately.**

- Move the fingers of the hand laterally until the edge of the placenta is located.
- **If the cord has been detached previously**, insert a hand into the uterine cavity.
  - Explore the entire cavity until a line of cleavage is identified between the placenta and the uterine wall.

FIGURE 2.13.41 Entering the uterus along the cord.

FIGURE 2.13.42 Supporting the fundus while detaching the placenta.

- Reach the placenta from the implantation site by keeping the fingers tightly together and using the edge of the

hand to gradually make a space between the placenta and the uterine wall.

- Proceed slowly all around the placental bed until the whole placenta is detached from the uterine wall.
- **If the placenta does not separate from the uterine surface** by gentle lateral movement of the fingertips at the line of cleavage, suspect placenta accreta.
  - Consider laparotomy and possible subtotal hysterectomy.
  - Alternatively, the placenta can be left *in situ* to spontaneously degenerate.
  - The main risk is that of infection and delayed haemorrhage, and follow-up needs to be maintained to assess the woman for signs of sepsis.
- Hold the placenta and slowly withdraw the hand from the uterus, bringing the placenta with it (see Figure 2.14.43).
- With the other hand, continue to provide counter-traction to the fundus by pushing it in the opposite direction to the hand that is being withdrawn.

FIGURE 2.13.43 Withdrawing the hand plus the placenta from the uterus.

- Palpate the inside of the uterine cavity to ensure that all placental tissue has been removed.
- Give oxytocin 40 units in 500 mL of IV fluids (Ringer-lactate or Hartmann's solution) over 4 hours.
- Ask an assistant to massage the fundus of the uterus to encourage a tonic uterine contraction.
- If there is **continued heavy bleeding**, give 10 units of oxytocin IM. If this does not work, try ergometrine 200–500 micrograms (not if there is or has been hypertension) IM and, if that does not work, give misoprostol rectally as 4 × 200 microgram tablets or pessaries (800 micrograms total) or, **if the woman is conscious**, misoprostol orally 3 × 200 microgram tablets.
- Examine the uterine surface of the placenta to ensure that it is complete. If any **placental lobe or tissue is missing**, explore the uterine cavity under strict surgical asepsis to remove it.
- Examine the mother carefully and repair any tears to the cervix or vagina, or undertake episiotomy repair.

### Problems

**If the placenta is retained due to a constriction ring or if hours or days have passed since delivery**, it may not be possible to get the entire hand into the uterus. Consider using a general anaesthetic to help to relax the cervix, and extract the placenta in fragments using two fingers or ovum forceps, but be very careful not to penetrate the soft uterine wall. If hours or days have passed and/or signs of sepsis are present, treat for puerperal sepsis with a full course of IV antibiotics (see Section 2.5.G).

### Post-procedure care

Observe the mother closely until the effect of IV analgesia has worn off.

- Monitor the vital signs (pulse, blood pressure, respiration and temperature) every 15 minutes for the first hour and then every 30 minutes for the next 6 hours or until the patient is stable.
- Palpate the uterine fundus to ensure that the uterus remains contracted.
- Check for excessive lochia.
- Continue infusion of IV fluids.
- Transfuse as necessary, especially if the mother is severely anaemic before the procedure.
- Warn the mother of the increased risk of this occurring at the time of the next pregnancy, and therefore advise her to deliver in a well-equipped comprehensive EmOC facility.

## Bilateral pudendal nerve block

### Indications

This technique is indicated for some instrumental deliveries, for repair of larger tears, and for craniotomy or craniocentesis.

A pudendal nerve block targets the pudendal nerve as it enters the lesser sciatic foramen, about 1 cm inferior and medial to the attachment of the sacrospinous ligament to the ischial spine. The aim is to block the nerve proximal to its terminal branches. Here the nerve is medial to the internal pudendal vessels. The transvaginal approach is described here, as it is the most reliable.

Dilute 20 mL of 1% lidocaine to 40 mL with Ringer-lactate or Hartmann's solution, to make a solution of 0.5%. This is used starting with 15 mL on each side. The remaining 10 mL can be used to infiltrate the perineum during repairs if these are needed.

Adrenaline is not used with the lidocaine.

Ensure that IV access is in place.

The needle used should be around 15 cm in length and 20–22 gauge.

The procedure must be undertaken with surgical sterility after cleaning the vagina with chlorhexidine (Hibitane) obstetric cream, and always using sterile gloves.

Resuscitation equipment and medications should always be readily available in case an adverse reaction to the local anaesthetic occurs.

### Procedure

Palpate the ischial spine through the vaginal wall.

A metal trumpet (see Figure 2.13.44) can facilitate the placement of the needle and limit the depth of submucosal penetration, but is not essential.

- 1 To perform a left-sided block, palpate the ischial spine with the index finger of the left hand, hold the syringe in the right hand, and guide the needle between the index finger and middle finger of the left hand toward the ischial spine (see Figure 2.13.45).
- 2 Place the end of the guide beneath the tip of the ischial spine.
- 3 Push the needle into the vaginal mucosa.
- 4 **Aspirate to ensure that the needle is not in one of the pudendal blood vessels, which could be very dangerous if lidocaine is injected.**
- 5 Inject 1 mL of local anaesthetic.

FIGURE 2.13.44 Metal trumpet to guide needle to site of pudendal nerve.

FIGURE 2.13.45 Inserting the needle using a trumpet guide. © 2012 Christy Krames.

- 6 Advance the needle through the vaginal mucosa until it touches the sacrospinous ligament 1 cm medial and posterior to the ischial spine.
- 7 **Aspirate to ensure that the needle is not in one of the pudendal blood vessels, which could be very dangerous if lidocaine is injected, and infiltrate with 3 mL of local anaesthetic.**
- 8 Next, advance the needle further through the sacrospinous ligament for a distance of 1 cm until a loss of resistance is detected.
- 9 The tip now lies in the area of the pudendal nerve. At this point, the pudendal vessels lie just lateral to the pudendal nerve, so care must be taken to avoid intravascular administration. **Aspirate to confirm that the needle placement is not intravascular prior to injecting lidocaine.**
- 10 Inject another 3 mL of local anaesthetic solution into this region.

- 11 Subsequently, withdraw the needle into the guide and move the tip of the guide to just above the ischial spine.
- 12 At this new location, reinsert the needle through the mucosa and again inject 3 mL of local anaesthetic.  
**Aspirate to confirm that the needle placement is not intravascular prior to injecting lidocaine.**

To block the right side of the pelvis, repeat these steps using the right hand to hold the needle and needle guide.

The block usually takes at least 5 minutes to become effective, and lasts for between 20 and 60 minutes. Check bilaterally for pain before starting the procedure.

A smaller repeat dose (up to 5 mL of 0.5% lidocaine) on each side can be used if an adequate block is not seen.

**A pudendal block does not provide adequate anaesthesia for deliveries that require uterine manipulation, postpartum examination and repair of the upper vagina and cervix, and manual exploration of the uterine cavity.**

Under these circumstances, the addition of intravenous narcotics or ketamine may be required.

### Vaginal examination in obstetrics

Vaginal examination should be performed only if it is essential, and the risk of infection must be minimised by hygienic

hand washing and the use of a new set of examination gloves. At all times it is important to preserve the patient's dignity and privacy. In labour, a chlorhexidine obstetric cream can prevent ascending infection.

Always undertake abdominal palpation first.

Do not undertake vaginal examination if there is a possibility of placenta praevia, if there are ruptured membranes and the woman is not in labour, or if there is active herpes simplex infection in ruptured membranes unless the patient is in labour.

If you are using a speculum, offer to demonstrate it, explain how it is inserted and ensure that the correct size is used.

Document any blood loss, discharge and its characteristics, and any amniotic fluid and its characteristics. If female genital cutting is present, record this and describe the type.

Document the cervical length, position, dilatation, and application to the presenting part of the fetus. Determine if possible the presentation of the fetus and whether there is caput and/or moulding present. Evaluate pelvic size by examining the ischial spines and suprapubic arch.

At the end, provide a clean sanitary pad, auscultate the fetal heart, describe the results of the examination to the woman, and record the findings in the notes.

# Section 3

## Neonatal care

## 3.1

## Preparation for and care of the baby at birth

**BOX 3.1.1 Minimum standards**

- Two clean dry towels.
- Firm work surface with padding.
- Stethoscope.
- Laryngoscope with straight blades size 0 and 1, spare bulbs and batteries.
- Set of ET tubes 2.5, 3.0, 3.5 and 4.0 with connectors to fit the inflation system.
- Umbilical catheter with fixating system.
- Adrenaline 1:10 000.
- Sodium bicarbonate 8.4%.
- Naloxone.
- Dextrose 10%.
- Ringer-lactate or Hartmann's solution.
- Soft suction device.
- Warming device.
- Food-grade plastic wrapping.

**Introduction**

Neonatal mortality in resource-limited countries runs at an unacceptably high level. The World Health Organization (WHO) estimates that worldwide there are 9000 neonatal deaths per day. Of these, approximately one-third are a result of neonatal infections, one-third are due to fetal hypoxia and a further one-third are due to prematurity and low birth weight.

If death and long-term or permanent disability are to be avoided, the management of neonatal emergencies must be both coordinated and effective. The care delivered in the first few minutes and hours of life is a major determinant of the outcome. Since in resource-limited countries almost half of the deliveries do not occur in hospitals, it is important that community-based skilled birth attendants (SBAs), traditional birth attendants (TBAs) and community health workers (CHWs) are encouraged to develop skills to recognise the vulnerable baby prior to delivery and provide effective intervention as required after birth.

**Basic aspects of newborn care that apply to both community and hospital deliveries**

In order to minimise the number of infants dying from birth-related problems (including perinatal asphyxia) or arriving at hospital with major complications which cannot be corrected, it is important for the hospital to work closely with the community.

The following approach has been shown to be helpful.

- All community-based healthcare professionals, including SBAs, TBAs and CHWs, should be able to undertake basic resuscitation of the newborn. Skills-based training involving manikins and the provision of a self-inflatable bag and mask to all these healthcare workers is essential, as delaying newborn resuscitation until the infant reaches the hospital will usually be too late, resulting in death or severe brain damage.

- Clean delivery kits should be available to all such health-care workers.
- There should be regular clinical audits and educational meetings with participation from all community-based healthcare workers.
- Community-based SBAs, TBAs and CHWs should ensure that mothers with pregnancy-related complications (e.g. preterm birth, breech presentation, twins) are identified and referred to the local hospital where there are good facilities for obstetric and newborn care.
- The local hospital must provide comprehensive emergency obstetric and neonatal care. Good management of labour and delivery is the key to intact neonatal survival.

**Mothers who require referral to hospital for delivery include those with:**

- peripartum bleeding
- malpresentation (breech, face, shoulder)
- preterm labour (< 35 weeks)
- twins
- abnormal fetal heart rate in labour.

**The baby at risk of developing problems at birth****Preterm birth**

Maturity matters more than birth weight. Prematurity is defined as gestation of less than 37 weeks (or less than 259 days from the first day of the mother's last menstrual period). In the absence of special facilities, mortality increases substantially in cases of gestation less than 32 weeks, and survival at less than 28 weeks is unlikely in resource-limited settings. When a preterm delivery is anticipated, realistic expectations should be discussed with the parents, and any limitations on resuscitative efforts should be agreed upon.

**Preventative strategies**

These may include **minimising the risk of surfactant deficiency** and **stopping premature uterine contractions**.

**Minimising the risk of surfactant deficiency:** this can be halved if the mother is given a short course of high-dose steroid treatment before delivery:

- dexamethasone, 12 mg IM, two doses 12 hours apart
- or dexamethasone, 6 mg IM, four doses 12 hours apart.

**Stopping premature uterine contractions:**

- Give 20 mg nifedipine orally. Up to three further doses can be given at 30-minute intervals if uterine contractions persist.
- If this stops labour, give 20 mg nifedipine orally three times a day for the next 3 days.

Other problems associated with preterm birth include the following:

- Even very small babies can survive preterm birth

successfully once the early problems associated with surfactant deficiency have been overcome, and as long as they are nursed in a clean environment and not allowed to get cold.

- Preterm babies are at increased risk of infection and hypothermia.

The main challenge is to give these babies enough nutrition for them to start growing again as soon as possible (see Section 3.3).

- Here, too, maturity is more important than weight. Babies born before 36 weeks' gestation nearly always need some help with feeding.
- Breast milk is ideal, and everything possible should be done to help the mother sustain her lactation until the baby is ready to feed reliably from the breast. A limited ability to suck and swallow usually appears from 32 weeks' gestation, but it remains unpredictable, unreliable and uncoordinated until 36 weeks' gestation. In the event that breastfeeding cannot be initiated immediately after birth, mothers should be encouraged to start expressing breast milk, to be given by nasogastric tube or cup and spoon.
- Partial breastfeeding can also help the mother to sustain her lactation, but in any event the mother should regularly express milk. Some mothers might find expressing breast milk difficult and may require help with this.

### Infection

It is important to identify babies at risk of infection prior to delivery. If identified, the mother should be given antibiotics appropriately. Many of the babies who become infected during delivery develop respiratory signs very soon after birth, but in a few, the features are those of neonatal sepsis. In addition, there are a proportion of babies who are initially asymptomatic, and therefore prophylactic antibiotics should be commenced in the infant if there are risk factors for infection.

### When to consider antibiotics for the mother and newborn

- **Symptomatic ascending infection *in utero*** needs urgent treatment. If this is overlooked, both the mother's and the baby's life will be in danger.
- **Asymptomatic infection is, however, a much commoner problem.** This occasionally progresses so rapidly once labour starts that, unless treatment is started at once, the baby will die even if the most appropriate antibiotic is given immediately after birth. Because such infection by definition is silent, it is important that treatment be considered in any mother going into active spontaneous labour before 35 weeks' gestation.
- **Membrane rupture can be both a sign of, and a risk factor for, ascending bacterial infection.** What most people mean by premature rupture of membranes (PROM) is really preterm pre-labour rupture of membranes (PPROM), where the membranes rupture before there is any overt sign of uterine activity or any detectable uterine contractions. When this happens in the preterm baby, it is often a sign of the start of some sort of ascending infectious process. This process has already weakened the amniotic membranes and may stimulate the onset of preterm labour. Antibiotics must be given to the mother.

- **Treatment with antibiotics should also be considered at any gestation if the mother's membranes rupture more than 18 hours before delivery.** If premature rupture of membranes occurs before the onset of premature labour contractions then infection is more likely.
- **Maternal fever (> 38°C) in labour** is a strong indication for initiating antibiotics for the mother. Similarly, foul-smelling or purulent liquor requires IV antibiotic treatment of the newborn from birth without waiting for any signs of infection.

- In mothers with PPRM who show signs of being clinically infected give IV antibiotics.
- In PPRM where there is no evidence of infection and no evidence of labour you can delay delivery by 1 week or more (on average) by giving the mother amoxicillin or, better still, erythromycin.
- In mothers who are in active labour 5 or more weeks before term and who give a clear history that the membranes had ruptured before they were able to detect any uterine contractions, the risk of the baby becoming infected during delivery can be reduced substantially by giving antibiotics IV (ideally probably both penicillin and gentamicin) during labour.

### Antibiotic management of perinatal infection

Where facilities allow, a blood count, C-reactive proteins and blood cultures should be taken before starting antibiotics. Because a range of bacteria can be involved, treatment of the baby needs to protect against group B streptococcal, coliform and *Listeria* infection, making a **combination of ampicillin and gentamicin** the best strategy:

- Give ampicillin 50–100 mg/kg IV 12-hourly and gentamicin 5 mg/kg every 24 hours IV if more than 32 weeks' gestation, and 3 mg/kg if less than 32 weeks.

**The WHO recommends that a neonate with risk factors for infection (i.e. membranes ruptured > 18 hours before delivery, maternal fever > 38°C before delivery or during labour, or foul-smelling or purulent amniotic discharge) should be treated with prophylactic antibiotics (IM or IV ampicillin and gentamicin) for at least 2 days. After this the neonate should be reassessed and treatment continued only if there are signs of sepsis (or a positive blood culture).**

### Hypothermia (see Section 3.3)

Hypothermia seriously increases the risk of surfactant deficiency and hypoglycaemia, and must be avoided.

### Preparation for birth in the home and in hospital

For the majority of deliveries, only a minimum amount of resuscitation equipment is needed.

### Equipment for basic resuscitation of the infant at home

The following equipment is needed:

- 2 clean dry towels
- a firm working surface (padded)
- a bulb suction device
- a well-fitting mask (size 0/1)

- a self-inflatable bag
- clean scissors or razor blade
- boiled string (two 6-inch lengths)
- woollen cap or head covering.

## Management at delivery of a baby not needing resuscitation

### Summary of management of the healthy baby at birth

- Deliver the baby on to the mother's abdomen or a warm surface, dry and cover.
- Clamp cord when pulsation stopped, usually between 2 and 3 minutes after birth and keep the baby between the mother's thighs level or below the placenta.
- Prevent hypothermia by nursing skin to skin with the mother.
- Initiate early breastfeeding.
- Minimise infection by hand washing, cord care and using clean materials.
- Give an injection of vitamin K.

Most babies do not need any resuscitation at birth but only require basic care to prevent infection and hypothermia. Extensive mouth suction, face mask oxygen, and vigorous stimulation in order to provoke a first gasp or cry are unnecessary rituals without clinical justification. As long as the baby becomes pink, and starts to breathe without distress, most babies should stay with their mothers and have a first feed at the breast within minutes of birth.

A simple approach would be to keep newborns without complications in **skin-to-skin contact** with their mothers during the first hour after birth to prevent hypothermia and **promote breastfeeding**. Colostrum, the initial milk with a clear, yellowish and thick appearance, is an extremely nutritious and concentrated feed rich in immunoglobulins (it is only present during the first 3 to 4 days). Mothers should be informed of its benefits and that it is ideal for their baby to feed on this as soon after birth as possible and as frequently as possible.

### Preventing heat loss after birth

- Once any necessary resuscitation process has finished and as soon as the baby becomes pink, and starts to breathe without distress, they can be given to the mother for skin-to-skin contact and their first feed at the breast. This practice, among other benefits, not only prevents hypothermia but also helps in better uterine contraction following delivery.
- The practice of using water or oil to clean the skin within a few hours of birth before the body temperature has stabilised can make the baby dangerously hypothermic. A simple drying of the skin with a warm towel or sheet is all that is required.
- There is no more effective source of warmth than the mother's own body, so long as the baby is first well dried to minimise evaporative heat loss. A larger sheet or blanket can then be used to protect both mother and baby from the convective heat loss caused by draughts.
- Babies have relatively large heads. Covering the head with a shawl, blanket or woollen cap can significantly reduce heat loss.
- Heat and water loss through the skin can be a particular problem in babies born before 32 weeks' gestation.

This can be limited initially by wrapping all but the face in a clean plastic wrapping such as cling film or a food-grade plastic bag with a hole cut in the end of the bag for the baby's head to protrude, for a few hours after birth. **Remember that plastic over the face can cause death from suffocation.** If plastic bags or cling film are not available, the preterm baby must be wrapped well in a clean towel or blanket. However, plastic bags are very good for preventing heat loss, but only in conjunction with an overhead heat source or heated mattress. If the fluid in the bag gets cold it will cool the baby quicker than drying and wrapping.

- Heat supplementation can be provided by locally built and maintained incubators, overhead heating systems, and skin-to-skin (kangaroo) care.
- Ideally, the first bath should be delayed for at least 24 hours.

### Managing the placenta, cord and umbilical stump

Babies often become relatively anaemic 4 to 6 months after birth because red cell production does not keep pace with body growth. This problem can be minimised by ensuring that blood intended for the baby is not left in the placenta at birth.

If the baby is held higher than the placenta (i.e. on the mother's abdomen) while the cord is still pulsating, blood will drain out of the baby and into the placenta, so hold the (covered) baby just below the placenta for 2 minutes if the cord is still pulsating. If the cord is clamped before it stops pulsating, this will also reduce the normal 'placental transfusion' at birth, especially if the uterus has not yet contracted.

If, however, blood is artificially 'milked' from the placenta into the baby, it is possible to leave the baby with so many red cells that the blood becomes thick and polycythaemic. Neonatal polycythaemia has many complications, including putting the circulation under strain, making the capillary circulation very sluggish, and increasing the risk of jaundice (see below).

**It is recommended after a vaginal delivery to wait for 2 minutes before cutting the cord if it is still pulsating, to maximise the baby's haemoglobin, unless there is a need to start resuscitating the baby.**

The cord must be cut cleanly, and the cut stump secured in a manner that minimises the risk of late haemorrhage. Remember that prevention rather than treatment is the key. A supply of fresh disposable razor blades is one widely adopted strategy in some communities where home birth is the norm.

The umbilical stump will shrink as it dries out. Plastic clamps that shut down further as the cord starts to shrink are very effective. They are relatively inexpensive, and they do make it possible to cut the stump about 2–4 cm from the skin. An elastic band, if carefully applied, is a cheap and well-tested alternative. A stump that is left too long provides a reservoir where bacteria can breed and multiply with great speed, and therefore should not be permitted. A length of 2–4 cm is ideal.

A short stump does not need to be covered except to keep it from snagging on clothes and blankets. Recent studies in resource-limited countries have shown that the application of 4% chlorhexidine solution immediately after birth can prevent omphalitis. Other possible antiseptics include surgical spirit or iodine.

Often the cord manifests a little 'stickiness', which may be of no concern. However, a local antiseptic should be applied if a red skin flare suggests early spreading staphylococcal cellulitis. Such babies must also be given an oral anti-staphylococcal antibiotic (cloxacillin or flucloxacillin). If the skin around the stump becomes oedematous with increasing redness, IV cloxacillin or oral flucloxacillin (25 mg/kg three times a day for 7 days) is usually the most logical choice. Babies who are systemically unwell always need urgent broad-spectrum antibiotic treatment, IV or IM, for septicaemia.

The risk of neonatal tetanus can be eliminated by ensuring that all mothers are immunised against tetanus with at least two injections of tetanus toxoid 1 month apart during pregnancy.

### The risk of cross-infection during or after birth

Puerperal infection ('child-bed fever') is an illness that killed thousands of recently delivered women for more than two centuries. The fact that this could be eliminated if birth attendants washed their hands thoroughly **every time they moved from one woman to the next** was shown many years before it was ever realised that this lethal illness was caused by group A streptococcal infection. The arrival of

antibiotic treatment has reduced the risk of death, but it has not lessened the need for meticulous hand washing before vaginal examination or delivery. Failure to observe this simple but important precaution also puts the baby at risk of cross-infection, especially if the baby is being cared for in a hospital setting.

**The WHO estimates that infection is responsible for one-third of all neonatal deaths (over 3000 deaths a day). Kangaroo care has significantly reduced the number of neonatal deaths from infection by colonising babies with the mother's bacteria rather than those of the hospital.**

### Neonatal examination before discharge of a baby from the hospital

Before discharging the baby it is important that some basic checks are made. These include ensuring that the baby is feeding well, has passed meconium and urine and does not have any gross congenital abnormalities. Always check for jaundice. If there are qualified personnel available, a more detailed check could be undertaken. All examinations should be documented, including abnormalities, even if there is no other action which can be taken. It is also important to check local guidelines, if any.

#### Pre-Discharge Newborn Checklist

**Name**  
**Date of birth**  
**Mode of delivery**  
**Birth weight**  
**Type of feed**

**Mother's name**  
**Gestation**  
**Need for resuscitation**  
**Head circumference**  
**Mother's blood group**

	Tick if normal/Describe if abnormal	Common problems to look for
<b>Head</b>		Anencephaly, occipital encephalocele, microcephaly, large fontanelle, abnormal shape of head
<b>Face</b>		Abnormal looking facies
<b>Ears</b>		Low set ears, absent ears, ear tags
<b>Eyes</b>		White-coloured pupil, white cornea
<b>Nose</b>		Blocked nostrils with breathing difficulty
<b>Lips</b>		Cleft lip
<b>Palate</b>		Missing palate
<b>Neck</b>		Swelling on the neck, holding neck to one side
<b>Clavicles</b>		Lumps or bumps on the clavicle
<b>Chest</b>		Shape of chest
<b>Abdomen</b>		Scaphoid (empty) abdomen
<b>Umbilicus</b>		Omphalocele, gastroschisis, hernia
<b>Genitalia</b>		Abnormal genitalia, undescended testis, hypospadias
<b>Anus</b>		Absent anus, abnormally placed anus
<b>Spine</b>		Spina bifida, meningomyelocele
<b>Upper limbs</b>		Absent limbs, contractures of limbs, not moving arm
<b>Lower limbs</b>		Not moving limbs, unequal limbs
<b>Hands</b>		Missing or extra digits
<b>Feet</b>		Abnormally shaped feet (talipes), missing or extra digits
<b>Hips</b>		Hip dysplasia (Barlow and Ortolani manoeuvres)
<b>Jaundice</b>		
<b>Chest</b>		Air entry (right and left)
<b>CVS</b>		Murmur, femoral pulse, cyanosis
<b>Abdomen</b>		Spleen, liver, kidney, palpable mass
<b>Birth marks</b>		

The following data should be recorded in the notes of every newborn baby.

**Baby's name (if given at the time)**

**Mother's data**

- Name, address, date of birth, and any identifying number
- Parity and previous obstetric history
- Blood group
- First day of last menstrual period
- **Results of any antenatal serology (e.g. rubella, syphilis, rhesus titres, HIV status)**
- Illness during the pregnancy
- Drugs taken during the pregnancy
- Family history of any illnesses

**Father's data**

- Full name, address and date of birth
- Family history of any illnesses

**Labour and delivery data**

- Time of onset: whether induction of labour or spontaneous
- Time membranes ruptured and any other known risk factors for infection (see below)
- Duration of first and second stage of labour
- Drugs given to the mother in labour
- Presentation and mode of delivery
- Full details of any resuscitation for baby or mother
- Time, dose, route of administration and full generic name of any drugs given to the mother

**Baby data**

- Temperature shortly after delivery, to document adequate thermoregulation
- Birth weight

- Head circumference (best measured after 24 hours when moulding has subsided)
- Length (ideally)
- Full physical examination, noting any abnormalities or evidence of birth trauma detected
- Details of dose, preparation and route of administration of any drugs given at delivery (e.g. vitamin K)
- **If not already given, ensure that vitamin K 1 mg IM is administered**

**Follow-up home visits**

Trials in South Asia have shown that three home visits in the first week of life (starting on the day of birth) by trained healthcare workers can reduce neonatal mortality by 30–60%. During their visits, the healthcare workers promote essential newborn care, examine babies for danger signs, and treat or refer when appropriate, counsel the families in how to recognise danger signs and emphasise the importance of prompt referral when they are identified.

The WHO and UNICEF recommend that skilled healthcare workers (nurses or midwives) should undertake these visits, but in many settings this is not possible. Volunteers have also been trained to do this, and recently the effectiveness of this has been shown in Ghana, where a fall in neonatal mortality followed two home visits during pregnancy and three visits in the first week of life.

## 3.2

## Resuscitation of the newly born

**Introduction**

**Respiratory changes at birth in a healthy term infant**

- During life *in utero*, the infant's lungs are full of lung tissue fluid. The fluid is removed during labour and at birth by the following mechanisms:
  - at the onset of labour, lung fluid production stops
  - as labour progresses, re-absorption of lung fluid occurs
  - about 35 mL of fluid are expelled from the lungs as a result of thoracic compression during vaginal delivery
  - the first breaths generate relatively high pressures to inflate the lungs, which has the effect of pushing this fluid into the circulation. These first breaths establish the infant's functional residual capacity.
- Surfactant is produced in the alveoli to prevent them collapsing completely during expiration.

- Production starts slowly at 20 weeks' gestation, and increases rapidly from 30–34 weeks and thereafter.
- Surfactant production is reduced by hypothermia, hypoxia and acidosis.

Caesarean section is associated with delayed clearance of pulmonary fluid, and reduces the initial functional residual capacity

Most infants breathe well and do not need active 'resuscitation' at birth. Simply drying the infant with a warm dry sheet/towel will in most cases stimulate a cry from the infant thus expanding the lungs (see Section 3.1). Attempts to clear the airway, to stimulate breathing, or to give facial oxygen are unnecessary. Therefore routine airway suctioning is not needed. Most infants make all the circulatory adjustments required at birth without external intervention as the lungs expand. All that the birth attendant has to do

is to optimise the conditions needed for these changes to occur smoothly

Around 5% of infants do not breathe spontaneously after delivery. However, breathing can be started in almost all these infants by correctly applying bag-and-mask ventilation. With lung inflation there is an immediate and easily detectable rise in heart rate. It may be difficult to identify the infant's pulse rate by palpation at any site, so the best way to determine the heart rate is to listen over the chest with a stethoscope.

Far less commonly, infants are born cyanosed, shocked, limp and hypotonic. Around 1% do not respond to bag-and-mask ventilation, and need further help with advanced resuscitation.

## Resuscitation at birth

### Equipment needed for resuscitation

The following equipment is needed:

- Two clean dry towels.
- A firm working surface.
- Heat and light source.
- Sterile gloves.
- Sterile scissors.
- Sterile cord clamps.
- Food-grade plastic wrapping (cling film).
- Clock.
- Soft well-fitting face masks (size 0/1 and 00).
- A self-inflatable bag.
- A source of oxygen.
- A pressure-limiting device at 30 cmH<sub>2</sub>O if T-piece is used.
- A stethoscope.
- A laryngoscope, with straight blades size 0 and 1, and spare bulbs.
- A set of endotracheal tubes (2.5, 3.0, 3.5 and 4.0mm) with adaptors to fit the inflation system.
- An endotracheal stylet.
- An umbilical venous catheter (or use a sterile feeding tube).
- A pulse oximeter (if available).
- A roll of zinc oxide tape for name-band.
- Syringes: 1 mL, 5 mL and 10 mL.
- Emergency drugs: 1 in 1000 adrenaline plus sterile water for dilution to make 1 in 10000.
- Ringer-lactate or Hartmann's solution.
- Glucose 10%.
- Nalorphine (naloxone) if opiates are used during labour.

### Immediate preparation

Two clean dry towels are needed, one to dry the infant and one to keep them warm, a firm working surface in a warm well-lit area, a self-inflating bag with good soft well-fitting face mask (see below), and a suction device and a source of oxygen if possible is all that most infants who have not started breathing spontaneously need.

### Self-inflating bag, valve and masks

A soft close-fitting face mask is essential. Access to a range of sizes of mask makes it possible to manage infants weighing as little as 500g or as much as 5000g at birth. It provides a near-airtight seal between mask and face in a way that mimics the effectiveness and efficiency of an endotracheal tube. Hence it is possible to use a mask as effectively as an endotracheal tube along with a self-inflating

bag to administer slow inflating pressures up to a maximum inspiratory pressure of 30 cmH<sub>2</sub>O to the fluid-filled lung of an infant who is not breathing or who is making poor respiratory efforts at birth. The bag-valve-mask inflates the lungs, enabling the infant's respiratory centre to be oxygenated and initiate spontaneous respiration.

### Suction devices

A range of simple suction devices, with a soft wide-bore tube (10 or 12) either mechanically or electrically operated, are available. Suction is rarely needed and should not be performed routinely. Mouth-to-mouth suction can be effective, but places the operator at risk of infections such as HIV or hepatitis. A double mucus trap may be used to help to prevent infected material being accidentally drawn into the mouth, but even this may be insufficient for user protection.

### Circulatory access and drugs

An umbilical vein catheter may be used to administer drugs, but it is important to note that infants who require drugs during resuscitation have poorer outcomes and are at increased risk of death and long-term neurological sequelae. Ringer-lactate or Hartmann's solution, plasma expander or blood in the case of hypovolaemia due to fetal bleeding (see below) may occasionally be required and would use the umbilical vein route. The intra-osseous route is also now being used, either using a purpose-made needle and drill set or by using a venepuncture needle and the medial side of the tibial bone, below the growth plate (see Section 8.N). For a discussion of drugs, see below.

### Timing

A clock will help you to document the duration of resuscitation and the timing of interventions.

### Additional equipment

A heat and light source is needed plus food-grade plastic wrapping for infants under 32 weeks' gestation.

An oxygen source is helpful but not essential for infants who need advanced resuscitation.

A pulse oximeter can be of help in monitoring the improvement in oxygenation and detecting the occasional infant with sub-clinical cyanosis requiring further intervention or evaluation for cardiac or pulmonary disease. It is also useful to prevent hyperoxia when oxygen is used in resuscitation, especially in the preterm infant.

A roll of zinc oxide tape half an inch wide can be used to make a simple name band for infants not delivered in their own homes. Take six inches of this tape, write the date and the mother's name at one end, turn the last two inches of the other end back on itself (so the tape does not stick to the skin), and then turn this into a simple bracelet round the child's wrist. Ensure that the bracelet is loosely fitting to avoid a tourniquet effect.

### Guidelines from the 2010 International Liaison Committee on Resuscitation (ILCOR)

The main changes that have been made to the Neonatal Life Support (NLS) guidelines relevant to resource-limited countries are as follows:

- The use of food-grade plastic wrapping (cling film) is recommended to maintain body temperature in very small preterm infants.
- Ventilatory resuscitation may be started with air. However,

where possible, additional oxygen should be available if there is no rapid improvement in the infant's condition.

- Adrenaline should be given by the IV route, as standard doses are likely to be ineffective if given via a tracheal tube.
- If there are no signs of life after 20 minutes of continuous and adequate resuscitation efforts, discontinuation of resuscitation may be justified.

### Sequence of actions during resuscitation of the newborn

There are agreed guidelines from the 2010 International Liaison Committee on Resuscitation (ILCOR). The sequence below and that of 'Helping Infants Breathe' are both practical applications of these principles.

#### First call for help

Start the clock or note the time. Keep the infant dry and warm and assess their breathing and heart rate.

- Infants are born small and wet. They get cold very easily, especially if they remain wet and in a draught. Whatever the problem, **dry the infant well, including the head.** Remove the wet towel, and **wrap the infant in a dry towel.** It is helpful if the towels are warm.
- There is good evidence that for very preterm infants (30 weeks' gestation or earlier), placing the infant under a radiant heater after drying, and immediately covering the head and body, apart from the face, with clean plastic wrapping, is the most effective way of keeping these very small infants warm during resuscitation.
- **Drying the infant** immediately after delivery will provide significant stimulation during which **colour, tone, breathing and heart rate can continue to be observed.**
- It is important to **monitor the infant's breathing.** **Observing the colour, heart rate and tone helps to document the infant's condition and assess their response to resuscitation.**
- **Reassess** these observations regularly (particularly the heart rate), every 30 seconds or so, throughout the resuscitation process. The first sign of any improvement in the bradycardic infant will be an increase in heart rate.
- A healthy infant may be born blue but will have good tone, will cry within a few seconds of delivery, will have a good heart rate (the heart rate of a healthy newborn infant is about 120–150 beats/minute) and will rapidly become pink during the first 90 seconds or so. An ill infant will be born pale and floppy, not breathing, and with a slow or very slow heart rate.
- The heart rate of an infant is best judged by listening to the chest with a stethoscope. It can also sometimes be felt by palpating the base of the umbilical cord, but a slow rate at the cord is not always indicative of a truly slow heart rate, and, if the infant is not breathing, must not delay the immediate application of lung inflations. In addition, if the infant is not breathing, feeling for peripheral pulses is potentially harmful as it delays the onset of life-saving lung inflations. If a stethoscope is not available, you can listen to the heart by placing your ear on the infant's chest or using a Pinard's stethoscope.

#### Airway: Keep the airway open

- Before the infant can breathe effectively the airway must be open.

- The best way to achieve this in an infant who is not breathing well is to place the infant on their back with the head in the **neutral position** (i.e. with the neck neither flexed nor extended). Most newborn infants will have a relatively prominent occiput, which will tend to flex the neck if the infant is placed on their back on a flat surface. This can be avoided by placing some support using a folded nappy or cloth under the shoulders of the infant, but be careful not to overextend the neck.
- If the infant is floppy it may also be necessary to apply chin lift or jaw thrust.

The best way to stabilise an infant's condition at birth is to ensure that the upper airway remains unobstructed. The child will then have little difficulty in drawing air into its lungs for itself when it takes its first spontaneous gasp or cry. Unfortunately, books often talk of the need to keep the airway 'clear', giving the false impression that the infant is going to find it difficult to breathe unless all the fluid and mucus is first sucked out of the way. There is no evidence that this is ever necessary unless the infant is meconium stained or does not breathe well. **Moreover, blind deep suction of the nose or mouth can stimulate the vagus nerve, leading to bradycardia, apnoea and laryngospasm.**

However, the upper airway of any infant who is born limp and hypotonic certainly needs to be opened and maintained in just the same way as the airway of any other unconscious patient. In an unconscious patient, pharyngeal tone decreases even more than it does during sleep, causing the upper airway to narrow or close. When such a patient is laid on their back the tongue also falls back, further obstructing the airway. There are three key ways to counter this:

- 1 Hold the head in the neutral position *and*
- 2 Support the chin *or*
- 3 Push the jaw forward.

Because of moulding, most infants have quite a prominent occiput at birth. Lying supine (on their back) on a flat surface, the neck becomes flexed, and the airway becomes obstructed. Exactly the same thing can happen if the neck is over-extended. The aim is to ensure that the head is in a 'neutral' position – a posture most easily achieved by placing a small (2 cm high) pad under the infant's shoulders.

It is important that all healthcare workers who conduct deliveries are taught how to open the airway correctly.

**FIGURE 3.2.1** Neutral position of the head and neck in a newborn. Reproduced with the permission of Medical Aid Films, [www.medicalaidfilms.org](http://www.medicalaidfilms.org)

FIGURE 3.2.2 Chin lift in a newborn.

FIGURE 3.2.3 Jaw thrust in a newborn. Note that the operator's thumbs are in a position to hold a mask in place.

If tone is poor it may also be necessary to support the chin. It is important to support the bony part of the chin. Pressure anywhere else may merely push the base of the tongue backwards, making matters worse.

If tone is **very** poor it may be necessary to use one or two fingers under each side of the lower jaw, at its angle, in order to push the jaw forwards and outwards ('jaw thrust'), but this will require a second person to give the inflation and ventilation breaths with the bag-valve-mask.

Although it is rare for debris to completely block the trachea, this should be suspected if an infant tries to breathe but remains cyanosed and bradycardic, with laboured breathing and marked inter-costal and/or sternal recession. This is one of the few situations where tracheal intubation can be life-saving at birth.

### Meconium

It is estimated that around 15% of infants have meconium-stained liquor at birth. Meconium aspiration syndrome (MAS) can occur in about 1 in 10 such infants. The development of MAS is not entirely dependent on suctioning at birth. It is possible for infants to aspirate meconium into the large airways *in utero* if there is hypoxia and gasping. However, some infants may aspirate meconium during delivery, and these are the ones in whom the risk of MAS can be reduced by suctioning when the infant's head is on the perineum.

Studies based on experience from Africa and India have shown that suctioning the mouth of infants with meconium-stained liquor during birth when the head is at

the perineum has dramatically reduced the incidence of meconium aspiration syndrome (MAS) and death. There is subsequently no need for further suctioning after birth if the infant breathes well.

### What to do if the trachea appears to be blocked

If the infant is born through meconium and is unresponsive (or 'not vigorous') at birth, the oropharynx should be inspected and cleared of meconium. If intubation skills are available, the larynx and trachea should also be cleared under direct vision. If meconium has entered the trachea, resuscitation here is only possible if the accumulated debris can be immediately removed. The easiest way to do this is to pass an endotracheal tube and then remove the debris by direct suction to the endotracheal tube. Sometimes the meconium debris is so large that it cannot be sucked through the tube. The tube can then be removed and replaced with a clean tube to clear the remaining obstructive material. Suction may also make it easier to see the larynx during intubation. Giving mask ventilation for the infant who is not breathing before the meconium has been cleared (as above) may force the meconium deeper into the lungs.

### Breathing

- If the infant is not breathing adequately **give five inflation breaths as soon as possible** (unless the baby is very preterm, in which case such breaths may injure immature lungs: give ordinary ventilation breaths in this situation). Until now the infant's lungs will have been filled with fluid. Aeration of the lungs in these circumstances is best with slow inflations at pressures of about 30 cmH<sub>2</sub>O with the bag and mask; these are called 'inflation breaths'. These initial ventilation breaths should last 2–3 seconds each. The aim is to mimic the initial breaths taken by a normal infant to open the airways, remove lung fluid and achieve its functional residual capacity.
- If the heart rate was below 100 beats/minute initially then it should rapidly increase as oxygenated blood reaches the heart. If the heart rate does increase then you can assume that you have successfully aerated the lungs and there is adequate tissue oxygenation. If the heart rate increases but the infant does not start breathing, then continue to provide regular ventilation breaths at a rate of about 30–40 breaths/minute until the infant starts to breathe.
- The chest may not move during the first one or two breaths as fluid is displaced. Adequate ventilation is usually indicated by either a rapidly increasing heart rate or a heart rate that is maintained at more than 100 beats/minute. Therefore reassess the heart rate after delivery of the first five breaths. It is safe to assume that the chest has been inflated successfully if the heart rate improves. Once the chest has been seen to move and the heart rate has increased, ventilation should be continued at a rate of 30–40 breaths/minute. Continue ventilatory support until regular breathing is established.
- If the heart rate does not increase following inflation breaths, then either you have not aerated the lungs or the infant needs more than lung aeration alone. By far the most likely possibility is that you have failed to aerate the lungs effectively. If the heart rate does not increase, and the chest does not passively move with each inflation breath, then you have not aerated the lungs.

Under these circumstances consider the following:

- Are the infant's head and neck in the neutral position?
- Do you need jaw thrust?
- Do you need a second person's help with the airway or to squeeze the bag? A relative or ward orderly can be shown immediately how to effectively squeeze the self-inflating bag while you ensure that the mask is held firmly and in the best position on the face over the mouth and nose with the airway open.
- Is there an obstruction in the oropharynx (laryngoscope and suction under direct vision)?

### **Bag-and-mask inflation of the lung**

Having positioned the infant correctly it is then usually quite easy to use a self-inflating bag and mask to provide inflations.

**Remember that the infant cannot breathe through the bag-valve-mask system, so do not leave the mask sealed to the face and expect the infant to breathe from the bag. The valve between the bag and the mask prevents this. When the infant is breathing, remove the mask and watch closely to ensure that adequate breathing continues.**

Most infants will respond to bag-and-mask ventilation by gasping and then starting to breathe on their own without further support. If this does not happen, it is still easy to confirm that lung aeration has been achieved, because the heart rate will rise reliably and consistently above 100 beats/minute. If lung aeration has been achieved and the infant still has a slow heart rate, proceed to support the circulation (C). If oxygen is available, applying this through the bag and mask may also help.

It is essential that the skills of correct bag-and-mask ventilation are taught to all healthcare workers who conduct deliveries. This is best done on a mannequin. Correct bag-and-mask ventilation is the single most important skill needed to provide active resuscitation.

There is good evidence that most infants can be resuscitated using mask resuscitation without any need for tracheal intubation. However, in certain situations (e.g. infants less than 1000g not responding to inflation, prolonged bag-and-mask ventilation with no spontaneous breathing, etc.) infants require early intubation, so the equipment and the skill to intubate should be available.

### **Deciding whether to use air or 100% oxygen for resuscitation of the newborn**

Concern about the possible injurious effects of excess oxygen, particularly in preterm infants, and the apparent effectiveness of air in a number of randomised controlled human studies of resuscitation at birth, have resulted in a change in guidelines.

There is evidence to suggest that air is safer for initial resuscitation. However, where possible, it is recommended that additional oxygen should be available for use if there is not a rapid improvement in the infant's condition. Equally, hyperoxia should be avoided, especially in the preterm infant. If a pulse oximeter is available this can be done. Try to keep the SaO<sub>2</sub> between 88% and 95%.

### **When to cut and clamp the cord in an infant who needs resuscitation at birth**

There are advantages to delaying clamping of the cord for 2 minutes after birth to allow placental transfer of blood to the infant (see above). However, it is important to ensure

that by doing this there is no harm to the mother (e.g. if she needs resuscitation) or to the infant (e.g. if they require resuscitation). Usually the umbilical cord is clamped and cut immediately if the infant needs to be moved for active resuscitation.

### **Mouth-to-mouth resuscitation**

Most current guidelines on neonatal care steer clear of discussing the role of mouth-to-mouth resuscitation. The risk of HIV infection or hepatitis has further fuelled that reluctance. However, there is no doubt that this can be a very effective way of reviving an apparently lifeless infant in the absence of equipment. Remember the following:

- Keep the upper airway open by optimising the position of the head and jaw as described above.
- Cover the infant's nose and mouth with your mouth (or cover the mouth of a big infant and just pinch the nose).
- Use the pressure you can generate with your cheeks, and try to aerate the lung by slow inflations for 2–3 seconds.
- Only use as much air for each breath as you can keep in your cheeks (i.e. do not 'blow' air into the infant, but just small puffs).
- Watch for chest movement, and allow time for lung recoil.
- Once the chest starts to move, sustain what has been achieved with 20–25 artificial breaths/minute.

### **Checking progress before moving on**

- If the heart rate has **not** risen to over 100 beats/minute after the five initial breaths or within 30 seconds of adequate ventilation, something is wrong. The most likely problem is that you have not successfully ventilated the infant. **Never** move on to deal with the issues covered under letter C of the resuscitation alphabet until you are quite sure you have achieved objectives A and B. To do so is quite futile. Chest compression will never restore the circulation until the blood being massaged from the lung to the heart contains oxygen.
- Look to see whether the chest moves each time you apply mask pressure. Movement should not be difficult to see once the first few breaths have aerated the lungs. It is usually easier to judge success with your eyes than with a stethoscope. In a newborn, breath sounds can be heard when only the airway is being aerated, so are not a good way to judge ventilatory success.
- Check that the infant's head is well positioned. Check chin support and jaw thrust, and that the mask is correctly applied with no air leaks. Ask a second person to help you position the infant optimally and provide inflations by squeezing the bag while you hold the airway open and the mask in place.
- Few infants need support with their breathing once their lungs have been aerated. Most will gasp, cry or breathe just as soon as an attempt is made to get air into the lungs, and then continue breathing adequately.
  - However, a few may benefit from further support if they do not start to breathe regularly, or only gasp occasionally. Some may have suffered severe hypoxia *in utero*, and a few may be drowsy because of drugs given to the mother during labour. Check that the heart rate remains normal (above 100 beats/minute) and that there is no central cyanosis (best judged by looking at the colour of the tongue).
  - Try to assess whether there is hypoxemia (cyanosis

or SaO<sub>2</sub> less than 90% with a pulse oximeter), if the infant's breathing remains laboured and irregular or if the child's colour remains blue. Give oxygen then if it is available, preferably with SaO<sub>2</sub> monitoring. Hyaline membrane disease, meconium aspiration syndrome, pneumonia or transient tachypnoea of the newborn are most likely.

Other possibilities include:

- intra-partum pneumonia (common)
- diaphragmatic hernia
- pneumothorax
- pulmonary hypoplasia (possibly associated with a skeletal or renal abnormality)
- cyanotic congenital heart disease (although this usually takes a little time to appear)
- persistent fetal circulation.
- If breathing requires continuous support it is important to try and reduce mask inflation pressures to little more than half of what was needed to aerate the lung in the first place. It is easy to over-ventilate an infant with healthy lungs and to wash out so much of the carbon dioxide that normally provides the main stimulus to breathing that all such activity stops for a while. There is also increasing evidence that sustained over-ventilation can seriously reduce cerebral blood flow.

### Endotracheal intubation

As discussed earlier, most infants who need resuscitation can be managed with bag-valve-mask intubation. However, occasionally endotracheal intubation is required, but this must be done by someone skilled and practised in the technique. It is most likely to be required for prolonged resuscitation, in meconium aspiration, and in preterm infants with surfactant deficiency. A straight-bladed laryngoscope is preferred, and tube sizes are around 3.5 mm for a term infant and 2.5 mm for a preterm infant. Sizes larger and smaller than these should be available.

### Preterm infants

- Infants with surfactant deficiency may have difficulty in expanding their lungs, and in developing a normal functional residual capacity at birth.
- However, the preterm lung is quite a delicate structure with relatively little elastic support, and any use of undue pressure or excessive ventilation during resuscitation can damage the lungs.

While an inspiratory pressure of 30 cmH<sub>2</sub>O may well be necessary to begin aerating the lungs at birth, the pressure should be reduced as rapidly as possible to a level that ensures that the chest is moving adequately. The key aim must be to conserve such surfactant as already exists by sustaining the lung's functional residual capacity (an objective best achieved by providing at least 5 cmH<sub>2</sub>O of positive end-expiratory pressure (PEEP). Aim to achieve this consistently throughout transfer to the nursery. This can be achieved using nasal prongs (nasal PEEP), thus avoiding tracheal intubation altogether (see Section 8.2).

### Circulation: chest compressions

- Most infants needing help at birth will respond to successful lung inflation with an increase in heart rate followed quickly by normal breathing. Chest compression

should be started only when you are sure that the lungs are being aerated successfully.

- If the heart rate remains very slow (less than 60 beats/minute) or absent following 60 seconds of ventilation with good chest movements, start chest compressions.
- In infants, the most efficient method of delivering chest compressions is to grip the chest in both hands in such a way that the two thumbs can press on the lower third of the sternum, just below an imaginary line joining the nipples, with the fingers over the spine at the back. This can only be done if there is a second operator ventilating the lungs (see Figure 3.2.4).
- If you are alone, the two-thumb method is not possible, as ventilations also need to be provided. In this situation, use the first two fingers of one hand to depress the lower sternum, while the other hand holds the mask in place. Then move the hand from the sternum to squeeze the bag.
- Compress the chest quickly and firmly, reducing the antero-posterior diameter of the chest by about one-third.
- Because oxygenation is such an important part of neonatal resuscitation, **the recommended ratio of compressions to inflations in newborn resuscitation is 3:1.**
- Chest compressions move oxygenated blood from the lungs back to the heart and out into the ascending aorta. From there the two coronary arteries will then quickly deliver oxygen to the failing anoxic heart muscle. It is important to allow enough time during the relaxation phase of each compression cycle for the heart to refill with blood, at the same time ensuring that the chest is inflating with each breath.

**FIGURE 3.2.4** Two-thumb compression of the chest, with a second operator ventilating the lungs, here using a T-piece as an alternative to bag and mask.

- The rate of chest compressions is around 120/minute. However, with pauses for ventilation, the actual number of compressions is less than 120/minute.

### Drugs

Rarely inflation of the lungs and effective chest compression will not be sufficient to produce adequate circulation and perfusion in infants. In these circumstances, drugs may be helpful. However, drugs are needed only if there is no significant cardiac output despite effective lung inflation and chest compression.

Very few drugs have proved to be of benefit in such circumstances. The drugs used are adrenaline (1:10000) and dextrose (10%). Drugs are best delivered via an umbilical venous catheter. In those where IV access is not possible, the intra-osseous route may be used. Each injection of a

drug should be followed with a bolus of 2–3 mL of Ringer-lactate or Hartmann's solution. Unfortunately, most of the infants in whom cardiac output only returns after such treatment require specialist neonatal care (often with mechanical ventilation) and do not survive to discharge. Most of those who do survive later develop profound disabling spastic quadriplegia.

Where the cause of the child's terminal apnoea is a sudden and much more abrupt hypoxic event (such as shoulder dystocia or an occasional case of late cord prolapse) these reservations may be less valid. Here there is at least anecdotal evidence that the outlook is much less bleak if the circulation can be restarted.

Acidosis not serious enough to precipitate circulatory standstill (asystole) will nearly always correct itself spontaneously within 90 minutes once the circulation has been restored and the infant starts to breathe for him- or herself. It does not therefore call for sodium bicarbonate, the use of which is controversial. Indeed, giving bicarbonate may increase carbon dioxide levels, worsening intracellular acidosis, and increases the amount of sodium that the potentially compromised kidney will need to excrete over the next few days.

- **Adrenaline:** The recommended dose of adrenaline is 10 micrograms/kg body weight (0.1 mL/kg body weight of 1:10 000 solution). If this is not effective, a dose of up to 30 micrograms/kg (0.3 mL/kg body weight of 1:10 000 solution) may be tried. Ideally, have ready-made and well-labelled 1:10 000 adrenaline solutions available on all emergency trolleys. In situations where this is not available in a ready-made state it could be prepared by adding 1 mL of 1:1000 solution to 9 mL of normal saline or Ringer-lactate or Hartmann's solution. **It is potentially dangerous to leave inadequately labelled and made up doses of adrenaline around, as giving the same volume of 1:10 000 as 1:1000 solution could cause cardiac arrest.** Do not use a higher dose by these routes (IV) as it is harmful.
- **Glucose:** The recommended dose of glucose is 200 mg/kg (2 mL/kg of 10% dextrose). Higher concentrations or larger doses can induce hyperglycaemia, which is associated with cerebral oedema and cerebral haemorrhage, and may lead to rebound hypoglycaemia. It is known that severe hypoglycaemia is rare immediately after birth, but tends to present after 1–2 hours. However, hypoglycaemia (**less than 2.5 mmol/litre (45 mg/dL)**) is a potential problem for stressed or hypoxic neonates, so 10% dextrose should be considered in cardiac arrest, as the heart will not recover in the presence of hypoglycaemia. This should be followed by an infusion of 5 mL/kg/hour of 10% glucose if there is confirmation of hypoglycaemia by a blood test. This should be continued until feeding is well established. **Never give any drug into the umbilical artery.**
- **Naloxone (nalorphine)** can be used to reverse profound opiate-induced respiratory depression, but has no real role in neonatal resuscitation. If it does prove necessary, it is best to give it intramuscularly and give a full 200-microgram 'depot' dose irrespective of body weight. If naloxone is given as a single dose IV it will be eliminated from the body faster than the opioid drug, causing a return of the respiratory depression, and therefore the infant will stop breathing again without a naloxone infusion. Naloxone

does not reverse the respiratory depressing effects of non-opiate drugs.

### Acute blood loss as a cause of circulatory arrest (circulatory volume support)

- Sudden acute blood loss is a rare, but often unrecognised, cause of acute circulatory collapse. Bleeding from an aberrant placental blood vessel (vasa praevia) or snapped umbilical cord can rapidly lead to hypovolaemic death. The response to a rapid generous infusion of any IV fluid can be equally dramatic. Speed is of the essence. Circulatory collapse probably does not occur until the infant has lost 30–40 mL/kg of blood, but 20 mL/kg of Ringer-lactate or Hartmann's solution will usually reverse the immediate critical hypovolaemia rapidly. The initial intravenous fluid bolus should be **10 mL/kg** of Ringer-lactate or Hartmann's solution or **blood group O Rh-negative blood (if immediately available)**. This can be repeated **once** if there is no or only minimal response. A similar response can be achieved with plasma, albumin or some artificial plasma-expanding agent (e.g. gelatin). A packed red cell transfusion using group-specific or group O Rh-negative duly cross-matched blood can be given later to correct the associated anaemia.
- Other less well-recognised causes of hypovolaemic collapse include acute fetomaternal blood loss, sudden twin-to-twin transfusion, and accidental incision of the placenta during Caesarean delivery and cord ligation that has come off and not been detected.

Apart from these specific indications, fluid should not be used during neonatal resuscitation. There is no evidence to suggest benefit from routine use, which only compounds the problem of fluid balance that can develop over the next 2 to 3 days if severe intrapartum stress causes secondary renal failure.

### Environment

This is always at risk of being overlooked, but it should be the first issue to receive attention in all infants, before and at birth.

- A **clean, warm** and **well-lit** environment for resuscitation is the objective in all cases. It only takes a few seconds to dry the infant and provide a clean dry blanket for warmth. The room in which delivery takes place should also be clean, warm and free of draughts.
- Small infants in particular rapidly become cold, especially if left wet, which can be lethal. Enclosing the trunk and the limbs in a clear plastic drape or bag (plus a woollen cap if available) can greatly reduce evaporative heat loss. Indeed, infants born more than 10 weeks early have skin that is so thin that it is not really 'waterproof'. This will cause excessive evaporative heat loss to persist for several days after birth.

### Family

- The mother's needs come first if you are on your own. Most infants are quite good at looking after themselves, once they are breathing and wrapped. If possible keep the infant with the mother.
- If you are not on your own, things become much easier. The 'ABC' summary really only comments on the care that should be given to the infant. Remember that

parents need to be told what is happening. They will fear the worst, more so if the infant was only taken away from them even for a few minutes at birth for stabilisation or resuscitation.

- If you tell the parents that their infant needed ‘resuscitation’ at delivery, they may well start to think that their child was in the process of dying. That might make you feel that you have done something useful, and it may make the parents very grateful. However, it will also make them feel that something must have gone ‘wrong’ during delivery, and it may lead them to worry that their child could be ‘brain-damaged’ as a result. The words that we use matter. Parents can easily read meanings into them that we never intended.
- Write down what you see and do, distinguishing fact from opinion and making no assumption as to the causation. Use adjectives with great care and do not make judgemental comments on the actions of others. Document everything.

### Poor response to resuscitation

If the infant either fails to respond or shows a poor response to resuscitation, the most likely problem is inadequate oxygenation. The following steps should be considered:

- Check the airway and ventilation.

- Check for technical faults if using equipment.
  - Is the oxygen attached?
  - Is the airway blocked?
  - Is the endotracheal tube in the correct place?
- Re-examine the chest to see if a pneumothorax has developed. This is not common, but may cause a problem. Drain a tension pneumothorax with a small cannula over needle (21 gauge) in the second intercostal space in the mid-clavicular line. This should be followed by the insertion of a chest drain (see Section 8.3).
- Consider the possibility of a congenital heart lesion if the infant remains cyanosed despite breathing and having a good heart rate.
- Consider the possibility of maternal opiates or sedation, such as diazepam or phenobarbitone, if the infant is pink, well perfused, but requires assisted ventilation.
- Shock, caused by acute blood loss, should respond to a rapid bolus of 10–20mL/kg of O-negative blood.
- Consider the possibility of hypoglycaemia.

### Stopping resuscitation

Even with the most effective resuscitation, not all infants will survive.

If the infant has been without a cardiac output after 20 minutes of resuscitation and does not respond despite

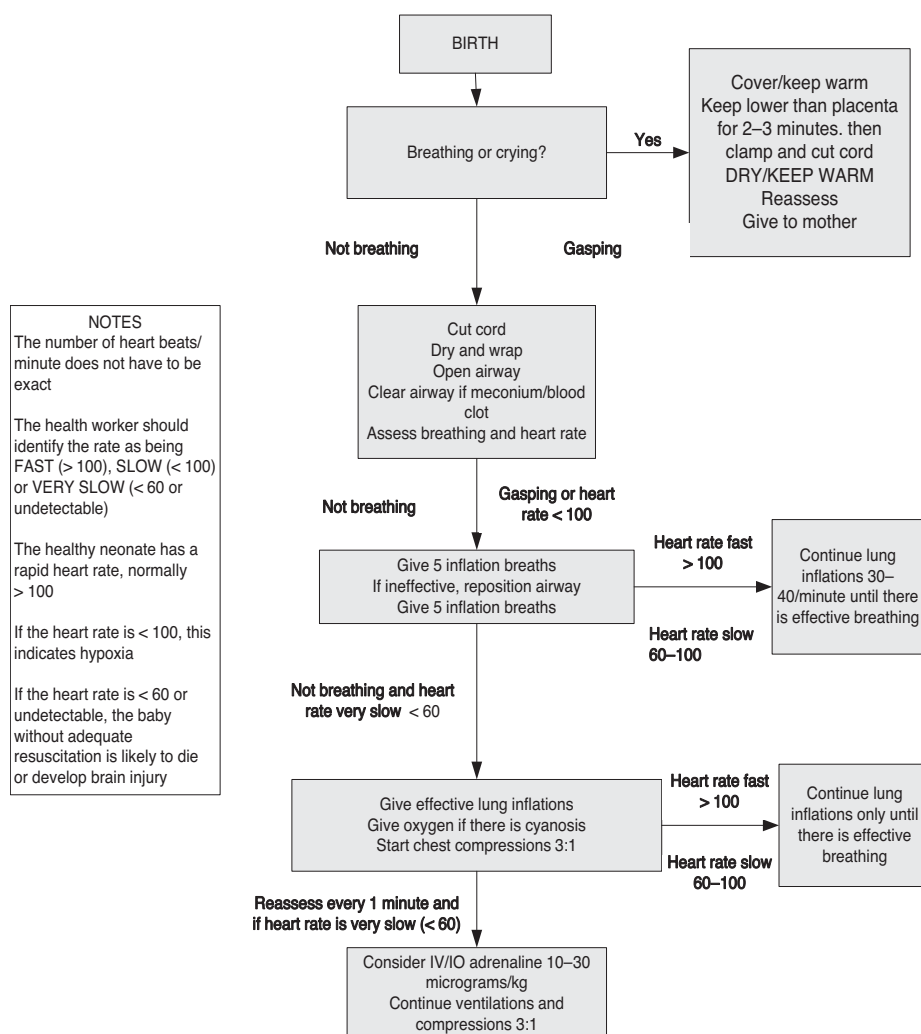

FIGURE 3.2.5 Algorithm for resuscitation of the baby at birth.

effective ventilations and chest compressions, the outcome is unlikely to be altered by the use of drugs, although these should be considered. The decision to stop resuscitation should be taken by the most senior healthcare worker present, and the reason for the decision should be clearly documented.

**Explain sensitively to the parents that the infant has died. The infant should then be handled in accordance with cultural preference and practice.**

### Documentation

**It is important to keep accurate records of the steps taken during resuscitation. The reason for any decision must be clearly documented, including the decision to start and end resuscitation. This is important irrespective of the immediate outcome of the resuscitation effort. As with any documentation, keep to the facts and make a complete record of all the steps taken, their timing, and the impact that they had on the infant's progress.**

**Remember to sign and date the record.**

### Vitamin K prophylaxis against haemorrhagic disease of the newborn

Following resuscitation/stabilisation, all newborn infants should receive vitamin K 1 mg IM. Vitamin K is given to prevent haemorrhagic disease of the newborn (HDN), which may cause significant bleeding and even death. The IM route is preferred as it provides a depot over many weeks.

Similarly, neonates requiring surgery, those with birth trauma, preterm infants and those exposed *in utero* to

maternal medication that is known to interfere with vitamin K are at especially high risk of bleeding and must be given vitamin K 1 mg IM. This is often forgotten in the rush to get the infant to the nursery.

### Resuscitation guidelines algorithm

As discussed earlier, all resuscitation guidelines are based on the international evidence-based science agreed in 2010 at the International Liaison Committee on Resuscitation. The algorithm shown in Figure 3.2.5 summarises the recommendations in the text.

## 3.3

### Clinical care of the infant in the early months of life

#### Prematurity and low birth weight

- A **low-birth-weight infant** is one weighing less than 2.5 kg at birth. Low birth weight may be attributable to preterm delivery or intrauterine growth restriction.
- A **preterm infant** is one born before 37 completed weeks have elapsed since the first day of the last menstrual period (259 days). Most preterm infants are born after 32 weeks' gestation.
- A **small-for-gestational age (SGA) infant** is one whose birth weight falls below the 10th percentile on a birth weight centile chart.

**Probably at least 25% of SGA infants are just constitutionally small by virtue of maternal weight, and not secondary to poor placental perfusion. The mean birth weight of infants born to mothers 4 feet 10 inches (147 cm) tall is about 500 grams less than that of infants born to mothers 6 foot 0 inches (183 cm) tall. This discrepancy increases to about**

**1 kg if extremes of mid-pregnancy weight are also taken into account.**

- **Intrauterine growth restriction (IUGR)** refers to a slowing of fetal growth velocity. Most but not all IUGR infants are SGA at birth. Some IUGR infants are just wasted.
- A **large-for-gestational age (LGA) infant** is one whose birth weight is greater than the 90th percentile on a birth weight centile chart.

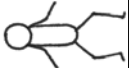

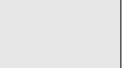

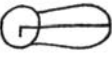

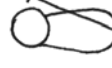

**For most clinical purposes it is sufficient to classify infants as 'low birth weight', 'preterm' or 'small-for-gestational age'.**

#### Assessing gestational age

Sometimes a mother cannot recall the date of her last menstrual period. The infant's gestational age can then be assessed to within  $\pm 2$  weeks based on a combined physical and neurological score (see Table 3.3.1). Wasted infants underscore on physical criteria.

TABLE 3.3.1 Ballard's scoring system for gestational assessment

Sign	Physical criteria score							Sign score
	-1	0	1	2	3	4	5	
Skin	Sticky, friable, transparent	Gelatinous, red, translucent	Smooth, pink, visible veins	Superficial peeling and/or rash, few veins	Cracking, pale areas, rare veins	Parchment, deep cracking, no vessels	Leathery, cracked, wrinkled	
Lanugo	None	Sparse	Abundant	Thinning	Bald areas	Mostly bald		
Plantar surface	Heel-toe 40–50 mm: -1 < 40 mm: -2	> 50 mm no crease	Faint red marks	Anterior transverse crease only	Creases anterior two-thirds	Creases over entire sole		
Breast	Imperceptible	Barely perceptible	Flat areola, no bud	Stippled areola, 1–2 mm bud	Raised areola, 3–4 mm bud	Full areola, 5–10 mm bud		
Eye/ear	Lids fused loosely: -1 tightly: -2	Lids open, pinna flat, stays folded	Slightly curved pinna; soft	Well-curved pinna; soft but ready recoil	Formed and firm; instant recoil	Thick cartilage, ear stiff		
Genitals (male)	Scrotum flat, smooth	Scrotum empty, faint rugae	Testes in upper canal, rare rugae	Testes descending, few rugae	Testes down, good rugae	Testes pendulous, deep rugae		
Genitals (female)	Clitoris prominent and labia flat	Prominent clitoris and small labia minora	Prominent clitoris and enlarging labia minora	Labia majora and minora equally prominent	Labia majora large, labia minora small	Labia majora cover clitoris and labia minora		
<b>Total physical maturity score</b>								

Sign	Neurological criteria score							Sign score
	-1	0	1	2	3	4	5	
Posture								
Square window	 >90°	 90°	 60°	 45°	 30°	 0°		
Arm recoil		 180°	 140°–180°	 110°–140°	 90°–110°	 <90°		
Popliteal angle	 180°	 160°	 140°	 120°	 100°	 90°	 <90°	
Scarf sign								
Heel to ear								
<b>Total neuromuscular score</b>								

Notes on calculating the scores:

**Posture:** With the infant supine and quiet, score as follows:

- Arms and legs extended = 0
- Slight or moderate flexion of hips and knees = 1
- Moderate to strong flexion of hips and knees = 2
- Legs flexed and abducted, arms slightly flexed = 3
- Full flexion of arms and legs = 4.

sufficient to get as much flexion as possible. The angle between the thumb and the anterior aspect of the forearm is measured and scored:

- > 90° = -1
- 90° = 0
- 60° = 1
- 45° = 2
- 30° = 3
- 0° = 4.

**Square window:** Flex the hand at the wrist. Exert pressure

**Arm recoil:** With the infant supine, fully flex the forearm for 5 seconds, then fully extend by pulling the hands and release. Score the reaction:

- Remains extended 180°, or random movements = 0
- Minimal flexion, 140–180° = 1
- Small amount of flexion, 110–140° = 2
- Moderate flexion, 90–100° = 3
- Brisk return to full flexion, < 90° = 4.

**Popliteal angle:** With the infant supine and the pelvis flat on the examining surface, the leg is flexed on the thigh and the thigh is fully flexed with the use of one hand. With the other hand the leg is then extended and the angled scored:

- 180° = -1
- 160° = 0
- 140° = 1
- 120° = 2
- 100° = 3
- 90° = 4
- < 90° = 5.

**Scarf sign:** With the infant supine, take the infant's hand and draw it across the neck and as far across the opposite shoulder as possible. Assistance to the elbow is permissible by lifting it across the body. Score according to the location of the elbow:

- Elbow reaches or nears level of opposite shoulder = -1
- Elbow crosses opposite anterior axillary line = 0
- Elbow reaches opposite anterior axillary line = 1
- Elbow reaches midline = 2
- Elbow does not reach midline = 3
- Elbow does not cross proximate axillary line = 4.

**Heel to ear:** With the infant supine, hold the infant's foot with one hand and move it as near to the head as possible without forcing it. Keep the pelvis flat on the examining surface. Score as shown in Table 3.3.1 above.

After assigning the score for the physical and neurological criteria, the sum of the two scores is then used to assess the gestation based on Table 3.3.2.

**TABLE 3.3.2** Assessment of gestation from total score

Total score	Gestational age (weeks)
-10	20
-5	22
0	24
5	26
10	28
15	30
20	32
25	34
30	36
35	38
40	40
45	42
50	44

## Low birth weight and/or preterm infants

### Infants with birth weight in the range 2.25–2.5 kg

- These infants are normally strong enough to start feeding themselves. They need to be kept warm and closely observed for infection, but otherwise no special care is required.

### Infants with birth weight in the range 1.75–2.25 kg

- These infants sometimes need extra care, but can normally stay with their mothers to receive feeding and warmth, especially if skin-to-skin contact can be maintained. Close monitoring by a healthcare worker is required.
- Feeds can be started within 1 hour of delivery. Many of these infants will be able to suck and can be breast-fed. Those who cannot breastfeed should be given expressed breast milk with a cup. When the infant is sucking well from the breast and gaining weight on a daily basis, they can be weaned off cup feeds.
- These infants should be reviewed at least twice a day to assess their feeding ability, fluid intake and the presence of any **danger signs** (see Box 3.3.1 below), including signs of serious bacterial infection. Such problems will necessitate close monitoring in a neonatal nursery (if available) in a similar way to the very low birth weight. The risk of keeping the child in hospital (including hospital-acquired infections) should be considered.

### Infants with birth weight below 1.75 kg

- These infants are at risk of hypothermia, apnoea, hypoxaemia, sepsis, feed intolerance and necrotising enterocolitis. The smaller the infant, the greater these risks. All infants with a birth weight below 1.75 kg should be admitted to a special care or neonatal intensive care unit (if available).

## Other treatments for low-birth-weight and/or preterm infants

### Oxygen

Oxygen should be administered via nasal cannulae, nasal prongs or a head box if there are signs of respiratory distress, such as moderate to severe recession (preterm infants may show mild recession with normal breathing), and definitely in the presence of cyanosis. **Pulse oximetry to measure oxygen saturation is a vital part of oxygen usage in the preterm infant.** Retinopathy of prematurity (ROP), previously known as retrolental fibroplasia, which leads to lifelong blindness in many cases, is caused by high blood levels of oxygen saturation in the preterm infant. There is no good evidence for the optimum oxygen saturation for preterm infants. On the one hand it is important to avoid hypoxia, which would lead to brain damage, as the infant is likely to have respiratory problems from surfactant deficiency, and on the other hand unrestricted oxygen may cause ROP, which would lead to blindness. Current advice is that the infant born at or before 32 weeks' gestation or weighing less than 1500 grams at birth should have a target oxygen saturation of 86–92%, which is higher than the oxygen saturation to which the fetus is exposed *in utero*.

### Prevention of hypothermia

To prevent hypothermia, nurse the infant in skin-to-skin contact between the mother's breasts ('kangaroo care')

or clothed in a warm room, or in an incubator. A hot water bottle wrapped in a towel can be useful for keeping the infant warm if no power for heating is available, but take care not to burn the infant. Aim for an axillary temperature of 36.0–36.5°C, with the feet warm and pink. When the mother is asleep or if she is ill, a clean incubator can be used. Incubators should be washed with disinfectant between infants, and should be of a basic design that can be used appropriately by the staff available.

### Fluids

It is best to give fluids enterally. However, if the infant is not well enough (e.g. due to severe respiratory distress), give IV fluids (see Section 3.4). Initially, consider giving approximately 2–4 mL of expressed breast milk every 1 to 2 hours through a nasogastric tube. This can be adjusted depending on the weight and the amount of IV fluids that the infant is receiving. With increasing age and weight gradually increase the volume and timing of each feed (the maximum time interval between feeds should not exceed 4 hours). The total fluid intake of enteral feeds plus IV fluids per 24 hours should adhere to the following fluid management guidelines:

- 60 mL/kg on day 1
- 80–90 mL/kg on day 2
- 100–120 mL/kg on day 3
- 120–150 mL/kg on day 4
- 150–180 mL/kg thereafter.

Some infants can be fed with a cup. Use only expressed breast milk if possible. If 2–4 mL per feed is tolerated (i.e. there is no vomiting, abdominal distension, or gastric

aspirates of more than half the feed) the volume can be increased by 1–2 mL per feed each day. Ideally, aim to have feeding established in the first 5 to 7 days so that the IV fluids can be tapered off. Reduce or withhold feeds if signs of poor tolerance occur. As the infant grows, recalculate the feed volume based on the higher weight. Feeds may be increased over the first 2 weeks of life to 150–180 mL/kg/day based on a 3- to 4-hourly feeding pattern.

### How to give gastric feeds (see also Section 8.5 on gastric tube management)

Place the baby's lips on the breast even though he or she is unable to suck or attach before each feed. Place expressed breast milk (EBM) in the syringe. Only use fresh milk or milk that has been stored in a refrigerator, and that has not been out of the fridge for more than 1 hour in a hot climate. Check that the tube is in the stomach before every feed or administration of enterally given drugs. Also check that there is not more than 10% of the previous feed in the stomach by gentle aspiration using a 2- or 5-mL syringe. Connect the syringe containing EBM and remove the plunger, giving the milk by gravity over 10–15 minutes per feed. Only if the feed does not flow in should you gently push with the plunger for a few seconds only to get it started. Never push the whole feed in. Observe the infant closely during the feed for signs of respiratory distress that might be due to lung aspiration. Replace the tube every 7 days, or sooner if it is blocked.

Give enteral feeds only if there is no abdominal distension or tenderness, bowel sounds are present, meconium has been passed, and there is no apnoea, low aspirates, no vomiting and adequate stool output.

**TABLE 3.3.3** Guide to volumes of each feed given every 3–4 hours at different infant weights

	Day 1	Day 2	Day 3	Day 4	Day 5	Day 6	Day 7	Day 8
Total (mL/kg/day)	60	80	100	120	140	150	160	170
1.25–1.4 kg	10	15	18	20	22	24	25	≥26
1.5–1.9 kg	15	17	19	21	23	25	27	≥27
2.0–2.4 kg	20	22	25	27	30	32	35	≥35
≥2.5 kg	25	28	30	35	35	≥40	≥45	≥50

### Blood glucose levels

Check blood glucose levels every 6 hours until enteral feeds are established, and immediately if there are any danger signs of infection.

### Infection or feed intolerance

Observe carefully and constantly for infection or feed intolerance.

### Apnoea

Monitor for apnoea, ideally with a pulse oximeter (which are now affordable and available in many resource-limited countries), supplemented by close visual monitoring of the infant by the mother or a close relative.

### Discharge and follow-up of low-birth-weight infants

Discharge when:

- there are **no danger signs** (see Box 3.3.1), including signs of serious infection
- the infant is gaining weight (at least 20 grams per day for 3 consecutive days) on breastfeeding alone

#### BOX 3.3.1 Danger signs associated with infection in the neonate

##### Common danger signs

- Infant feeding less well than before.
- Infant lying quietly and making few spontaneous movements.
- Hypothermia or fever > 38°C.
- Capillary refill time > 3 seconds.
- Respiratory rate ≥ 60 breaths/minute.
- Indrawing of the lower chest wall when breathing, or grunting.
- Cyanosis.
- History of a convulsion.

##### Less common but important signs

- Low respiratory rate (< 20 breaths/minute) or apnoea.
- Jaundice.
- Abdominal distension.

- the infant is able to maintain temperature in the normal range (36–36.5°C axillary) in an open cot or with skin-to-skin care
- the mother is confident and able to take care of the infant.

*Low-birth-weight infants should be given all scheduled immunisations by the time of discharge from the health facility or soon after.*

**Counsel the parents before discharge on:**

- exclusive breastfeeding
- keeping the infant warm
- the danger signs that necessitate seeking care (see Table 3.3.4), plus advice on when to return for healthcare
- basic life-saving manoeuvres to use in the event of an emergency, particularly mouth-to-mouth and nose ventilation if prolonged apnoea occurs.

**Low-birth-weight infants should be followed up at regular intervals following discharge for weighing, assessment of feeding, and assessment of general health until they have reached 2.5 kg in weight.**

**TABLE 3.3.4** Danger signs for parents of discharged newborns

Seek advice immediately if any of the following occur:	Seek advice very quickly if any of the following occur:
Convulsion(s)	Infant refuses feeds
ANY bleeding	Minor diarrhoea or vomiting
Severe diarrhoea or vomiting	Minor breathing problems
Infant appears unresponsive	Infant is less active/interested
Severe breathing problems	Infant feels abnormally hot
Infant feels cold	Jaundice

## Enteral feeding for the newborn infant in hospital

### Type of milk

Breast milk will provide the nutrients required by almost all infants. However, for preterm infants the following supplements are needed:

### Vitamin D supplementation

Term breastfed infants generally do not need extra vitamin D. However, this is only true if the mother has an adequate vitamin D status. Maternal vitamin D deficiency during pregnancy and lactation is common in resource-limited countries, contributing to the low vitamin D content of breast milk. Newborn infants of mothers who have dark skin or wear concealing clothes are also at greater risk of vitamin D deficiency at birth.

Large amounts of calcium and phosphorus are transferred from the mother to the infant during the last 3 months of pregnancy, helping the infant's bones to grow. Therefore a preterm infant may not receive sufficient amounts of calcium and phosphorus for this purpose. Vitamin D helps the body to absorb calcium from the intestines and kidneys. Very preterm infants require adequate vitamin D supplements. Liver problems such as cholestasis and prolonged use of diuretics or steroids may also cause problems with blood calcium levels.

Therefore, without further supplementation, preterm and also some full-term breastfed infants may be at risk

of vitamin D deficiency. This risk may be minimised either by supplementing the mother with large amounts of vitamin D (4000 IU/day) during pregnancy and lactation, or by supplementing the infant directly (400 IU/day) during the period of lactation.

### Phosphorus supplements

These may be needed in the case of very small infants, who can become hypophosphataemic (i.e. with plasma phosphorus levels of < 1.5 mmol/litre). If untreated, this may result in metabolic bone disease. The addition of a concentrated phosphorus salt (50 mg/kg/day of phosphorus) to feeds will prevent this. Adding 0.05 mL/kg of a 4 mmol/mL phosphorus solution to each of eight feeds per day will give 50 mg/kg/day of supplemental dietary phosphorus.

### Vitamin A supplementation

In resource-limited countries, vitamin A supplementation of the newborn infant reduces mortality. Preterm infants are at high risk of vitamin A deficiency. This important subgroup of our infant population is not only born with inadequate body stores of vitamin A, but is also often unable to tolerate routine oral supplementation. Vitamin A supplementation programmes significantly reduce infant mortality as well as the incidence of xerophthalmia, respiratory infection, and morbidity from gastrointestinal disease. Oral supplementation of 4000 IU/kg/day has been recommended for very-low-birth-weight (VLBW) (< 1500 grams at birth) infants from establishment of full enteral feeding until discharge from the neonatal unit. Supplementing term newborn infants with vitamin A (100 000 IU as a single dose) within 48 hours of birth reduces infant mortality by almost 25%, with those of low birth weight deriving the greatest benefit. Alternatively, **a single dose of 200 000 units can be given to all postpartum mothers within 6 weeks of delivery, when the likelihood of pregnancy is very low, and when infants benefit most from the presence of vitamin A in breast milk.**

### Vitamin K

**All neonates should be given vitamin K 1 mg IM within 1 hour of birth. Those who require surgery, those with birth trauma, those who are preterm and those exposed before birth to maternal medication (that can interfere with vitamin K) are at high risk of bleeding and must be given vitamin K. If the need for surgery only becomes apparent some time after birth, we suggest that a repeat dose should be given before surgery.**

### Multivitamin preparation

A multivitamin preparation (preferably containing adequate vitamins A and D) for preterm infants may be commenced from 3 weeks of age. A supply of vitamin D (400 IU/day) is particularly important for bone mineralisation.

### Iron supplements

Iron supplements for preterm infants are usually commenced from about 6 weeks of age. Preterm infants have reduced iron stores compared with term infants, especially if the umbilical cord is clamped early. The daily dietary iron supplementation is 2–4 mg/kg of elemental iron, up to a maximum of 16 mg/day.

### Breast milk banking

The WHO recommends that low-birth-weight babies who cannot be fed their own mother's breast milk should receive donor milk. The high maternal mortality and morbidity in low-income countries mean that there are many infants who cannot be put to the breast within a few hours of birth, and donor milk is suitable for them. In addition, there is evidence that human donor milk reduces the incidence of severe infection and necrotising enterocolitis (NEC) in low-birth-weight babies, compared with formula milk.

It is possible to establish safe donor milk banks in resource-limited settings, provided that there is a microbiology laboratory able to process donor samples, and a power supply to keep the banked milk frozen. A nurse or other staff member must be trained in good hand hygiene, and the importance of labelling and storage. Only simple equipment is needed.

Milk can be collected from lactating mothers who are known to have tested negative to HIV and syphilis, and are non-smokers. Ideally they have also been screened for hepatitis infections. Milk is collected by hand expression under supervision (as 'drip milk' is lower in calories than expressed milk). A 1-mL aliquot from each donor's sample is sent to the microbiology lab. If colony-forming organisms are grown, the whole sample is discarded. Milk can be stored in a refrigerator while awaiting the microbiology results.

Milk is pasteurised by heating for 30 minutes at 62.5°C, and then cooled and frozen. Pasteurised frozen milk can be stored for up to 6 months from the date of collection. Supplementary formula feeding for the infants of mothers who cannot provide breast milk, or whose mothers have died, may be needed after discussion with the infant's carers.

### Fluid and electrolyte management for the neonate in hospital

**When giving fluid or blood intravenously, best practice is to use an in-line infusion chamber/burette to avoid fluid overload.**

#### Fluid requirements

Body water content is high at birth and urine output is low for the first few days. Therefore giving large volumes of fluid in the first few days may make an infant oedematous and worsen any respiratory disease. **A simple general rule** is to start an ill newborn infant who cannot take enteral fluids (breast milk) on 60 mL/kg/day IV as 10% dextrose solution, increasing in daily steps of 20–30 mL/kg/day to a maximum of 140–180 mL/kg/day. However, in a small-for-gestational-age infant it may be necessary to begin with 70–90 mL/kg/day in order to meet the glucose requirements.

**Ideally, use a 100-mL paediatric intravenous burette where 60 drops = 1 mL and therefore 1 drop/minute = 1 mL/hour.**

**So for an infant weighing 1.8 kg on day 1:  $1.8 \times 60 = 108$  mL.**

**In each hour the fluid will be  $108 \div 24 = 4.5$  mL, which corresponds to 9 drops every 2 minutes.**

The rate of insensible water loss (mainly through the skin) is high in some circumstances, particularly in infants under 29 weeks' gestation or when an overhead heater (radiant warmer) rather than an incubator is used. Helpful

measures for reducing insensible water loss in such cases include the following:

- Place the infant from below the neck in a clean plastic bag to maintain humidity. Maintaining humidity helps to keep very premature infants warm by reducing evaporative heat loss.
- Clothe the infant, or wrap the body below the head with bubble wrap or aluminium kitchen foil (with the shiny side facing inward towards the infant).
- When an overhead heater is used, the infant should not be covered, and the heater output must be adjusted in direct response to the infant's skin temperature (typically achieved by a continuous temperature probe servo system). Alternatively, a plastic bag over the infant's body from the neck down can help to preserve heat.
- In the first week of life, high rates of insensible water loss will be reflected by high rates of weight loss (more than 10% of birth weight), and often an increase in the plasma sodium concentration to 150 mmol/litre or higher. If either occurs, the infant is dehydrated and fluid intake should be increased by 30 mL/kg/day. When nursing a low-birth-weight infant under an overhead heater, it is advisable to add an extra allowance of 30 mL/kg/day right from the start (i.e. start on day 1 at 90 mL/kg/day rather than 60 mL/kg/day).

**Note, however, that even 30 mL/kg/day might not be enough to meet the insensible losses of a very preterm infant (29 weeks or less) under a radiant heater. Such infants are much better nursed in closed incubators.**

In very-low-birth-weight infants, enteral feeds should be advanced slowly in 20–30 mL/kg/day increments. Infants who are being enterally fed but who are unable to breastfeed can be given expressed breast milk by orogastric tube or cup. A general plan for fluid enhancement is as follows:

- day 1: 60 mL/kg/day
- day 2: 85 (range 80–90) mL/kg/day
- day 3: 110 (range 100–120) mL/kg/day
- day 4: 135 (range 120–150) mL/kg/day
- day 5 and thereafter: 165 (range 150–180) mL/kg/day.

Monitor the fluid intake by weighing the infant daily and recording the frequency of urine output.

To weigh the baby, first place a blanket in the scales, set them to zero and then place the baby naked in the scales and cover the infant with the blanket to keep them warm. Fluid intake may need to be adjusted frequently to maintain fluid balance. Urine output can be monitored by measuring the difference between wet nappies (diapers) and a dry one using accurate scales. Generally expect at least eight wet nappies in a 24-hour period. Look out for signs of fluid overload (oedema) or dehydration. If possible measure the plasma electrolytes, but remember that these cannot be interpreted without information on body weight and urine output.

#### Electrolyte requirements when giving IV fluids

##### Sodium requirements

Infants over 48 hours of age need some sodium supplementation in a dose of 2–3 mmol/kg/day. This can most easily be given by adding 20 mL/kg of normal saline (0.9%) to the daily requirement of 10% glucose to make up the

total daily fluid volume needed. This gives approximately 3 mmol of sodium per kg.

Adding sodium is open to many errors. Ready-made neonatal fluids are available in some countries, and may be used to avoid this problem in some situations. The sodium requirements of very preterm infants may be much higher, as urinary sodium losses may approximate 10 mmol/kg/day in those of 29 weeks' gestation or less.

Sodium can be commenced on the third day of life (after 48 hours) in infants receiving intravenous fluids, but if there is respiratory distress it is wise to wait until the diuresis associated with recovery begins (this is often delayed until the third or fourth day of life).

### Potassium requirements

Potassium supplementation in a dose of 1–2 mmol/kg/day will meet requirements and can be provided by adding mathematically correct and small amounts of potassium chloride to a 10% glucose fluid. If IV potassium is given, the plasma potassium concentration must be monitored daily. Potassium can be added to fluids but this should be done very carefully. **Remember that too much IV potassium can be fatal.** The concentration of KCl in peripheral IV solutions should never exceed 40 mmol/litre. **Do not add KCl until the urine output is well established.**

**Remember that it is best to give potassium and calcium supplements orally, unless very low serum values are identified.**

### Glucose requirements

Infusing glucose at the following rates will match the normal hepatic glucose output and therefore maintain the blood glucose concentration at an acceptable level:

- term infant: 3–5 mg/kg/minute
- preterm, appropriate weight for gestation: 4–6 mg/kg/minute
- small for gestational age: 6–8 mg/kg/minute.

**A solution of 10% glucose at 60 mL/kg/day will give 4 mg (0.22 mmol) glucose/kg/minute.**

These infusion rates provide minimal glucose requirements to maintain a normal blood glucose level, but higher rates will be required for growth. Consider hyperinsulinism as a cause of the problem if an infant requires higher rates of infusion to maintain normoglycaemia. Always use 5% or ideally 10% glucose/dextrose for peripheral IV infusions; an umbilical venous catheter will be needed if high glucose requirements or limits on fluid volume necessitate a more concentrated solution which will be damaging to thin peripheral veins.

### Composite maintenance fluid

An alternative way to make a simple composite maintenance fluid is by adding the following to give a total volume of 100 mL:

- 1/5 dextrose saline (0.18% normal saline with 5% dextrose) = 71 mL
- 7.4% KCl = 2 mL
- 10% calcium gluconate = 2 mL
- 25% dextrose = 25 mL
- **Total volume = 100 mL.**

Each 100 mL of the above solution would contain dextrose 10%, KCl 2 mEq, Ca 2 mEq and sodium 2.5–3 mmol. **Any**

**such mixture must be prepared under sterile conditions.**

**Remember that KCl should not be added until urine output is well established.**

### Drug use in the newborn infant

Relatively few drugs are needed to deal with most common neonatal emergencies.

The IV route should be used if the infant is already being given IV fluids, as this will reduce the amount of pain to which the child is subjected. There are dangers associated with rapid administration or breaking into an existing IV line, leading to an increased risk of sepsis. Erecting an IV line merely to administer drugs also risks exposing the child to dangerous fluid overload, unless a syringe pump can be used to control the rate at which fluid is infused.

### Common emergency problems that require hospital care in the first month of life

Many emergencies can be prevented by attention to good feeding practices, providing adequate warmth and preventing infection. The more preterm or low birth weight the infant, the more likely it is that the following complications will occur:

- feeding difficulties
- poor temperature control, especially hypothermia
- infection – prevention and early recognition and safe management are essential
- polycythaemia
- respiratory distress and apnoeic attacks
- bleeding
- jaundice and neonatal anaemia
- reduced conscious level and seizures, including hypoglycaemia
- surgical problems.

### Feeding difficulties

Infants born after 34 weeks are generally mature enough to suck and swallow well, but may be less demanding of feeds than term infants. Attention to the following can help all newborn infants, especially those born preterm, to establish breastfeeding:

- Encourage early and prolonged skin contact.
- Encourage small frequent feeds by waking the infant every 2 to 3 hours and putting them to the breast.
- If the infant will not latch on and suck, the mother can be encouraged to express breast milk and offer it to the infant by cup and/or spoon or if not accepted by orogastric or nasogastric tube.
- If an otherwise well infant on breast milk feeds is experiencing inadequate growth, an inadequate milk supply may be the problem. There are several possible causes for this, which can usually be identified by listening to the mother and then watching the infant feed. A relaxed mother will have a good 'let-down' reflex which gives the infant the more calorie-rich hind milk as well as the fore milk. The mother can tell when she has 'let down' by a tingling feeling in her breasts, and the infant starts to swallow rapidly. The infant must latch on properly for feeding to be successful, and this may need some assistance from the midwife. The best way to increase the milk supply for a hungry infant who is not thriving is to increase the feed frequency. Breast milk works on

a demand-and-supply system, so the more the infant demands, the more the breast supplies. If the infant is not feeding vigorously enough to increase the milk supply, the mother should express milk after feeding and give it to the infant as described above.

- Avoid giving formula or breast milk by bottle. A small feeding cup (about the size of a medicine measuring cup, with a smooth rim) or a spoon can be used to feed the infant.
- Give expressed breast milk via orogastric or nasogastric tube if the infant is too unwell to suck or drink from a cup.
- As the infant becomes stronger, encourage a transition to demand breastfeeding.

### Feeding problems

- **Ingested meconium/blood.** Infants who have swallowed a lot of meconium or blood before birth may retch and appear distressed after birth. Such problems almost always settle within a few hours without any intervention.
- **Uncoordinated feeding.** Infants born before 32 weeks' gestation often have difficulty sucking and swallowing in a coordinated way. Most will initially need some tube feeds. They are not likely to start gaining weight until they are taking at least 120 mL/kg of milk a day. Infants need to be fed regularly at least once every 4 hours, day and night. Breast milk can be supplemented with formula milk at this time if donor milk is not available. However, every effort needs to be made to sustain the mother's lactation by expression and by keeping the mother in hospital to be near her infant.
- **Regurgitation.** Hurried frequent feeding may cause regurgitation. A poorly developed cough reflex can cause the infant to inhale milk into the lung, resulting in possible pneumonitis and even pneumonia. Newborn infants benefit from frequent small feeds every 2 to 3 hours. Feeds should be increased gradually over the first 3 to 5 days of life. Patience is required. Dehydration (and the risk of hypoglycaemia) need to be monitored, and can be prevented during this period by giving supplemental gastric or IV fluids so that total fluid intake (i.e. taking the gastric/IV and the oral intake together) does not fall below 120 mL/kg per day.
- **Feeding tubes.** Tube feeding is the best option for infants who have not yet developed a coordinated suck and swallow reflex. Nasogastric tubes are popular, easier to secure and less easily pushed out by the infant's tongue, but they can almost completely block one nostril, significantly increasing the work of breathing. Therefore orogastric tubes are preferred if respiratory distress is present. Alternatively, a fine-bore nasogastric tube can be left in place and changed as required (up to a maximum of 7 days). Small frail infants should be handled as little and as gently as possible, and can be left lying undisturbed in their cots during a tube feed so long as the head end of the cot is elevated 25 cm.

### Temperature control and hypothermia prevention and treatment

Hypothermia can be due to a cold environment, but remember that **starvation** or **serious infection** can present as hypothermia.

Normal temperatures for newborn infants are **36.5–37.5°C (axillary)** if measured over 3 minutes, and lower (around **36.0–36.5°C**) if measured over at least 1 minute. Rectal thermometers are difficult to use and can be dangerous. If the trunk is cold, the infant is almost certainly hypothermic.

Use a **low-reading digital thermometer**, not a mercury thermometer. If the axillary temperature is less than 32°C, hypothermia is severe; if it is in the range 32–35.9°C the infant has moderate hypothermia. If the infant's temperature does not register on the normal thermometer, assume that they have hypothermia.

Hypothermia can be prevented by the following measures:

- Dry the infant well immediately after birth and place them in skin-to-skin contact with the mother. This is especially important for low-birth-weight infants who do not have other complications. For those with medical problems, warm the infant by skin-to-skin care. If there are adequate resources and staff, an overhead radiant heater **or** an air-heated incubator (set at 35–36°C) can be used.
- 'Kangaroo care' (skin-to-skin contact with the mother between her breasts and covered with a blanket) is the most effective method for all infants, especially for those of low-birth-weight. Randomised trials in both well-resourced and resource-limited countries have shown significant advantages to this technique for the infant and the mother, including an increased prevalence of breastfeeding, a reduced incidence of apnoea and a reduced risk of infection. Take care when examining the infant not to allow the temperature to fall (ideally room temperature in the hospital ward should be higher than 25°C).
- A cot heated **with a hot-water bottle with the top screwed in tightly and wrapped in a clean towel** can be just as effective if the above are not available. Ordinary domestic radiant heaters or electrical blower type heaters can also be effective.
- Cover the infant's head with a warm woollen hat and dress them in **warm, dry clothes**. Keeping the nappy dry is also very helpful.
- Avoid overheating by monitoring the axillary temperature 4- to 6-hourly.
- Feed the infant 2-to 3-hourly, and continue with 4-hourly feeds during the night.
- Avoid washing the infant before they are 24 hours of age.
- Do not leave the infant where there are any draughts.
- The infant should sleep either with or next to the mother during the night.

The development of incubators earlier in the twentieth century significantly reduced the mortality of preterm infants, but they are expensive, and require regular maintenance, thorough cleaning and sufficient numbers of trained staff. The nursing of infants in incubators is covered by standard texts, but Table 3.3.5 gives the settings from which to start, adjusting the incubator temperature up or down to maintain the infant's axillary temperature at 36.0–36.5°C.

TABLE 3.3.5 Incubator temperature guidelines

Weight of baby (grams)	Day 1	Day 2	Day 3	Day 4 and subsequently
< 1200	35.0°C	34.0°C	34.0°C	33.5°C
1200–1500	34.0°C	34.0°C	33.5°C	33.5°C
1500–2500	33.5°C	33.0°C	32.0°C	32.0°C
> 2500	33.0°C	32.5°C	31.0°C	30.5°C

Do not use antipyretic drugs to control fever in a newborn infant. Instead control the environment (e.g. remove some clothes, adjust incubator temperature) and always consider the possibility of serious infection.

### Prevention of neonatal infection

A newborn infant with risk factors for infection (membranes ruptured more than 18 hours before delivery, mother with fever > 38°C before delivery or during labour, or foul-smelling/purulent amniotic fluid) should be treated with prophylactic antibiotics (ampicillin and gentamicin IM or IV) for at least 2 days. After 2 days the infant should be reassessed and treatment continued if there are signs of sepsis (or a positive blood culture).

Simple measures that can prevent infection in the newborn include the following:

- Ensure a **clean delivery environment** for the mother and infant, including disinfectant cream for all maternal vaginal examinations (e.g. Hibitane cream).
- **Good cord care:** the WHO recommends that the cord be kept clean and dry. It should not be covered. Local applications of creams, ointments, etc. are generally not required except in high-risk settings, where application of an antiseptic is recommended. An antiseptic solution or cream such as 4% chlorhexidine has recently been shown to reduce omphalitis and resulting neonatal mortality. It should be applied immediately after birth and for several days thereafter if possible, preferably after every nappy change. Similarly, there is extensive successful experience with the application of surgical spirit or iodine solution to the cord.
- **Exclusive breastfeeding.**
- Strict procedures for **hand washing** or the use of hand sprays or hand rubs for all staff and for families before and after handling infants.
- **Not using water for humidification** in incubators (where *Pseudomonas* can easily colonise).
- **Cleaning incubators with an antiseptic before use** (if skin-to-skin mother care is not possible).
- **Strict sterility for all invasive procedures.**
- **Sterile injection practices.**
- **Remove intravenous drips** when they are no longer necessary.
- **Keep invasive procedures (e.g. blood sampling, unnecessary IV cannulation) to a minimum**, only undertaking them when they are essential.

### Early-onset sepsis (first 72 hours)

Early-onset sepsis usually occurs as a result of bacteria acquired by vertical transmission from mother to infant during labour and delivery. The most frequently observed organisms vary from one part of the world to another. Gram-negative enteric bacteria (especially *Escherichia*

*coli* and *Klebsiella* species) predominate in many regions. Gram-positive cocci are also common, and include group B beta-haemolytic streptococcus, other streptococcal species, *Staphylococcus* and *Enterococcus*. Rarely *Listeria monocytogenes* is isolated from newborn infants with sepsis, especially when there are foodborne epidemics.

### Maternal risk factors for early-onset sepsis

These include the following:

- maternal fever (especially 38°C or higher) before delivery or during labour
- pre-labour rupture of membranes
- prolonged rupture of membranes (18 hours or longer)
- preterm labour
- maternal bacteriuria during pregnancy (including *E. coli* and group B beta-haemolytic streptococcus)
- prior infected infant (group B beta-haemolytic streptococcus).

Early-onset sepsis in the newborn usually results from bacteria acquired from the mother at or shortly before delivery. These infants mostly present with respiratory distress, and have bacteraemia or pneumonia. However, vaginal cultures cannot be used to determine the choice of antibiotics when treating the symptomatic newborn.

### Late-onset sepsis

Organisms are less likely to reflect those of the maternal genital tract, although the same pathogens may be identified in infants presenting from home. The most common infections are focal ones such as conjunctivitis, omphalitis, skin infections and meningitis. A circumcision wound can also be the site of serious infection.

In the hospital setting, infection is more commonly due to nosocomial pathogens, including coagulase-negative staphylococci, Gram-negative enteric bacteria (e.g. *Klebsiella oxytoca*, *Klebsiella pneumoniae*, *Enterobacter cloacae*), *Staphylococcus aureus*, *Pseudomonas* species, streptococcal species and *Enterococcus*. Fungal sepsis must also be considered. Investigate as for early-onset sepsis, with the inclusion of a lumbar puncture and suprapubic urine for analysis and culture if indicated, and treat empirically with parenteral broad-spectrum antibiotic therapy directed towards the most commonly encountered pathogens for the particular nursery. Once cultures are positive, therapy can be directed accordingly. (For details of treatment of sepsis, see Section 3.4.)

### Laboratory evaluation of the unwell infant

In an infant who is generally unwell with no clinically obvious infective focus, the following investigations should be performed:

- **Blood culture (about 1 mL of venous blood):** This should be obtained from a peripheral vein after preparing

the skin with an antibacterial wash such as povidone-iodine and/or 70% ethanol or isopropyl alcohol. Blood culture is the gold standard for neonatal sepsis, but it is not 100% sensitive. The sensitivity may be further reduced if intrapartum antibiotics were administered to the mother antenatally. The results can be assessed at 48 hours.

- **White blood cell and differential cell count are not helpful in most situations.**
- **Chest X-ray:** This may be helpful if there are any respiratory signs, but not if it means taking the infant to another department in the hospital. A portable chest X-ray is ideal.
- **Lumbar puncture if indicated:** cytology, chemistry, Gram stain and culture. Not routinely done on all infants with suspected infection unless there are neurological signs.
- **C-reactive protein (CRP):** This is an inexpensive and useful test which may take 12 hours to become positive after the onset of an infection if this is present.
- **Blood glucose concentration.**
- **Serum bilirubin concentration:** if the infant appears jaundiced.
- **Surface cultures (ear canal, umbilical stump) and gastric aspirate cultures:** these do not correlate with either the likelihood of sepsis or the causative agent in septic infants. **These cultures should not be obtained.**
- **Midstream or suprapubic aspirate of urine for culture:** This procedure is of little value in the infant with suspected sepsis shortly after birth, but may be positive in infants with new-onset symptoms later in the first week ( $\geq 3$  days). A urinary tract infection should always be considered in neonates with late-onset sepsis.

**In seriously sick infants with suspected sepsis, priority should be given to the structured ABC approach, while simultaneously obtaining a blood culture followed by prompt administration of antibiotics. Other tests, such as a lumbar puncture if needed (see above), can be performed once the infant is stable and antibiotics have been started.** (For details of treatment of sepsis, see Section 3.4.)

## Infants who are vulnerable to maternal factors

### The infant of a diabetic mother

If a diabetic mother is poorly controlled, her infant may be large for gestational age, putting him or her at risk of slow progress in labour and perhaps shoulder dystocia. At birth, the infant, although large, behaves in a similar manner to a preterm infant. There is a major risk of hypoglycaemia, caused by the intrauterine over-stimulation of the infant pancreas to produce abnormally high levels of insulin. The infant must be monitored at least hourly for hypoglycaemia in the first 6 hours, and should then be monitored 4-hourly for hypoglycaemia, which should be treated as described above with an infusion of 10% dextrose. The infant of a diabetic mother has immature lung maturation and is liable to surfactant deficiency (see Section 3.4), poor feeding and jaundice. Polycythaemia is also more likely.

### The infant of a mother who is dependent on alcohol or drugs of addiction

These infants have been exposed to significant levels of narcotic drugs or alcohol *in utero*, causing an increased risk of congenital abnormalities and of abnormal neurological development and behaviour during childhood. Soon after birth they may show hyper-irritability and convulsions, requiring treatment and gradually reducing sedation as they are 'weaned off' the addictive drugs to which they have been exposed. These infants are also at risk of having been exposed to bloodborne viruses such as HIV and hepatitis B and C.

## Birth injuries

### Swellings around the head

- The commonest is a **caput succedaneum**, which is oedematous tissue over the occiput present after a vaginal delivery. This usually resolves within a few days and is of no consequence, requiring no intervention.
- A **cephalhaematoma** is a lateral (sometimes bilateral) fluctuant swelling, well circumscribed by the sutures. It does not cross the midline and anatomically represents a sub-periosteal haemorrhage. There may be an associated skull fracture, but neither this nor the swelling itself usually needs treatment. The only important complication can be worsening of jaundice as the blood is degraded and reabsorbed. **Never aspirate blood from a cephalhaematoma, as this can cause a serious infection.**
- A **subaponeurotic haemorrhage** (bleeding between the skull periosteum and the scalp aponeurosis) is the least common but most dangerous scalp swelling. It represents haemorrhage beneath the aponeurosis of the scalp. Onset and progression is often insidious, with progressive pallor due to significant haemorrhage. The boggy swelling of the head, extending from above the eyes to the occiput, may only be noticed after the infant has developed hypovolaemic shock. The infant may develop bruising behind the ears and around the eyes. This must be recognised early, as these infants often need urgent transfusion. Injection of vitamin K should be given.

### Nerve palsies

- **Facial nerve palsies** are sometimes associated with forceps delivery. They usually resolve within a few days, requiring little intervention.
- **Brachial plexus trauma** may follow shoulder dystocia or a difficult breech delivery, and reflects traction injury to the upper roots of the brachial plexus. The arm is flaccid and the wrist flexed. This can most clearly be demonstrated by eliciting an asymmetric Moro reflex. Look for signs of respiratory distress, as the phrenic nerve on the same side is sometimes affected. An X-ray should be obtained to exclude a pseudoparesis associated with clavicular fracture or syphilitic osteitis. The humerus should also be included in the X-ray to rule out **humeral fractures**, which may occasionally be present. Most brachial plexus palsies resolve within 3 to 4 weeks of delivery, but rarely they can be permanent. Once fractures have been ruled out, the mother can be shown how to perform passive movements to reduce the possibility of joint contractures developing. Refer

the infant for a surgical opinion if they are not better by 4 weeks.

### Fractures

The most common types are **skull and clavicular fractures**. These usually require no specific treatment. However, significant skull fractures must be evaluated for intracranial bleeding. There should also be consideration of whether the injury is a birth-associated one or a subsequent inflicted injury perpetrated by a caregiver.

## Common external congenital abnormalities

### Talipes equinovarus

Talipes equinovarus is a fixed inversion and flexion deformity of the foot at the ankle, in which the foot cannot easily be put in a normal position. It is helpful to note that this form of fixed talipes is usually associated with the presence of a groove on the medial aspect of the foot. Treatment is required. The foot should be splinted and strapped in the position closest to normal, and an orthopaedic surgeon's advice must be sought (see Section 5.17). Whenever talipes is present, be sure to examine the hips carefully for evidence of developmental dysplasia (also known as 'congenital

dislocation of the hip'). It is also important to examine the back for a spinal defect and evidence of neurological deficit.

The common variation (positional talipes) where the foot can easily be brought into the normal position does not require treatment.

### Extra digits

These are very common. It is important to distinguish a simple skin tag from a true extra digit containing bone or cartilage. The latter may be associated with other congenital anomalies, particularly of the heart, spine, kidney or gut. Skin tags are inherited and are of cosmetic significance only. Skin tags are often held by only a thin pedicle of tissue, which can be ligated at the base, usually causing the tag to fall off a few days later.

### Supernumerary nipples and pre-auricular skin tags

These are often found and are of cosmetic concern only. No intervention is required.

## 3.4

## Neonatal illnesses and emergencies

### Sepsis in the neonate

#### Recognising and treating neonatal infection

Bacterial sepsis (septicaemia) in the newborn infant may present with any number of subtle non-specific changes in activity or physical findings. A change in feeding pattern, vomiting, irritability, pallor, diminished tone and/or decreased skin perfusion is suggestive of neonatal infection. Other presenting physical findings may include lethargy, apnoea, tachypnoea, cyanosis, petechiae or early jaundice. There may be fever, but this is not common, especially with bacterial infections occurring in the first week. However, temperature instability with hypothermia may be seen. Abnormal glucose homeostasis (hypoglycaemia or hyperglycaemia) and/or metabolic acidosis are commonly associated findings. Infants, especially preterm infants, are very prone to infection and can become ill very rapidly once infection takes hold. Antibiotic treatment is only likely to work if started early, but the recognition of early infection is not easy. A WHO study showed that more than a third of all deaths in the first month of life in most resource-limited countries were caused by infection. It also found that more than 80% of these infants, when first seen, had **one or more of the following eight danger signs associated with infection in the neonate:**

- infant feeding less than well than before
- infant lying quiet and making few spontaneous movements

- hypothermia or fever > 38°C
- capillary refill time > 3 seconds
- respiratory rate  $\geq$  60 breaths/minute
- indrawing of the lower chest wall when breathing, or grunting
- cyanosis
- history of a convulsion.

#### Less common but important signs include the following:

- low respiratory rate (< 20 breaths/minute) or apnoea
- jaundice
- abdominal distension
- skin infections.

All neonates with signs of sepsis need immediate hospital admission if they are not already there, and must be treated with IV antibiotics for at least 10 days after blood and other appropriate cultures have been taken.

Ampicillin (or penicillin) plus gentamicin are the first-line drugs to be used. Consider adding cloxacillin or flucloxacillin if there are signs suggesting that *Staphylococcus aureus* is a cause (e.g. skin pustules, abscess, omphalitis). Blood cultures are ideal although not always possible before starting antibiotics. If the infant does not respond within 48 hours, consider changing the antibiotic. If there is a possibility of meningitis, risk of resistance or Gram-negative organisms, a third-generation cephalosporin such as cefotaxime or ceftriaxone should also be added.

**Causes of early-onset sepsis (first 72 hours)**

Early-onset sepsis usually occurs as a result of bacteria acquired by vertical transmission from mother to infant during late pregnancy, labour and delivery. The most frequently observed organisms vary from one part of the world to another. Gram-negative enterics (especially *Escherichia coli* and *Klebsiella* species) predominate in many regions. Gram-positive cocci are also common, and include group B beta-haemolytic streptococcus, other streptococcal species, *Staphylococcus* and *Enterococcus*. Less commonly, *Listeria monocytogenes* is isolated from newborn infants with sepsis, especially when there are foodborne epidemics.

These infants mostly present with respiratory distress. However, vaginal cultures cannot be used to determine the choice of antibiotics when treating the symptomatic newborn.

**Late-onset sepsis**

Organisms are less likely to reflect those of the maternal genital tract, although the same pathogens may be identified in infants presenting from home. The most common infections are focal infections such as conjunctivitis, omphalitis, skin infections and meningitis. A circumcision wound can also be the site of serious infection.

In the hospital setting, infection is more commonly caused by nosocomial pathogens, including coagulase-negative staphylococci, Gram-negative enteric bacteria (e.g. *Klebsiella oxytoca*, *Klebsiella pneumoniae*, *Enterobacter cloacae*), *Staphylococcus aureus*, *Pseudomonas* species, streptococcal species and *Enterococcus*. Fungal sepsis must also be considered. Investigate as for early-onset sepsis (see below), with the inclusion of a lumbar puncture and suprapubic urine for analysis and culture if indicated, and treat empirically with parenteral broad-spectrum antibiotic therapy directed towards the most commonly encountered pathogens for the particular nursery. Once cultures are positive, therapy must be directed accordingly.

**Laboratory evaluation of the unwell infant**

In the case of an infant who is generally unwell with no clinically obvious infective focus, the following investigations should be performed if laboratory facilities are available:

- **Blood culture (about 1 mL of venous blood):** This should be obtained from a peripheral vein after preparing the skin with an antibacterial wash such as povidone-iodine and/or 70% ethanol or isopropyl alcohol. Blood culture is the gold standard for neonatal sepsis, but it is not 100% sensitive. The sensitivity may be further reduced if intrapartum antibiotics were administered to the mother antenatally.
- **White blood cell count (WBC) with differential cell count is generally unhelpful in this setting.**
- **Chest X ray:** This may be helpful if there are any respiratory signs, but not if it means taking the infant to another department in the hospital. A portable chest X-ray is ideal (if available).
- **Lumbar puncture if indicated:** cytology, chemistry, Gram stain and culture. Not routinely done on all infants with suspected infection unless there are neurological signs.
- **C-reactive protein (CRP):** This is an inexpensive and useful test which may take 12 hours to become positive if an infection is present. A negative test at 48 hours in a well infant suggests that antibiotics can be stopped.

- **Blood glucose concentration.**
- **Serum bilirubin concentration** if the infant appears jaundiced.
- **Surface cultures** (ear canal, umbilical stump) and gastric aspirate cultures do not correlate with either the likelihood of sepsis or the causative agent in septic infants. **These cultures should not be obtained.**
- **A midstream or suprapubic aspirate of urine for microscopy and culture:** This procedure is of little value in the infant suspected of having sepsis shortly after birth, but it may have a greater yield in infants with new-onset symptoms later in the first week ( $\geq 3$  days). A urinary tract infection should always be considered in neonates with late-onset sepsis, and the same antibiotics should be used as for other serious infections unless cultures dictate otherwise.

**In seriously ill infants with suspected sepsis, priority should be given to the structured ABC approach, while simultaneously obtaining a blood culture followed by prompt administration of antibiotics. Other tests, such as a lumbar puncture, can be performed once the infant is stable and antibiotics have been started.**

**Specific neonatal infections****Meningitis and/or septicaemia**

Meningitis may occur at any time in the neonatal period, and is frequently fatal, with some survivors experiencing long-term sequelae. Survival and later prognosis depend on early diagnosis and rapid treatment. Confirmatory diagnosis from a lumbar puncture may take several hours. Therefore it is urgent and appropriate to start antibiotic treatment empirically as soon as the diagnosis is suspected.

**Presenting features of meningitis:** These include lethargy, reduced or complete lack of willingness to take feeds, irritability, a high-pitched cry, apnoeic episodes, lowered conscious level or even coma, hypotonia, convulsions, generalised signs of accompanying sepsis, and a bulging or tense anterior fontanelle. **Always measure and record the head circumference.**

However, once signs such as the above are present, treatment may be unsuccessful and survivors may be handicapped. **Therefore any infant with the following danger signs should be started on antibiotics IV and the relevant investigations undertaken:**

- infant feeding less well than before
- infant lying quiet and making few spontaneous movements
- hypothermia or fever  $> 38^{\circ}\text{C}$
- capillary refill time  $> 3$  seconds
- respiratory rate  $\geq 60$  breaths/minute
- indrawing of the lower chest wall when breathing, or grunting
- cyanosis
- history of a convulsion.

**Less common but important signs include the following:**

- low respiratory rate ( $< 20$  breaths/minute) or apnoea
- jaundice
- abdominal distension
- skin infections.

### **Treatment of suspected bacterial septicaemia with or without early meningitis**

- Ensure that the **airway** is open and keep it open.
- Ensure that the infant is **breathing** adequately, and if they are apnoeic, gasping or have a very low respiratory rate, consider **ventilation** using a bag and mask until they are breathing adequately.
- If the infant is cyanosed, give them **oxygen** until they are pink or show normal oxygen saturation in air (> 92%).
- Insert an **IV cannula**, using full sterile precautions. Umbilical vein catheterisation may be the most effective way to gain vascular access quickly in a shocked infant less than 1 week old (see Section 8.4.B). Otherwise it might be necessary to site an **intra-osseous** line or cannulate a **scalp vein**.
- Take samples for full blood count, CRP, blood culture, lumbar puncture, blood glucose and other tests (urine microscopy and culture, chest X-ray, biochemical tests) if needed (and available). Failure to sterilise the skin rigorously can render blood culture results uninterpretable. Chlorhexidine, 0.5% aqueous solution, is a very effective antiseptic. Use two different swabs, applying each for 10 seconds, and then leave the skin to dry for 30 seconds. A keyhole drape and no-touch technique will reduce the risk of recontamination, especially when performing lumbar puncture or suprapubic aspiration.
- If possible, check **blood glucose levels**, but if facilities do not allow this, give 2 mL/kg of 10% glucose IV over 2–3 minutes as an initial bolus, followed by 5 mL/kg of 10% glucose per hour for the next few days while enteral feeds are established. An infant who becomes alert and active immediately following the initial bolus is suggestive of hypoglycaemia (i.e. a blood glucose concentration of < 2.5 mmol/litre, or < 36 mg/dL), and this may be part of the problem. If an IV line cannot be inserted and hypoglycaemia is suspected, give expressed breast milk or 10% glucose by nasogastric tube or sublingual sucrose. Further intermittent monitoring of the blood glucose level should be undertaken and the infusion continued until it is clear that the infant is well enough to be fed orally.
- Give the first dose of **ampicillin and gentamicin** (or **cefotaxime** or **ceftriaxone**) intravenously using the dose regimen outlined at the end of this section. Remember to use the high meningitic dose if meningitis is suspected, and continue it for the duration of therapy if meningitis is confirmed. If IV access is not immediately possible, give the initial antibiotic dose IM. Never wait for the results of cultures before starting antibiotics. Any delay can reduce the infant's chances of survival as well as leading to permanent damage if meningitis is present.
- Start an IV infusion of 60 mL/kg/24 hours of 10% dextrose (or 1/5 normal saline with 5% dextrose) if at all possible.
- If the infant is shocked, give an IV bolus of 10 mL/kg of Ringer-lactate or Hartmann's solution. This can be repeated twice (giving a total of 30 mL/kg) if the infant remains shocked. The use of inotropes (dopamine and dobutamine) (if available) can be considered in such situations, although the outlook is bleak if they are needed.
- If the child has any respiratory symptoms, take a portable chest X-ray (if facilities are available). Do not take a sick infant to an X-ray department for this, as the resulting information is not worth the risks of moving them. Look regularly to see whether cyanosis is developing, or use

a pulse oximeter (if available) and give supplemental oxygen, preferably using nasal cannulae rather than a head box. Infants who become infected during delivery develop respiratory symptoms with progressive signs of septic shock within a few hours of birth. Do not give anything by mouth to an infant who is breathless, especially if there is additional evidence of oxygen dependency.

### **Points to consider**

- Undertake the **ABC approach**. Oxygen may be needed. If the conscious level is impaired, the airway may be at risk.
- Be alert for the presence of seizures, and treat them as appropriate. **Always consider meningitis as a possible cause.** If there are any features suggestive of meningitis, perform a lumbar puncture at the same time as blood cultures or within 2 hours of starting antibiotic treatment, because the blood culture is sterile in 15% of infants with early meningitis. **Do not delay antibiotic therapy pending the undertaking of a lumbar puncture.** Treat seizures with phenobarbitone 20 mg/kg IM or by slow IV injection. If needed, continue with phenobarbitone at a maintenance dose of 3–5 mg/kg/day. Diazepam or midazolam can also sometimes be used to control seizures. However, always have a bag and mask available if diazepam or midazolam are given to stop fitting, as these drugs cause temporary apnoea in some patients, which can easily be managed with bag-and-mask ventilation until the infant is breathing adequately.
- Microscopic examination of the CSF (in meningitis the white blood cell count is  $\geq 25$  cells/mm<sup>3</sup>), low glucose levels and high protein levels with or without Gram stain can provide early confirmation of meningitis. **Remember that a differential white blood cell count or a differential count in the CSF do not help with the decision to initiate or continue antibiotic treatment.**
- Surface swabs and gastric aspirate cultures have no diagnostic significance. However, urinary tract infection can occasionally be the primary focus of a Gram-negative septicaemic illness. Simple microscopy on a clean catch or suprapubic urine specimen may be used to rule out a urinary tract infection. Identification of a urinary tract infection may suggest the need for ultrasound imaging of the renal tract and long-term prophylactic antibiotics.
- Watch for, prevent and correct any sign of hypothermia (skin-to-skin mother care).
- Antibiotics can be stopped after 48 hours if the blood cultures are negative **and** the infant is clinically well. If available, a normal CRP at 48 hours can help to exclude sepsis. If blood cultures are not available, continue the antibiotics for the full course appropriate for the site of infection (meningitis 14–21 days).
- Think also of herpes infection, congenital TORCH infection (newborn intrauterine-acquired infections, including toxoplasmosis, parvovirus B19, syphilis, HIV, varicella, coxsackie, rubella and cytomegalovirus) or neonatal malaria (rare) in a malaria-endemic region.

### **Antibiotic treatment**

- **Beta-lactam antibiotics plus aminoglycosides** act synergistically in treating some of the most frequently encountered neonatal pathogens. Commonly used

agents are ampicillin and gentamicin, but alternative broad-spectrum coverage may be used. Penicillin may be used if ampicillin is not available, but it has a narrower spectrum, limited to Gram-positive bacteria. Ampicillin may also provide better coverage for certain Gram-positive pathogens, including *Listeria*.

- **Third-generation cephalosporins** such as cefotaxime and ceftriaxone may be used, but some Gram-positive bacteria may not be covered (e.g. *Enterococcus*, *Listeria*) if a penicillin derivative is not included. Infants with suspected Gram-negative meningitis and accompanying early-onset sepsis may benefit from inclusion of a third-generation cephalosporin which offers a theoretically greater penetration and killing power for enteric bacteria in the cerebrospinal fluid. These antibiotics may be given intramuscularly if IV access cannot be obtained.
- Frequent use of these drugs may contribute to the development of multi-drug-resistant strains of bacteria in nurseries.** Ceftriaxone has a longer half-life and can be dosed once daily.
- **Cloxacillin** (IV or oral) is preferable if septic spots are present, as these are usually caused by coagulase-positive staphylococci.
  - **Second-line antibiotics** (e.g. ciprofloxacin, vancomycin, meropenem, piperacillin-tazobactam, linezolid) may be helpful for treating nosocomial infections and resistant organisms. However, their use should be limited to proven multi-drug-resistant organisms. Advice can always be sought on these from nearby referral centres. Inappropriate use of these expensive antibiotics may lead to even more multi-drug-resistant organisms (the so-called 'superbugs'). It is recommended that these agents should only be used in specified clinical settings.

Empirical antibiotic therapy includes antibiotics used for neonatal sepsis (i.e. a beta-lactam antibiotic plus an aminoglycoside) and a third-generation cephalosporin (e.g. cefotaxime or ceftriaxone) with excellent CSF penetration and bactericidal effect on sensitive Gram-negative bacteria. Therapy can be adjusted once the bacteria have been identified and antibiotic sensitivities determined. The duration of treatment is at least 14 days for uncomplicated Gram-positive bacteria and 21 days for Gram-negative bacteria.

The most frequently used initial combination is ampicillin and gentamicin (see the neonatal formulary at the end of this section). Benzyl penicillin may be preferable for known or suspected group B streptococcal infection. Cefotaxime or ceftriaxone is the drug of choice for most Gram-negative organisms, and ceftazidime is used for *Pseudomonas* infection.

#### Investigations for meningitis

- Lumbar puncture is potentially helpful if meningitis is suspected, and should be considered in all newborn infants with neurological signs. It is important to only attempt lumbar puncture once the infant has been stabilised, and ideally within 2 hours of initiating antibiotic treatment. Lumbar puncture is more likely than blood culture to identify the organism responsible, and within a shorter period of time.
- Cerebrospinal fluid (CSF) cell counts, chemistry and Gram stain would often point towards meningitis. An elevated CSF leucocyte count ( $\geq 25$  white blood cells/ $\text{mm}^3$ ) with pleocytosis is characteristic of neonatal

meningitis. The CSF protein level in meningitis may be high ( $> 2.0$  g/litre in a term infant), and the CSF glucose level is typically low ( $< 30\%$  of blood glucose value). Gram staining may reveal bacteria, but antibiotic therapy should not be directed on the basis of this result, as rapidly growing bacilli may be mistaken for cocci, or the state of the organism may result in variable staining.

- Sometimes the CSF picture in preterm infants who have sustained an intra-ventricular haemorrhage can show a mild reactive pleocytosis in the first few weeks of life, which can be quite misleading. If there is clinical suspicion this should be treated as bacterial meningitis until cultures are known to be negative.
- If a 'bloody tap' is obtained it is best to treat the infant as having meningitis, and repeat the lumbar puncture after 24–48 hours. The finding of many white cells or bacteria is significant even if the CSF is bloodstained.

#### Diarrhoea in the newborn

##### Special points to remember

- Encourage frequent breastfeeding, as it helps in both preventing and treating diarrhoea in the newborn.
- If the infant is dehydrated, give low-osmolarity oral rehydration solution (ORS) in addition to breast milk.
- In the case of sick infants or those infants who are unable to feed orally, consider IV fluids.
- If bloody diarrhoea occurs, it is best to assume that the infant has dysentery, and initiate antibiotic therapy. Avoid the use of co-trimoxazole in the light of much better and more effective antibiotics with better side-effect profiles.
- In the case of the septic and unwell infant, give IV antibiotics as outlined in Table 3.4.1 (p. 358).

Sometimes what is described as diarrhoea by the mother is in fact the normal loose breastfed stools of some infants in the first few days of life. Usually the number of stools passed per day declines quickly, and in some breastfed infants may be as infrequent as once daily.

#### Congenital syphilis (see Section 2.8.H)

Congenital syphilis may be acquired from an infected mother via trans-placental transmission of *Treponema pallidum* at any time during pregnancy.

**Clinical signs in infants** may include any of the following:

- low birth weight with a heavy placenta
- palms and soles showing a red rash, grey patches, blisters or skin peeling
- abdominal distension due to large liver and spleen
- jaundice
- anaemia
- some low-birth-weight infants with syphilis show signs of severe sepsis, with lethargy, respiratory distress, skin petechiae or other signs of bleeding.

#### Investigation

No newborn infant should be discharged from hospital without determination of the mother's serologic status for syphilis at least once during pregnancy, and also at delivery in communities and populations in which the risk of infection with congenital syphilis is high.

If you suspect syphilis, perform a venereal disease research laboratory (VDRL), rapid plasmin reagent (RPR) or rapid syphilis test.

**Treatment****All newborns of mothers with syphilis should be investigated and treated.**

Infants should be treated for congenital syphilis if they have proven or probable disease demonstrated by one or more of the following:

- 1 physical, laboratory or radiographic evidence of active disease
- 2 a reactive result on maternal or infant VDRL testing where the mother has not had 3 weekly doses of benzathine penicillin.

Parenteral penicillin G remains the preferred drug for treatment of an infant with any signs of congenital syphilis.

**Asymptomatic neonates** born to VDRL-positive or RPR-positive women should receive 37.5 mg/kg (50 000 units/kg) of benzathine benzyl penicillin as a single IM dose into the anterolateral thigh. Ensure that the needle is not in a vein when this drug is given, by drawing back and ensuring that no blood is in the needle, as it can cause cardiac arrest and severe CNS damage if given IV.

**Symptomatic infants** require treatment with:

- procaine penicillin 50 000 units/kg or 50 mg/kg as a single dose by deep IM injection daily for 10 days.

**Caution: Accidental intravascular administration may result in cardiac arrest and/or neurological damage**

- or benzyl penicillin (aqueous crystalline penicillin G) 30 mg/kg or 50 000 units/kg IV, 12-hourly for 7 days and then 8-hourly for 3 days.

Treat the **mother and partner** for syphilis, and check for other sexually transmitted infections.

**The infant of a mother with tuberculosis (see Section 2.8.G)**

- If the mother has active lung tuberculosis and was treated for less than 2 months before birth, or was diagnosed with tuberculosis soon after birth, the infant should be evaluated for congenital tuberculosis.
- Women with tuberculosis who have been treated appropriately for 2 or more weeks and who are not considered contagious can breastfeed. Reassure the mother that it is safe for her to breastfeed her infant.
- Do not give the tuberculosis vaccine (BCG) at birth. Instead give prophylactic isoniazid 5 mg/kg body weight orally once daily. Separation is not necessary unless the mother (or household contact) has possible multi-drug-resistant tuberculosis.
- At the age of 6 weeks, re-evaluate the infant, noting weight gain and taking an X-ray of the chest if possible. Congenital TB is most often intra-abdominal, so look for signs suggesting this. If there are any signs or findings suggestive of active disease, start full anti-tuberculosis treatment according to national guidelines. If at the age of 6 weeks the infant is doing well and tests are negative, continue prophylactic isoniazid to complete 6 months of treatment.
- Delay BCG vaccination until 2 weeks after treatment is completed. If BCG vaccine has already been given, repeat it 2 weeks after the end of the isoniazid treatment.
- If the mother is suspected of having multi-drug-resistant tuberculosis, an expert in tuberculosis disease treatment should be consulted.

**Infant of a mother with HIV infection**

See Section 2.8.C.

**Skin, eye and mucous membrane infections****Conjunctivitis**

Most conjunctivitis presents as 'sticky eyes', but this may not always be of bacterial origin, especially if it occurs in the first few days. However, a bacterial process must be considered in all cases. Infants with a serous discharge without significant conjunctival inflammation may simply have blocked naso-lacrimal tear ducts. This usually responds to gentle pressure/massage applied in a downward motion along the nose immediately adjacent to the eyes. The discharge may be cleaned from the eye with sterile 0.9% saline drops. Show the parent how to clean the infant's eyes with sterile normal saline or boiled and cooled clean water. The eyes should be wiped from the inside to the outside edge using a clean cotton wool swab for each eye. The hands should always be washed before and after the procedure.

If the condition worsens or if there is conjunctival inflammation or a purulent discharge, use of topical therapy should be considered. Erythromycin, tetracycline, neomycin or chloramphenicol ophthalmic ointments or drops may be considered. Sometimes this condition is due to chlamydia. Apply the ointment 2 to 4 times a day for 5 days after washing away any pus with sterile normal saline as described above. Treat this level of infection as an outpatient, but review every 48 hours.

**Gonococcal conjunctivitis**

**A severe rapidly progressive purulent conjunctivitis occurring within the first few days must always be assumed to be due to *Neisseria gonorrhoeae*, which must be promptly identified and aggressively treated in hospital with parenteral antibiotics and irrigation.**

Most strains are now resistant to penicillin. Swab the eye for microscopy (Gram-negative intracellular diplococci) and culture (special medium is required, such as Thayer–Martin agar with incubation under increased carbon dioxide). Treatment should be initiated immediately before culture confirmation. Treatment with IV penicillin for 7 days has been used successfully, but because of increased worldwide resistance (penicillinase-producing gonococcus), a third-generation cephalosporin is often selected as the first-line therapy:

- ceftriaxone 125 mg IM, as a single dose
- or cefotaxime 25 mg/kg (maximum 125 mg) IM, as a single dose
- or cefixime 20 mg/kg orally, as a single dose.

It is important to repeatedly clean the eye, or irrigate with saline until pus formation stops. It is vital to prevent corneal rupture and subsequent blindness.

In the case of a presumed or diagnosed gonococcal or chlamydial infection, the mother and partner should also be treated.

In countries with a low rate of sexually transmitted diseases, staphylococcal and Gram-negative organisms are more likely to be responsible. Staphylococcal infections can be treated with cloxacillin or flucloxacillin 30 mg/kg orally or IV every 6–8 hours for 5 days.

### **Chlamydial conjunctivitis**

*Chlamydia trachomatis* is a common cause of infectious conjunctivitis in the newborn infant. It typically presents between 5 and 14 days. The presentation can vary from mild to moderate conjunctival erythema, and from scant mucoid discharge to copious purulent discharge. Eyelid oedema, chemosis or pseudomembrane formation may also be present. Corneal involvement is unusual initially, although untreated chlamydia conjunctivitis can result in varying degrees of conjunctival scarring and corneal infiltrates.

Chlamydia can be confirmed by culture or rapid antigen detection, but these are highly specialised procedures that may not be readily available. Without a positive laboratory diagnosis, treatment is based on clinical severity. If the condition is mild, clean the eye only. If it is moderate, use a topical antibiotic and consider giving erythromycin 10 mg/kg orally, 6-hourly for 14 days. This effectively treats this infection and may also eradicate upper respiratory tract colonisation. Drug interactions with erythromycin include increased serum levels of digoxin, theophylline and potentially caffeine.

If the condition is severe, beware gonococcal infection, irrigate and use IV or IM cefotaxime or ceftriaxone.

Ensure that the mother is appropriately referred for treatment.

### **Skin pustules**

Skin pustules are most commonly caused by *Staphylococcus aureus*. Most often these occur in small clusters in an otherwise healthy asymptomatic infant. Topical therapy with chlorhexidine 0.5% may be all that is needed in most of these cases. Oral therapy with a penicillinase-resistant penicillin (e.g. flucloxacillin 25 mg/kg 6-hourly) or first-generation cephalosporin (e.g. cephalexin 25 mg/kg 6–12-hourly for 7 days) may also be used if extensive pustules are found. If septicaemia is suspected, septic investigations and IV antibiotics after hospitalisation may be needed. Sometimes staphylococcal pustules can be difficult to distinguish from **erythema toxicum** (a benign, non-infectious newborn rash).

### **Umbilical infection**

A clinically relevant infection of the umbilical stump (omphalitis) presents as redness and oedema of the skin extending from the umbilicus. This should be distinguished from the ooze resulting from an umbilical granuloma, which may develop after a few weeks. If there is skin redness plus oedema extending from the umbilicus, appropriate antibiotics, usually anti-staphylococcal, should be used. Clean the area with soap and warm water and remove or drain pus and crusts. Dry and paint the area with antiseptic such as gentian violet, or use a simple alcohol swab to clean the area at the time of every nappy change. If there is only a 'sticky cord', manage it with local treatment only. Pus can be easily removed with a swab, whereas normal cord degeneration cannot be removed.

### **Cellulitis**

This is most commonly caused by streptococci, but *Staphylococcus aureus*, Gram-negative enterococcus and anaerobes should also be considered when infection occurs at sites where there have been breaks in the skin. Treatment with **parenteral antibiotics** (e.g. Flucloxacillin, a penicillinase-resistant penicillin, and gentamicin, an aminoglycoside) should be directed against both Gram-negative

and Gram-positive bacteria. Omphalitis may become rapidly progressive and spread to deeper tissues. Infection with *Clostridium* is common in the setting of poor maternal immunity or poor umbilical cord care, and can cause neonatal tetanus.

### **Scalded skin syndrome**

This is a rare infection caused by toxin-producing staphylococcal organisms which leads to a toxic reaction producing the effect of both serious infection and burns. Treat it with IV cloxacillin or flucloxacillin.

### **Superficial candidiasis ('thrush' and 'monilial' rash)**

Superficial candidiasis of the oral mucosa ('thrush') commonly manifests as white patches which are not easily scraped with a spatula. The nappy area may also be affected ('monilial' rash). Unlike irritant dermatitis, the erythema extends into skin folds and there may be small raised erythematous lesions. Treat with oral nystatin suspension, 1 mL after feeds (divide it between each cheek with a small syringe). Topical nystatin ointment may be used to treat the skin rash, but only in combination with oral nystatin. Keep the nappy area dry. Apply local treatment to the mother's nipples if they are also infected.

**Warning: Excess and inappropriate antibiotic usage, besides being costly and generating a lot of nursing work, also leads to multi-drug resistance. Excess use can cause overt *Candida* infection (thrush), and also risks the eventual emergence of multi-drug-resistant organisms, especially in a hospital setting. The widespread use of ampicillin has caused many coliform organisms to become increasingly resistant to this antibiotic, while units that use cefotaxime extensively are starting to encounter serious *Enterobacter* and other multi-drug-resistant Gram-negative sepsis.**

### **Drugs used to treat severe infection in the neonate**

#### **Ampicillin (or amoxicillin)**

Give 100 mg/kg per dose IM or IV where meningitis is a possibility, and 50 mg/kg per dose in other situations. Give one dose every 12 hours in the first week of life, every 8 hours in an infant aged 1–3 weeks, and every 6 hours in an infant older than this. Oral dosing can sometimes be used to complete a course of treatment.

#### **Benzyl penicillin**

Give 60 mg/kg (100 000 units/kg) IV if meningitis or tetanus is a possibility. Give 30 mg/kg (50 000 units/kg) per dose in all other situations, including syphilis. Time the interval between each dose as for ampicillin. Oral dosing (with phenoxymethylpenicillin) can sometimes be used to complete a course of treatment.

#### **Cefotaxime**

Give 50 mg/kg per dose IV or IM. Time the interval between each dose as for ampicillin, except in meningitis, where doses are given 6-hourly.

#### **Chloramphenicol**

This remains a useful antibiotic, although there is a serious risk of death from liver failure if the dose suggested here is exceeded. **Warning: The problem is not the dose**

**but incorrect mixing, as the bottle contains 1000 mg, so it is easy to overdose.** Give a 25 mg/kg loading dose IM followed by 12.5 mg/kg once every 12 hours to infants less than 1 week old. Give this dose every 8 hours to infants aged 1–4 weeks, unless there is evidence of liver damage or renal failure. Infants older than this can be given 12.5 mg/kg once every 6 hours from the outset. Oral dosing can be used to complete any course of treatment. (The dose can be doubled in those over 1 month of age with severe infection.) Be very careful if the IV dose has to be diluted to obtain the correct dosage.

#### **Cloxacillin (or flucloxacillin)**

Give 100 mg/kg per dose IM or IV if serious infection is present, and 50 mg/kg per dose in other situations. Time the interval between each dose as for ampicillin. Oral treatment can often be given to complete a course of treatment (25 mg/kg standard, 50 mg/kg severe, 100 mg/kg in infections such as osteomyelitis).

#### **Erythromycin**

Give 12.5 mg/kg per dose orally once every 6 hours. There is no satisfactory IM preparation.

#### **Eye drops (and ointments)**

Prophylactic chloramphenicol 0.5% eye drops or 1% eye ointment can be used to minimise the risk of gonococcal infection (IM/IV ceftriaxone is being used for overt infection). Tetracycline ointment 1% should be used (with oral erythromycin) to treat chlamydia conjunctivitis (this condition is not prevented by silver nitrate use). *Pseudomonas* infection requires treatment with systemic antibiotics and topical gentamicin 0.3% eye drops.

#### **Gentamicin**

Give 5 mg/kg IM or IV once every 24 hours. If the infant weighs less than 2 kg, give 4 mg/kg per dose. Leave 36–48 hours between each dose if there is renal failure.

- If the infant is less than 32 weeks' gestation, give 4–5 mg/kg 36-hourly.
- If the infant is more than 32 weeks' gestation, give 4–5 mg/kg 24-hourly.

#### **Hepatitis B vaccine**

Give 0.5 mL IM into the thigh as soon as possible after or within 12 hours of birth. Remind the mother that the infant will require booster injections at 6 weeks and 14 weeks after birth. Infants born to mothers infected during pregnancy or who are known high-risk carriers with a positive

hepatitis B e-antigen should also be given 200 units of hepatitis B immunoglobulin (HBIG) IM into the other thigh within 24 hours of birth. Breastfeeding can safely continue.

#### **Isoniazid**

See Section 6.1.N for the latest advice on the treatment of children with TB or suspected TB.

#### **Metronidazole**

Give a 15 mg/kg loading dose and 7.5 mg/kg per dose once every 12 hours in infants less than 4 weeks old, and every 8 hours in children older than this. Treatment can be given IV or orally, but solubility makes IM use unsatisfactory. If the IV route is used, start the maintenance dose 24 hours after loading. If the oral route is used, give the first dose 12 hours after loading.

#### **Miconazole**

This controls infection with candida ('thrush') more effectively than topical nystatin. Use the oral gel at least four times a day and the skin cream twice a day for at least 7 days. Topical treatment with 0.5% aqueous gentian violet for not more than 4 days may be equally effective. Oral nystatin drops (1 mL four times a day) can be used to reduce heavy intestinal tract carriage.

#### **Nevirapine**

See Section 2.8.C and national protocols for the latest advice on the use of Nevirapine in the prevention of mother-to-child transmission of HIV infection.

#### **Procaine and benzathine penicillin**

Give asymptomatic infants born to mothers with evidence of untreated syphilis a single 37.5 mg (50 000 units/kg) dose of benzathine penicillin **IM** injection. **Never give this drug IV.** Infants thought to be infected at birth are often given procaine penicillin 50 mg/kg (50 000 units/kg) IM once a day for 10 days, but repeated IM injections can cause a sterile abscess with subsequent muscle fibrosis and atrophy. IV benzylpenicillin for 10 days (as specified above) is just as effective. Infants born to mothers who have been fully treated for syphilis (1.8 grams, or 2.4 mega-units, of benzathine benzylpenicillin) at least 4 weeks before birth need no further treatment after birth.

#### **Zidovudine**

See Section 2.8.C and national protocols for the latest advice on the use of Zidovudine in the prevention of mother-to-child transmission of HIV infection.

**TABLE 3.4.1** Antibiotics and other drugs for use in the neonatal period

Drug	Route	Single dose	Frequency	Postnatal age	Gestation
Ampicillin	IV, IM	50–100 mg/kg	12 hourly	< 7 days	Any
		50–100 mg/kg	8 hourly	7–21 days	Any
		50–100 mg/kg	6 hourly	> 21 days	Any
<i>Reduce dose frequency in severe renal impairment and birth asphyxia</i>					
<i>Use higher doses in case of suspected Group B strep infection or meningitis</i>					

Drug	Route	Single dose	Frequency	Postnatal age	Gestation
<b>Benzyl Penicillin</b>	IV, IM	25–50 mg/kg	12 hourly	< 7 days	Any
		25–50 mg/kg	8 hourly	7–21 days	Any
		25–50 mg/kg	6 hourly	> 21 days	Any
<i>Reduce dose frequency in severe renal impairment and birth asphyxia</i>					
<b>Cefotaxime</b>	IV, IM	50 mg/kg	12 hourly	< 7 days	Any
		50 mg/kg	8 hourly	> 7 days	Any
		<i>Reduce dose by 50% in severe renal impairment</i>			
<b>Ceftazidime</b>	IV, IM	50 mg/kg	12 hourly	< 7 days	Any
		50 mg/kg	8 hourly	> 7 days	Any
		<i>Reduce dose interval to 24 hours in severe renal impairment</i>			
<b>Ceftriaxone</b>	IV, IM	50 mg/kg	24 hourly	Any	Any
		<i>Avoid in infants &lt; 36 weeks' gestation or if jaundiced. Follow special IM preparation instructions</i>			
<b>Chloramphenicol</b>	IV, IM	12.5 mg/kg	12 hourly	< 7 days	
		12.5 mg/kg	8 hourly	> 7 days	
		<i>There is a serious risk of death from liver failure if the dose suggested is exceeded Oral dosing can be used to complete any course of treatment</i>			
<b>Clonazepam</b>	IV infusion	100 micrograms/kg	<b>(loading dose)</b>		
		10–30 micrograms/kg/ hour	<b>Not for &gt; 3 days</b>	Not for > 3 days	
		<i>Up to 200 micrograms/kg/24 hours may be required in first 48 hours Use slow IV over 20 minutes Caution: respiratory depression and increased pulmonary secretions particularly if accumulation occurs If not ventilated use lower doses because of respiratory depression</i>			
<b>Cloxacillin</b>	IV, IM	50 mg/kg	12 hourly	< 7 days	Any
		50 mg/kg	8 hourly	> 7 days	Any
		<i>Double the dose in severe infection and if CNS is involved Increase dose interval to 24 hours in severe renal impairment</i>			
<b>Erythromycin</b>	PO	12.5 mg/kg	6 hourly		
		<i>There is no satisfactory IM preparation</i>			
<b>Gentamicin</b>	IV	5 mg/kg	48 hourly	< 7 days	< 29 weeks
		4 mg/kg	36 hourly	> 7 days	< 29 weeks
		4 mg/kg	36 hourly	< 7 days	30–33 weeks
		4 mg/kg	24 hourly	> 7 days	30–33 weeks
		4 mg/kg	24 hourly	< 7 days	> 34 weeks
		4 mg/kg	24 hourly	> 7 days	> 34 weeks
<i>Trough and peak levels are not needed</i>					
<b>Isoniazid</b>	<i>See Section 6.1.N for details on its use.</i>				
<b>Metronidazole</b>	IV, PO	5 mg/kg	<b>(loading dose)</b>		
		7.5 mg/kg	12 hourly	< 28 days	
		7.5 mg/kg	8 hourly	> 28 days	
<i>Infuse over 30 minutes Injection solutions can be given rectally</i>					

(continued)

Drug	Route	Single dose	Frequency	Postnatal age	Gestation
<b>Miconazole</b>	Oral gel		6 hourly		
	Skin ointment		6 hourly		
	<i>This controls infection with Candida ('thrush') better than topical nystatin Use for at least 7–10 days</i>				
<b>0.5% Aqueous Gentian violet</b>	Apply		Once daily for 4 days		
<b>Oral nystatin drops</b>	PO	1 mL	6 hourly		
	<i>Can be used to reduce heavy intestinal tract carriage</i>				
<b>Nevirapine</b>	<i>See Section 2.8.C for details on its use.</i>				
<b>Paraldehyde</b>	Rectal	0.2 to 4 mL/kg	<b>(loading dose)</b>		
		<i>Can repeat once 4–5 hours later</i>			
	<i>Use injection rectally or ready-diluted rectal solution Dilution with an equal volume of olive oil or any edible oil If using a plastic syringe administer immediately IM injections may cause sterile abscessed (maximum 1 mL at one site)</i>				
<b>Phenobarbitone</b>	IV, IM, PO	20 mg/kg	<b>(loading dose)</b>	<i>followed by maintenance 12–24 hours later</i>	
	<i>Slow IV over 5 minutes. Loading dose may be repeated by at 10 mg/kg if clinically indicated</i>				
		3–5 mg/kg/24 hours	Once daily	<i>Once daily generally but with time may need to be give 12 hourly</i>	
	<i>Monitor plasma levels Therapeutic range: 15–30 mg/L although increasing up to 40 mg/L should be considered in resistant seizures</i>				
<b>Phenytoin</b>	IV, PO	15–20 mg/kg	<b>(loading dose)</b>		
	<i>Give IV infusion over 20–30 minutes diluted in 10 mL of normal saline</i>				
		1.5–3 mg/kg	12 hourly		
	<i>Slow IV over 20–30 minutes Usual maximum dose 7.5 mg/kg 12 hourly Therapeutic range 5–17 mg/L</i>				
	<i>Oral dose is poorly absorbed particularly in premature infants Wide variation in levels, so monitor and adjust dose and interval accordingly Measure trough level. May not reach steady state for up to 14 days</i>				
<b>Procaine penicillin</b>	IM	10 mg/kg	Single dose		
	<i>Give to asymptomatic babies born to mothers with evidence of untreated syphilis</i>				
		100 mg/kg	Once daily		
	<i>Babies thought to be infected at birth are often give once daily for 10 days <b>Never give this drug IV</b> Rarely repeated IM injections can cause a sterile abscess with subsequent muscle fibrosis and atrophy Alternatively IM or IV benzylpenicillin for 10 day (as specified above) is just as effective Babies born to mother fully treated for syphilis need not further treatment after birth (Maternal treatment = 1.8 grams or 2.4 mega units of benzathine benzylpenicillin at least 4 weeks before birth)</i>				
<b>Zidovudine</b>	<i>See Section 2.8.C for details on its use.</i>				

### Polycythaemia

This potentially harmful condition occurs in up to 4% of births and risk factors are: being both small or large for gestational age or wasted, born to mothers with diabetes and being one of a multiple birth. Milking of the umbilical cord at birth, by increasing the amount of blood transferred into the baby, can also produce this condition.

Polycythaemia is defined as a venous haematocrit > 65% or Hb > 22 g/dL. Capillary samples can have higher haematocrit and if > 65% should be confirmed by venous sample.

Screen high risk babies at 2, 12 and 24 hours by capillary blood measurement of PCV and then if > 65% confirm by venous sample.

Above a PVC of 65%, the viscosity of blood increases exponentially and can produce dangerously reduced capillary perfusion in many organs which, when most severe, can produce cerebral, renal or mesenteric vein thrombosis.

### Clinical presentation

The baby can be hypotonic, drowsy, have poor sucking, be irritable, jittery and, when severe, have convulsions. These are important danger signs.

There may also be jaundice, hypoglycaemia, and hypocalcaemia. With a high PCV the blood glucose reading may be falsely low with a normal serum glucose.

### Management

First exclude dehydration and if present treat by supervised feeding and if necessary increased enteral or even IV fluids. The best way to check for dehydration is to weigh the baby and compare weight with that at birth. Normally babies lose 5–7% of their body weight in the first 3–4 days and regain their birth weight level by 10–14 days. If the baby's weight at 24 hours of age has dropped by 5% or more from the birth weight then dehydration is present.

Check blood glucose and bilirubin levels and treat appropriately (see below).

If venous PCV is 65–70% and no signs, bilirubin is below phototherapy levels, and no hypoglycaemia is present treat conservatively by regular examination for the signs described above, ensure adequate fluid intake by direct observation of feeding and regular accurate weighing before and after feeds.

If venous PCV is 70–75% and there are no danger signs, treat polycythaemia by giving additional fluid of 20 mL/kg per day enterally or IV. Also treat jaundice with phototherapy and hypoglycaemia with glucose, if necessary IV.

If PCV is > 75% or there are any danger signs as described above then partial exchange transfusion (PET) should be undertaken urgently.

PET involves the exchange of 20 mL/kg by repeatedly taking off aliquots of blood of up to 5 mL at a time and replacing IV with equal volumes of Ringer-Lactate or 0.9% saline. Ideally blood will be taken from a peripheral vein but, if this is not possible, either use an umbilical venous catheter placed aseptically or a peripheral arterial cannula. At the end of the procedure, re-check the PCV, Hb, bilirubin and blood glucose levels (ideally also blood calcium value).

Continue to monitor the clinical state of the baby and the PCV until it is shown to fall below 60%. Re-check blood glucose and bilirubin levels as appropriate.

## Respiratory disorders

### Features of respiratory distress in the newborn

These include the following:

- tachypnoea (respiratory rate > 60 breaths/minute)
- recession of the chest wall and sternum
- expiratory grunting
- nasal flaring
- prolonged apnoea (lasting for more than 20 seconds) or intermittent shorter apnoea with cyanosis or severe falls in oxygen concentration (< 90%)
- gasping
- tachycardia
- SaO<sub>2</sub> < 92% in air

- cyanosis is a relatively late presentation of a respiratory or cardiac cause.

These signs are relatively non-specific, arising from conditions that affect the respiratory system, as well as from cardiac, neurological and metabolic abnormalities.

### Cardinal signs that characterise distress due to respiratory disorders

- **Central cyanosis in room air.**
- **Tachypnoea:** respiratory rate > 60 breaths/minute (always measure over at least 1 minute, as the infant's breathing may be irregular).
- **Retractions (recessions):** tugging of the soft tissues between the ribs or at the edges of the rib cage.
- **Grunting:** a prolonged expiratory effort, usually with an audible noise.

Two of these signs are sufficient to make the diagnosis. Cyanosis may not be present, especially if the infant is receiving oxygen.

If pulse oximetry is available, the SaO<sub>2</sub> in infants with respiratory impairment will usually be less than 92% in air (often less than 90% in more severe cases).

### Causes of early respiratory distress

'Early' respiratory distress (presenting in the first 12 hours of life) may result from a number of causes, including the following:

- **'transient tachypnoea of the newborn'** associated with a delay in clearing of fetal lung fluid
- **congenital pneumonia or sepsis** (e.g. group B streptococcus sepsis)
- **surfactant deficiency** (hyaline membrane disease or respiratory distress syndrome)
- **pneumothorax**
- **meconium aspiration**
- **congenital abnormalities** of the lung or airways (including diaphragmatic hernia)
- **hypothermia.**

Maternal fever during labour and prolonged rupture of the membranes (more than 18 hours) particularly point to **pneumonia** or **sepsis**. Pneumonia may also be due to congenital syphilis. **Pneumothorax** should be considered if the infant has been resuscitated using positive-pressure ventilation (although it has also been described as occurring spontaneously in about 1% of normal term infants). **Transient tachypnoea** is more common among infants delivered by elective Caesarean section (in the absence of spontaneous labour). **Surfactant deficiency** and **infection** are the most likely causes in preterm infants.

Congenital heart disease does not usually cause early respiratory distress. Cyanosis/severe hypoxaemia is the more likely presentation (see Section 5.4.A).

Respiratory distress associated with heart failure normally occurs after the first week of life, in association with tachycardia, pallor, sweating, hepatomegaly and excessive weight gain.

## Causes of respiratory distress in the newborn

### Common causes

- Lack of surfactant causing respiratory distress syndrome in the preterm infant.
- Infection acquired before or during delivery.
- Transient tachypnoea of the newborn (wet lung).

### Less common causes

- Meconium aspiration.
- Persistent pulmonary hypertension of the newborn.
- Pneumothorax.

### Rare causes

- Pulmonary hypoplasia.
- Congenital abnormalities (e.g. diaphragmatic hernia, choanal atresia, tracheo-oesophageal fistula).
- Pulmonary haemorrhage.
- Metabolic causes (inborn error of metabolism).

### Non-respiratory causes

- Congenital heart disease.
- Hypothermia.
- Severe anaemia.

## Principles of treatment of respiratory diseases of the newborn

- Ensure that the **airway** is open and that it remains so. Thick secretions from the throat may be cleared by intermittent suction using direct observation
- Ensure that the infant is **breathing**. If the infant is apnoeic, gasping or has a very slow respiratory rate, use chest inflations with a bag valve mask to re-establish breathing.
- The infant should be offered enough supplemental oxygen to treat any degree of central cyanosis and ideally to keep SaO<sub>2</sub> in the normal range (86–92% in preterm and 92–96% in term infants). It should never be in the hyperoxic range (above 96%), especially in a preterm infant who is receiving additional inspired oxygen.
  - Oxygen should be given either with an oxygen concentrator or from cylinders. An oxygen supply must be available at all times in areas where newborn infants are treated.
  - Pulse oximetry should be employed (if available) to assess initial disease severity, to monitor subsequent progress, and to ensure that such supplies of oxygen as are available are optimally used. Wind-up versions of pulse oximeters are available ([www.PET.org.za](http://www.PET.org.za)).
  - Tents and incubators are not an efficient way of giving oxygen. Giving oxygen into a clear plastic hood (head box) placed over the head stops the oxygen supply from dropping every time a tent or incubator door is opened. **Oxygen is an expensive resource and must not be wasted by giving it into incubators.**
  - **Nasal cannulae optimise the efficient use of the available oxygen supply.** They prevent wasting of oxygen, and also make it very much easier to move and handle the infant without disrupting the supply. However, they make it rather more difficult to quantify how much oxygen is needed to control cyanosis.

- Infants should ideally have their actual oxygen needs monitored and adjusted at regular intervals.
  - Measuring the inspired oxygen concentration needed is one way of assessing the infant's changing condition. This can be done using a combination of a pulse oximeter with an inspired oxygen monitor placed in a head box next to the infant's face.
  - A simpler alternative for achieving this objective involves titrating the oxygen flow to maintain saturation on the pulse oximeter in the range 92–96% for term infants and lower, at 86–92%, for preterm infants, as described earlier.
- Keeping the infant fully clothed with a pulse oximeter attached makes it possible to dispense with any other monitoring of pulse and respiration, thus keeping the infant warm with minimal handling.
- If assisted ventilation is available and there is very severe respiratory failure, an arterial or capillary blood gas measurement can be helpful for determining the severity of respiratory acidosis and the need for ventilator support such as nasal continuous positive airway pressure (nCPAP) or intubation and ventilation.
- Infants with serious respiratory distress should not be offered feeds until their condition has stabilised. Support expression of milk by the mother so that she is ready to provide breast milk when her infant has recovered. In such situations, IV infusion of 10% glucose (60 mL/kg/day) is safest. If there are no facilities for IV infusion, breast milk or 10% glucose may be given in limited quantities (up to 60 mL/kg/day) by orogastric tube. **Nasogastric tubes may contribute to upper airway resistance, so an orogastric tube is preferred in infants with respiratory distress, although it is more difficult to keep in place, so compromise may sometimes be necessary.**
- Infants less than 2 days old should be started on an IV infusion of 10% dextrose at 60–90 mL/kg/24 hours. For infants more than 3 days old sodium chloride should be added to 10% dextrose to provide 2–3 mmol/kg/day and used at the age-appropriate giving rates (see fluid management section on p. 347). It is recommended that in neonates it is best to use a paediatric burette (chamber) where 1 mL = 60 micro-drops (1 drop/minute = 1 mL/hour). **Caution: A standard infusion set gives 20 drops/mL and can lead to dangerous fluid overload if it is not carefully controlled.**
- Give antibiotics IV or IM (the IV route is preferable) at least for the first 48 hours in all infants with respiratory distress, as bacterial infection is a likely reason for the infant's respiratory problems. Take blood for culture first wherever possible. Antibiotics can be stopped if the blood culture results are negative and the infant is well after 72 hours.
- In order to gain further insight into the probable cause of the problem, a portable chest X-ray machine (if available) can be useful.
- Take stringent steps to prevent nosocomial cross-infection within the unit. This can be a particular problem not only with some bacterial infections (e.g. *E. coli*, *Klebsiella*), but also with some troublesome viral infections (e.g. respiratory syncytial virus, RSV) that are more commonly seen later in the first month of life.

## Management issues in specific respiratory conditions

### Primary surfactant deficiency (respiratory distress syndrome (RDS), or hyaline membrane disease)

The principles of treating IRDS are as follows:

- 1 Minimal handling of the infant.
  - 2 Supplementary oxygen.
  - 3 IV fluids.
  - 4 No oral feeding.
  - 5 Continuous positive airways pressure (CPAP).
  - 6 Avoidance of hypothermia.
- Surfactant deficiency is by far the commonest cause of respiratory distress in a preterm infant in the first 3 days of life. It is a self-limiting condition, because birth always triggers a gradual increase in surfactant production. The challenge therefore is to support the infant for the first 2–3 days (72 hours) of life without doing further damage to the lung, until such time as the deficiency resolves itself.
  - The key features of RDS (cyanosis, an expiratory 'grunt', tachypnoea, and intercostal and/or subcostal recession) become clinically obvious within 4 hours of birth. Supplemental oxygen, minimal handling and IV fluid, keeping the infant 'nil by mouth', have been the standard ingredients of care for the last 50 years. Elective surfactant administration (which is expensive) and ventilation (which is complex) have become the standard approach to management in the last 20 years. However, it is now becoming clear that the very small infant can pay a high price for chronic tracheal intubation, which by interrupting ciliary flow can interfere with the way that necrotic material is normally cleared from the lung.
  - Most infants will manage well for themselves as long as they are offered help in preventing the lung from closing down and becoming airless for the 72-hour period it takes for the surfactant production to 'switch on'. The expiratory grunt that is a characteristic feature of this condition is the infant's own method of sustaining

**FIGURE 3.4.1** Nasal continuous positive airway pressure (CPAP) nasal prongs.

positive end-expiratory pressure (PEEP) and holding the alveoli open. Making the infant breathe against a constant positive airway pressure gradient achieves the same result. By applying this pressure at the nose (nasal CPAP), the complications associated with tracheal intubation can often be avoided.

- To be maximally effective, we now know that CPAP should be applied as soon as there is any evidence of respiratory distress in a preterm infant. CPAP given via paired short cannulae or a specially made nasal mask is probably best, as it minimises airway resistance.

**FIGURE 3.4.2** Nasal continuous positive airway pressure (CPAP) equipment in place.

Even though the 3-mm nasal cannulae that are normally used to provide supplemental oxygen can provide some CPAP, especially when higher flow rates are applied (6–8 litres/minute), there is a need for an air–oxygen blender to ensure that excessive and harmfully high concentrations of oxygen are not given. Humidification of the air–oxygen mixture is also required. Purpose-built CPAP systems with special nasal cannulae are better able to provide pressures of 5–8 cmH<sub>2</sub>O (a system specially designed for resource-limited settings based on an oxygen concentrator has recently become available: [www.diamedica.co.uk](http://www.diamedica.co.uk)). In general, all that is then required is a controlled flow of blended humidified air and oxygen with a simple device for producing controlled adjustable CPAP. Regular nursing attention is necessary to make sure that the nasal cannulae remain correctly positioned and do not cause necrotic pressure damage to the nose. This is a skill that does not take long to acquire.

### Transient tachypnoea of the newborn

This is almost indistinguishable from RDS. However, unlike RDS, the signs do not progress with time in the hours after birth. Most of these infants are born at or near term. All are tachypnoeic, and a few are obviously cyanosed for 6–12 hours after birth. The condition seems to be caused by a delay in clearing lung fluid after birth. All of these infants will recover on their own so long as handling is kept to a minimum and they are not fed until their respiratory signs

have subsided. Some need supplemental oxygen, but few need it for more than 72 hours. The condition appears to be more common after Caesarean section.

### Aspiration pneumonia

Aspiration of particulate matter can occasionally almost completely block the trachea. More commonly it can also cause a chemical pneumonitis. Meconium can be particularly irritant in this regard, making the term infant very oxygen dependent for the best part of a week. Aspiration of particulate matter may also trigger **persistent fetal circulation** (see below).

Contrary to the findings of some studies originating from well-resourced centres in the developed world, suctioning meconium-stained infants during deliveries as soon as the head is on the perineum has made a dramatic difference to the risk of meconium aspiration syndrome in India and South Africa.

Nevertheless, with minimal handling, IV fluid and supplemental oxygen, most of these infants can be expected to make a complete recovery provided that there has been no associated hypoxic cerebral damage. Providing unnecessary respiratory support may actually make matters worse by increasing the risk of pneumothorax. Antibiotics should probably be given until it is clear that there is no associated bacterial infection.

Aspiration after birth can cause a similar picture. Milk can block the trachea, but it seldom causes much of an inflammatory reaction. However, gastric acid can be much more damaging. Recurrent minor unrecognised reflux and aspiration is probably more common than a single massive episode of aspiration, and it can certainly over time render the infant quite oxygen dependent. Infants who are hypotonic and have a poor cough reflex or repeated apnoea are probably at particular risk in this regard. **Aspiration is common after an apnoeic event.**

### Bacterial pneumonia

This should be managed as outlined in the section on suspected infection, remembering that there may be septicæmia as well as pneumonia.

### Persistent fetal circulation

- This is relatively common in resource-limited countries, and is a potentially life-threatening condition leading to poor lung perfusion after birth. It may complicate fetal hypoxia, meconium aspiration, early bacterial pneumonia, diaphragmatic hernia, respiratory distress syndrome or (very occasionally) be a primary disorder.
- After birth the pressure in the pulmonary vessels remains high, so that the normal fall in pressure in the right atrium, right ventricle and pulmonary arteries does not occur. As a result of this, the blood flows via the fetal circulation (i.e. the foramen ovale and ductus arteriosus) from the right side of the heart to the left. This blood has not been oxygenated, so the infant soon becomes cyanosed. It is difficult to differentiate this from a congenital cardiac malformation. Serious cyanosis in an infant with a well-aerated lung on chest X-ray and progressive acidosis can cause rapid self-perpetuating cyclical deterioration.
- The treatment in the first instance is oxygenation, minimal handling, IV fluids and avoidance of oral feeds. Metabolic acidosis should be vigorously and rapidly corrected or even over-corrected. **Drugs that cause**

pulmonary vasodilation, such as sildenafil or magnesium sulphate, have been used to some effect. However, they can lead to serious hypotension and should be used very selectively in a controlled environment in specialised centres.

- Survival is more likely in a unit that is capable of providing sustained respiratory support, and early transfer should be considered when possible.

### Pneumothorax

This is present more frequently than expected, and may occur spontaneously in up to 1–2% of infants. It is often asymptomatic, and may be associated with meconium aspiration, too high inflation pressures used during mechanical ventilation or resuscitation, and respiratory distress syndrome. It does not automatically need to be treated, unless there is progressive respiratory distress. Confirmation by chest X-ray (if available) is often too time-consuming, especially in the case of a rapidly developing tension pneumothorax. It may be possible to diagnose a pneumothorax clinically by simple observations. The abdomen is often distended by downward displacement of the liver and spleen. The breath sounds may be reduced on the affected side. **A hyper-resonant chest with mediastinal shift (trachea deviated away from the side of the suspected pneumothorax) and rapidly deteriorating clinical condition with severe hypoxaemia and/or cardiovascular compromise (bradycardia, hypotension) strongly suggests a tension pneumothorax. This requires an immediate needle thoracocentesis followed (if this results in an immediate improvement in respiratory and cardiovascular function) by the insertion of a chest drain into the fourth or fifth intercostal space in the mid to anterior axillary line (see Section 8.3). In an emergency situation with a rapidly deteriorating cardiac and respiratory function, this must be done without prior X-ray confirmation.** Transillumination can be useful if a 'cold light' (fibre-optic light source) is available (the affected side may glow brightly).

A pneumothorax that does not result in severe respiratory distress, and is not under tension, may spontaneously resolve without mechanical removal of the pleural air, but oxygen and careful monitoring are required.

### Lung hypoplasia due to oligohydramnios

Chronic loss of liquor for many days before birth can occasionally impede lung growth enough to threaten survival, but what looks like a serious problem at delivery can occasionally resolve quite rapidly after 1–2 days. However, where the oligohydramnios is due to bilateral renal agenesis or dysplasia, the prognosis for survival is very poor. The stiffness of the small malformed lungs in these cases causes marked intercostal and subcostal recession with unrelievable cyanosis. Chest X-ray will often reveal an untreatable pre-terminal pneumothorax. The infant's face may appear flattened and there may be limited extension of the elbows and knees due to oligohydramnios.

### Congenital malformations

The most common congenital defect causing respiratory distress soon after birth is **diaphragmatic hernia**. This occurs in 1 in 4000 births, and more commonly affects the left side. Clinical examination reveals respiratory distress, and reduced air entry on the affected side with a displaced

apex beat and scaphoid abdomen. The chest X-ray is diagnostic. It used to be thought that early surgery improved the likelihood of survival, but it is now known that this is not the case. Therefore immediate transfer does not have to be considered until the child's initial respiratory problems have stabilised. During the interim period, an IV line and open nasogastric tube should be in place to keep the gut empty of gas, and feeding should be withheld. Restricted lung growth means that only about 50% of these infants have any chance of survival. Use a headbox rather than nasal cannula oxygen, and place an open nasogastric tube to prevent bowel distension, which makes the condition worse.

### **Management of diaphragmatic hernia**

This includes the following:

- oxygen supplements
- minimal handling
- IV fluids and withholding of oral feeds
- a nasogastric tube to keep the stomach empty
- stabilisation of respiration with mechanical ventilation following intubation or continuous negative extra-thoracic pressure (CNEP) can be helpful if available
- transfer to surgical care if the infant responds to treatment.

A number of rare generalised skeletal abnormalities that affect rib growth also cause severe untreatable lung hypoplasia.

**Congenital heart disease** can occasionally cause overt cyanosis from birth, but there are seldom any associated signs of respiratory distress (see Section 5.4.A).

### **Apnoeic/hypoxaemic episodes**

Apnoea is the cessation of respiration or a hypoxaemic event associated with signs of cardiorespiratory decompensation (bradycardia, cyanosis and pallor). Apnoeic episodes are common in preterm infants under 32 weeks' gestation ('apnoea of prematurity'). In term infants, apnoea usually signifies an underlying pathological condition.

### **Apnoea of prematurity**

This is often characterised by a brief cessation of respiration that responds to gentle tactile stimulation, and may vary significantly in duration and severity, especially in very-low-birth-weight infants. Sometimes, isolated bradycardia with brief oxygen desaturation events is identified without a clinically apparent apnoea. The aetiology of apnoea of prematurity is often a mixture of impaired central nervous system respiratory control ('central apnoea'), intrapulmonary shunting and upper airway obstruction. Sometimes recurrent apnoea is associated with gastro-oesophageal reflux, particularly in neurologically compromised infants with poor airway-protective reflexes. Oral theophylline or caffeine, by its effect on the respiratory centre, may reduce or even eliminate the severity and frequency of apnoeic events. Caffeine has become the preferred methylxanthine by some neonatologists, because it has a long half-life (allowing once daily dosing), fewer side effects and serum levels do not have to be monitored. Continuous positive airway pressure (CPAP) or rarely mechanical ventilation may become necessary to control recurrent apnoea.

The diagnosis of 'apnoea of prematurity' is one of exclusion, as various other processes may cause or exacerbate

apnoea. In the case of a preterm infant, these include the following:

- respiratory distress (surfactant deficiency, pneumonia, pulmonary oedema due to a persistent ductus arteriosus)
- intraventricular haemorrhage
- hypoglycaemia
- over-heating or hypothermia
- sepsis
- severe anaemia may also contribute to apnoea.

### **Pulmonary parenchymal disease**

Any condition that causes decreased lung compliance or impaired gas exchange can contribute to apnoea. Appropriate pulmonary support should be provided for adequate gas exchange, and the underlying pulmonary condition should be treated.

### **Airway obstruction**

This may result from simple malpositioning of the head (e.g. hyper-flexion or hyper-extension of the neck), especially in preterm infants. Congenital airway anomalies such as tracheo-oesophageal fistula or an aberrant thoracic blood vessel compressing the trachea (vascular sling) may also present as apnoea. Maintaining proper head positioning or surgical correction of the underlying anomaly should be provided.

### **Infection**

Infection must always be excluded and antibiotics administered until infection has been ruled out by subsequent clinical findings and laboratory results (complete blood counts, chest X-ray, blood cultures, etc.).

### **Convulsions (see below)**

Convulsions may present primarily as apnoea. This possibility should be considered especially in term or near-term infants with no other identifiable cause of apnoea. In such cases there may be a poor response to positive pressure ventilation. Convulsions in the first 1 to 3 postnatal days are usually due to intrapartum hypoxia. If there is a history of an operative vaginal delivery (e.g. forceps) or other birth trauma, this may indicate the possibility of an intracranial haemorrhage.

### **Maternal medication**

A common cause of apnoea in the newborn can be intrapartum morphine or pethidine administration for maternal pain or sedation during the last 4 hours before delivery. The effects can be reversed by administering naloxone hydrochloride (100 micrograms/kg, usually given IM). Naloxone should not be given if there is a history of drug abuse with narcotics in pregnancy, as acute neonatal narcotic withdrawal may be precipitated (see Section 3.3).

Exposure to high levels of magnesium sulphate has also been associated with apnoea in the immediate postnatal period. This is usually a self-limiting process that very rarely requires mechanical ventilation.

Continuous monitoring, preferably with a pulse oximeter, is needed especially if the infant becomes bradycardic or cyanosed with the apnoea.

### Treatment

- Gentle stimulation is usually all that is required to start the infant breathing again.
- Bag-and-mask resuscitation may occasionally be called for, and there should always be equipment immediately available and ready to use (not locked away in a cupboard) should this be necessary.
- If available, oral caffeine may reduce the number of episodes in a preterm infant. Caffeine seldom causes the tachycardia and other side effects associated with

theophylline. It is advisable to continue caffeine for 4–5 days after cessation of apnoea. Recurrent apnoea that does not respond to caffeine occasionally requires a period of nasal CPAP or mechanical ventilation.

- If an apnoea monitor is available it can be used, but a pulse oximeter with the alarm turned on for hypoxaemia is much safer, as apnoea (absent ventilation) can occur despite continued breathing movements. This will also identify any baseline low oxygen saturation which, when treated, may help to prevent apnoea.

**TABLE 3.4.2** Caffeine doses for apnoea of prematurity given intravenously or orally

Preparations	Each dose	Dose frequency	Notes on administration
Caffeine citrate	20 mg/kg	Loading dose	If oral dose is too large, divide into two and give 1 hour apart
	5–8 mg/kg maintenance	Once daily	
Caffeine base	10 mg/kg	Loading dose	Give IV loading dose over 30–60 minutes diluted as much as possible
	2.5–4 mg/kg maintenance	Once daily	

## Haemorrhage in the neonate

### Causes of haemorrhage

An infant's blood volume approximates 80 mL/kg of body weight. Peripartum haemorrhage of relatively small amounts of blood can therefore result in hypovolaemic shock in the newborn. Common causes may include a slipped ligature on the umbilical cord, intrauterine feto–maternal haemorrhage (diagnosed by the Kleihauer–Betke test), or subgaleal haemorrhage. Vasa praevia or an accidental incision of the placenta during Caesarean section are other causes.

The Kleihauer–Betke test is a blood test used to measure the amount of fetal haemoglobin transferred from the fetus to the mother's bloodstream. It is usually performed on Rhesus-negative mothers to determine the dose of Rho(D) immune globulin needed to inhibit the formation of Rh antibodies in the mother and prevent Rh disease in future Rh-positive children. It is also the standard method of quantitating feto–maternal haemorrhage.

The test exploits the differential resistance of fetal haemoglobin to acid. A standard blood smear prepared from the mother's blood is exposed to an acid bath. This removes adult haemoglobin, but not fetal haemoglobin, from the red blood cells. Subsequent staining makes fetal cells (containing fetal haemoglobin) appear rose-pink in colour, whereas adult red blood cells are only seen as 'ghosts'. The percentage of fetal to maternal cells is calculated under a microscope.

Bleeding in the first week of life is uncommon, but may signify haemorrhagic disease of the newborn or clotting factor deficiency.

### Presenting features

The infant will appear pale with weak peripheral pulses, tachypnoea and a tachycardia that may exceed 200 beats/minute. Blood pressure may be low or undetectable even in a term infant but is very difficult to measure in neonates.

**The haematocrit and haemoglobin concentration may be normal in an infant with acute hypovolaemic shock, and are an unreliable early indicator of the amount of blood lost in the first few hours after the bleed.** Obvious blood loss rarely results in hypovolaemic shock. Common sites of blood loss include the umbilical stump and the gastrointestinal tract. In the latter case, there may be doubt as

to whether blood is of maternal origin (blood swallowed at delivery or from a bleeding nipple) or infant origin. In some cases this can be resolved by the Apt test.

### Apt test

Mix 1 part of the blood-containing fluid (vomit, gastric aspirate or liquid stool) with 5 parts of distilled water. Centrifuge it, and then mix 1 mL of the supernatant with 0.25 mL of 0.25% sodium hydroxide (NaOH). A yellow-brown colour signifies maternal blood, whereas fetal haemoglobin remains pink. The solution must be pink to start with.

### Treatment

- In an emergency in a shocked infant take a blood sample for blood grouping and cross-matching. Give O Rh-negative or cross-matched blood (20 mL/kg) at a rate depending on the degree of shock (usually the first 10 mL/kg can be safely given over 5 minutes), monitoring the response and reducing the rate of infusion as improvement occurs. Sometimes a further 10–20 mL/kg of cross-matched blood may be necessary.
- If O-negative or cross-matched blood is not available, use 10–20 mL/kg of 4.5% albumin or Ringer-lactate or Hartmann's solution.
- If there is overt bleeding, take a blood sample for blood grouping and cross-matching, haemoglobin, platelet count, film and clotting studies. Then give 1 mg of vitamin K (phytonadione or phytonadione) IV. If bleeding continues, give 20 mL/kg of fresh-frozen plasma (if available). Administer platelets if the count is < 60 000/mm<sup>3</sup>. Bleeding due to haemorrhagic disease of the newborn usually stops within 30 minutes of vitamin K administration.

## The neonate with jaundice

Many infants become jaundiced for a few days after birth. This is because bilirubin released from the breakdown of red blood cells has to be excreted by the infant after birth. *In utero*, bilirubin would cross the placenta to reach the maternal liver, from where it would be processed and eliminated. The neonatal liver takes time to develop normal

functioning. The serum bilirubin level usually rises after the first 24 hours of life and peaks at 100–300  $\mu\text{mol/litre}$  by 3 to 5 days after birth.

Causes of physiological jaundice in the neonatal period include the following:

- increased breakdown of red blood cells in the first few days of life
- reduced lifespan of red blood cells (70 days, compared with 120 days in the adult)
- less efficient metabolism of bilirubin by the immature liver enterohepatic circulation of bilirubin.

'Physiological jaundice' is common, affecting at least one-third of normal term infants. Jaundice can be considered physiological and does not require treatment or investigation if the following criteria are met:

- Jaundice is not present in the first 24 hours of life.
- The infant is well, and free from signs of infection, without enlargement of the liver or spleen.
- The bilirubin concentration does not exceed 300  $\mu\text{mol/litre}$  (approximately 17 mg/dL) at any stage (term infants only). A much lower acceptable level is set for preterm infants.
- The bilirubin concentration reaches a peak on the fourth or fifth day of life.
- The jaundice has fully resolved by the end of the second week of life.

The risk of jaundice can be reduced by encouraging early unrestricted demand breastfeeding.

**There is no evidence whatsoever to support the widely held belief that giving extra water for the infant to drink either reduces the risk of jaundice or is helpful in treatment. In fact the opposite has been shown. Giving water is likely to reduce the frequency of breastfeeds and increase the risk of jaundice. Dehydration should be avoided by encouraging frequent breast feeds.**

### Assessing the degree of jaundice

Various means of estimating the degree of jaundice make it easier to determine which infants really need any intervention. Healthcare professionals can sometimes make a rough estimate of the degree of jaundice by looking at the skin colour (this is best undertaken in natural daylight), but it can only be divided into simple categories such as 'slight', 'moderate' or 'severe'. The face is often the first part of the body to show signs of jaundice. The trunk usually only becomes yellow as jaundice deepens. Finally, the palms of the hands and soles of the feet become jaundiced. These observations are just estimates, and sometimes have to be confirmed by other means. Jaundice in the newborn infant can be missed in infants with dark skin, but can be more easily judged once the skin is blanched free of blood by finger pressure.

Bilirubin encephalopathy (kernicterus) in the absence of overt haemolysis is excessively uncommon in the term infant, unless the serum bilirubin level exceeds 425  $\mu\text{mol/litre}$ .

#### Note:

- $\mu\text{mol/litre}$  divided by 17.1 = mg/dL
- mg/dL multiplied by 17.1 =  $\mu\text{mol/litre}$ .

Several electronic devices have been developed for assessing skin colour, but none have yet been shown to work

significantly better than the simple 'icterometer' devised in 1960 and still in use. Jaundice is assessed by pressing the clear plastic of this simple device against the tip of the nose (or against the gums or tongue in a dark-skinned infant, where it has been shown to be accurate in a South African study), and then matching the colour of the skin against the icterometer's colour scale. Levels in excess of 350  $\mu\text{mol/litre}$  are unlikely to be missed if a blood sample is taken once the icterometer reads  $\geq 3.5$ . This too little known device, which costs only US\$39, is still made by Cascade Health Care Products of Salem, Oregon, in the USA. Measuring the degree of jaundice by this method is of no value once phototherapy has been started.

The bilirubin concentration can be most simply and accurately measured by simple spectrophotometry of serum obtained by centrifuging blood in a capillary tube. Several easily operated machines are available. Ward-based devices for assessing the bilirubin content of a spun micro-haematocrit tube optically are accurate until the level exceeds 350  $\mu\text{mol/litre}$ , and are adequate for most clinical purposes. If these devices are used, staff should be trained in this technique, and the machine should be calibrated daily and checked with control specimens of known bilirubin content. Using dirty tubes (or cuvettes), haemolysed or lipaemic samples can produce significant errors. Use plastic tubes, not glass ones, to avoid HIV infection if the tubes break.

The accurate measurement of values in excess of 350  $\mu\text{mol/litre}$  is only possible in a biochemistry laboratory. A laboratory spectrophotometer reading is needed before initiating an exchange transfusion.

Direct or conjugated bilirubin presents no threat to the brain. It only accounts for a small fraction of the total serum bilirubin level in the first week of life. Decisions about treatment should therefore be based on the total serum bilirubin level, remembering that even laboratory estimates have limited precision.

### Collecting blood

- Only a small amount of blood is needed to check the bilirubin level. Although described as a heel prick, sticking a needle into the heel runs a high risk of entering the underlying bone, and can lead to osteomyelitis, so should be avoided.
- It is safe to take blood from any part of the back third of the foot.

Try to use a disposable 2.4-mm blood lance, but never use the same lance for more than one infant, because of the risk of transmitting hepatitis or HIV infection. It is not necessary or appropriate to try to sterilise the skin first, so long as it is clean. A spring-loaded lance does seem to render the procedure less painful. The infant will also show fewer signs of distress if held or given something to suck during the procedure.

Grip the foot firmly enough to make it go red but not white. Stab the back of the foot just once and then squeeze gently and intermittently to stimulate blood flow. The use of a standard lance should optimise blood collection because it helps to ensure that the skin is punctured to a standard depth. A shallower prick is unlikely to reduce the pain inflicted because it will almost certainly prolong the procedure. A double puncture may help if a lot of blood is needed. Slight finger pressure exerted through a cotton ball on the site for about a minute is usually enough to stop any further

bleeding after the procedure is over. The healthcare worker should be careful not to prick their own finger.

**FIGURE 3.4.3** Unsuitable (top) and suitable (bottom) positions from which to obtain capillary blood from the foot of a neonate.

### **Biliary atresia**

In prolonged jaundice (jaundice persisting beyond 14 days of age), it is important to determine not only the total bilirubin concentration but also **the proportion of conjugated bilirubin**. Conjugated bilirubin is not neurotoxic, but its presence signifies the presence of biliary obstruction attributable to potentially serious conditions such as neonatal hepatitis or biliary atresia.

The history can be informative if laboratory investigations are not available. The presence of pale unpigmented stools or dark urine would be suggestive of biliary obstruction. Urine can also be tested with a reagent strip for bilirubin (if positive for bilirubin, the diagnosis of biliary obstruction is supported, provided that the infant is not receiving phototherapy when unconjugated bilirubin appears in the urine).

It is important to identify biliary atresia promptly, as operative intervention is more likely to be successful if undertaken within 8 weeks of birth. Even mild jaundice merits review if the stool becomes grey or putty coloured rather than yellow or green. Similarly, in the absence of a neonatal screening programme (a situation that is prevalent in the majority of resource-limited countries), it is important that congenital hypothyroidism and glucose-6-phosphate dehydrogenase (G6PD) deficiency are identified. This can be done by tests including  $T_4$ , TSH, G6PD assay, bilirubin (total and direct), complete blood picture and reticulocyte count.

### **Breast milk jaundice**

Around 10% of breastfed infants are still slightly jaundiced 1 month after birth. Laboratory investigations seldom reveal anything that needs treatment, and the infant is otherwise well. This scenario may be suggestive of breast milk jaundice. However, it is important that other common causes, including congenital biliary atresia, hypothyroidism and G6PD deficiency, are ruled out. Remember that breast milk jaundice is a diagnosis of exclusion.

Ill infants with continuing jaundice should be given a prophylactic 1 mg IM injection of vitamin K if it is not clear that they received such an injection at birth, to minimise the risk of potentially fatal late vitamin K deficiency bleeding.

### **Pathological jaundice**

There is an increasing risk that high levels of unconjugated serum bilirubin will breach the blood–brain barrier, causing critical damage to many cells in the brain. This becomes more likely if, in the presence of haemolysis, the unconjugated serum bilirubin level is allowed to rise above 350  $\mu\text{mol/litre}$ . Indeed, in a small preterm infant who is also ill, the safe limit may be nearer to 250  $\mu\text{mol/litre}$ , or sometimes even less.

Once this happens there is nothing that can usefully be done to reverse the resultant brain damage. Infants may manifest this by seizures, or by becoming stiff with arching of the back and neck signifying a severe encephalopathy. Many of these infants will die after becoming severely ill. The survivors will almost all become severely deaf, and the majority may develop athetoid cerebral palsy.

### **Causes of abnormally raised bilirubin levels**

These include the following:

- haemolytic disease
- neonatal sepsis
- polycythaemia
- severe malnutrition
- hypothyroidism
- congenital infection (usually obstructive jaundice):
  - syphilis
  - toxoplasmosis
  - cytomegalovirus
  - rubella
  - hepatitis.

In the first week of life, the following factors may lead to jaundice that is sufficiently severe to require treatment:

- **Preterm delivery:** Even moderate prematurity significantly increases the risk of early or severe jaundice and associated sequelae. Consequently, the bilirubin treatment charts give lower treatment thresholds for infants born at 31–34 weeks' gestation. At less than 31 weeks, treatment is started at even lower bilirubin levels.
- **Haemolytic disease:** This may be isoimmune (e.g. Rh or ABO incompatibility) or due to red blood cell disorders (e.g. hereditary spherocytosis, G6PD deficiency).
- **Infection:** Haemolysis and impaired elimination of bilirubin may be associated with septicaemia. Congenital infection (e.g. syphilis) may also be associated with jaundice, but other features such as rash, hepatosplenomegaly and thrombocytopenia will be present, and there is usually a significant conjugated bilirubin level.
- **Polycythaemia.**
- **Rarer causes:** These include inborn errors of metabolism (e.g. galactosaemia), congenital hypothyroidism, other intrauterine infections and neonatal malaria.
- **Obstructive jaundice:** This rarely presents in the first week of life, but is important in the differential diagnosis of prolonged jaundice.

### **Haemolysis**

Clinically noticeable jaundice within 24 hours of birth, especially if the mother is blood group O and the infant is blood group A or group B, or the mother is Rhesus negative and the infant is Rhesus positive, should suggest the possibility of a haemolytic disease.

Term infants with physiological jaundice seldom need treatment with phototherapy unless there is an unusually

high rate of red cell breakdown. However, phototherapy should be started as soon as jaundice becomes apparent if there is evidence of haemolytic disease. The trend in the bilirubin level should then be checked twice a day (the level cannot be assessed from skin colour once phototherapy has commenced).

### Investigation

A good principle to remember is to measure bilirubin levels and investigate if:

- jaundice appears on day 1 in any infant
- jaundice appears on day 2 in any preterm infant
- the palms of the hands or soles of the feet are yellow in any sick neonate and in any infant of any age.

Jaundice should never last for more than 3 weeks.

In an infant who develops jaundice in the first 24 hours, the most likely causes are infections, haemolytic disease and polycythaemia. The history and examination may be helpful. It is important to determine whether the mother has previously had affected infants, or if she is known to have a hereditary haemolytic disorder, or if risk factors for infection or clinical signs of sepsis exist. Hepatosplenomegaly could be suggestive of congenital infection.

The following should suggest a high risk for haemolysis:

- red cell antibodies in the mother's blood
- a positive Coombs' or direct antiglobulin test on blood samples from the umbilical cord
- a packed cell volume > 65%, Hb > 220 g/litre
- a family history of G6PD deficiency or congenital spherocytosis
- a history of previous children being seriously jaundiced in the first week of life
- otherwise unexplained neonatal anaemia at birth (haemoglobin level < 140 g/litre or haematocrit < 40%).

Useful laboratory tests include the following:

- the mother's and infant's ABO and Rhesus blood groups.

Save serum to cross-match if exchange transfusion is needed

- direct Coombs' test (if positive this indicates an isoimmune haemolytic anaemia)
- complete blood count and reticulocyte count (anaemia and reticulocytosis indicate haemolysis, high PCV suggests polycythaemia and/or abnormal white blood cells indicate possible infection)
- peripheral blood smear (abnormal red cell morphology and/or fragmented red cell forms suggest a specific red cell disorder and/or haemolysis)
- G6PD screen
- syphilis serology
- thyroid function tests (T<sub>4</sub>, TSH)
- urine test for non-glucose-reducing substance (for possible galactosaemia)
- ultrasound scan of liver.

### Treatment

The bilirubin treatment charts (see Table 3.4.3) show intervention levels for the two principal treatments (i.e. phototherapy and exchange transfusion). In general, the smaller the infant and the sicker the infant, the more urgent the need to intervene. Bilirubin in plasma is normally bound to albumin, but in a sick acidotic infant less binding occurs, and more 'free' bilirubin will be available to enter the central nervous system. Therefore consider intervening about 40 µmol/litres below the indicated line in such circumstances.

The specific bilirubin levels for which phototherapy and exchange transfusions need to be considered in infants born before 31 weeks' gestation are less certain. A frequently used guideline is to **initiate phototherapy when the bilirubin level approaches 85 µmol/litre/kg birth weight (which equals approximately 5 mg/dL/kg birth weight), and to consider an exchange transfusion for levels above 170 µmol/litre/kg birth weight (which equals approximately 10 mg/dL/kg birth weight).**

TABLE 3.4.3 WHO recommendations (2012) for phototherapy and exchange transfusion levels of unconjugated bilirubin

Age	Phototherapy		Exchange transfusion	
	Healthy newborns ≥ 35 weeks' gestation	Newborns < 35 weeks' gestation or any risk factors	Healthy newborns ≥ 35 weeks' gestation	Newborns < 35 weeks' gestation or any risk factors
Day 1	Any visible jaundice		260 mmol/litre (15 mg/dL)	220 mmol/litre (10 mg/dL)
Day 2	260 mmol/litre (15 mg/dL)	170 mmol/litre (10 mg/dL)	425 mmol/litre (25 mg/dL)	260 mmol/litre (15 mg/dL)
Day 3+	310 mmol/litre (18 mg/dL)	250 mmol/litre (15 mg/dL)	425 mmol/litre (25 mg/dL)	340 mmol/litre (20 mg/dL)

### Phototherapy

This uses light in the blue-green region of the spectrum (**not ultraviolet**) to convert bilirubin to its water-soluble isomer **lumirubin**, which can be excreted in urine and stools.

In infants who are very yellow, it is best to use light from a bank of at least six 60-cm 20-watt fluorescent strip lights suspended not more than 30 cm above the unclothed infant (lights placed 60 cm from the infant are only about half as effective). Placing a white sheet under and round the infant will increase the effectiveness of any treatment. While under phototherapy, it is important to monitor body temperature

and to protect the infant from draughts. It is also standard practice to mask the eyes to protect them from the bright light. The infant should be nursed naked in an incubator, under a radiant heater or in a cot, allowing maximum skin exposure. Feeding, especially breastfeeding, should continue without interruption, as more frequent breastfeeding is helpful not only in eliminating meconium from the bowel but also in enhancing bilirubin clearance via the stools and urine. During phototherapy, the infant can be removed for breastfeeds as necessary (intermittent treatment has been shown to be as effective as continuous treatment). Fluid

other than breast milk (e.g. breast milk substitute, water, sugar water) should not be given. However, the total daily fluid intake may need to be increased by about 10%, especially in preterm infants, in order to minimise additional water losses from evaporation and convection.

Troublesome side effects of phototherapy include rashes and profuse watery stools, but these are rare and do not require treatment. Phototherapy can be stopped when the serum bilirubin level is 50 mmol/litre (3 mg/dL) below the phototherapy threshold.

### Exchange transfusion

Bilirubin levels that rise above certain threshold values place the infant at risk of developing bilirubin encephalopathy (kernicterus). In such cases, the bilirubin level needs to be immediately lowered with a double-volume exchange transfusion. A volume of the infant's blood equal to the body weight in kg  $\times$  2  $\times$  80 mL is exchanged in small aliquots with O Rhesus-negative blood, or blood cross-matched against maternal antibodies.

Double-volume exchange transfusion is recommended in **term infants** if:

- they are haemolysing or are ill and have a bilirubin level higher than 300  $\mu$ mol/litre
- they are well and not haemolysing but their bilirubin level is higher than 425  $\mu$ mol/litre.

The **functions of exchange transfusion** include the following:

- removal of maternal antibodies
- removal of antibody-coated red blood cells before they haemolyse
- correction of anaemia
- lowering of total bilirubin levels, if there is sufficient time for equilibration between intravascular and extravascular levels.

Exchange transfusion is generally only undertaken if the rate of red blood cell breakdown is likely to exceed the ability of phototherapy to control bilirubin levels. This is very likely to occur in infants with a positive Coombs' test who are already anaemic (because of fetal haemolysis) at birth. A cord blood haemoglobin level of less than 140 grams/litre serves to identify most of these infants.

Human immunoglobulin 500 mg/kg, given as an IV infusion over 2 hours, reduces the number of infants who require an exchange (especially if due to Coombs' positive Rhesus or ABO incompatibility). It also decreases the number who require a 'top-up' transfusion for late neonatal anaemia.

### Exchange transfusion

- 1 Calculate the infant's circulating volume (= 80 mL/kg). Twice this amount of blood will be required. Do not exceed this (usually 1 bag of whole blood = 450 mL). Do not use blood that is more than 4 days old.
- 2 Check that the blood has either the same ABO group as the infant or is blood group O Rhesus-negative and in addition is compatible with the mother's serum.
- 3 Ensure that the infant is closely monitored throughout the procedure.
- 4 This is a sterile procedure, so gloves and gowns must be worn and universal precautions applied.
- 5 Secure umbilical vein access. Pass the umbilical venous

catheter (UVC) as described in Section 8.4.B, and check its position with an X-ray (if available). Ideally it should be positioned in the vena cava just outside the right atrium, but a position below the liver is also acceptable if the line will sample and flush easily. A line positioned in the liver should not be used.

- 6 Ideally, use a blood warmer (especially for low-birth-weight infants). Otherwise warm the blood bag by placing it under the mother's clothing next to the skin.
- 7 Set up a closed circuit with either a four-way tap, or two three-way taps. The four links are:
  - the infant
  - the syringe for removing and replacing blood
  - the blood to be transfused
  - the route for discarding the infant's blood.
- 8 Make sure that the total blood in and out is recorded. Plan to spend 1.5–2 hours on the procedure.
- 9 Decide on the size of aliquot you will be exchanging with each draw and infusion. This is roughly as follows:
  - baby weighing < 1500 grams: 5 mL
  - baby weighing 1500–2500 grams: 5–10 mL
  - baby weighing 2500 grams: 10–15 mL.

If you use small aliquots, remember to add an allowance for the 'dead space' in the tubing between the syringe and the baby. You should draw out each aliquot over 2–3 minutes to avoid abrupt changes in blood pressure, and replace over 3–4 minutes with the observer keeping a running total.

- 10 Send the first aliquot for measurement of bilirubin, electrolyte and calcium concentrations.
- 11 Halfway through the procedure check the blood glucose, calcium and potassium concentrations.
- 12 Measure them again, together with the bilirubin concentration, at the end of the procedure.
- 13 Sometimes it is necessary to exchange more than once in quick succession. Symptomatic hypocalcaemia may occur as the citrate in donor blood binds calcium. This responds best to halting the procedure for 15 minutes. Giving calcium gluconate is of little benefit and may be hazardous, so is best avoided.

### Although the potassium concentration of the blood is often 8–10 mmol/litre, this does not usually cause significant hyperkalaemia.

Exchange transfusion should only be undertaken once all of the attendant risks have been considered. Even in experienced hands, 1% of infants may suffer a sudden cardiac arrest during or shortly after the procedure. This should respond to prompt intervention using the approach adopted when dealing with cardiac arrest at birth, but the infant needs to be monitored closely, and staff need to be prepared for such a possibility if this is not to prove fatal. Air embolism can kill within minutes, and faulty technique can cause sudden hypo- or hypervolaemia, or introduce later sepsis. The use of donor blood more than 5 days old can cause serious hyperkalaemia and an arrhythmia. Blood used straight from the fridge at 4°C can impose a major cold stress. Cytomegalovirus (CMV) infection may occur if the blood does not come from a CMV-negative donor. It is also critical to avoid causing HIV or hepatitis B or C infection. In addition, there is a definite but poorly understood risk that the procedure will trigger serious necrotising enterocolitis. If possible it is best to avoid the use of heparinised blood.

Because of all these risks, if at all possible exchange transfusion should only be undertaken in a neonatal unit where the staff are experienced in the use of this procedure.

### The neonate with anaemia

#### Causes of anaemia

These include the following:

- haemorrhage
- twin-to-twin transfusion
- feto–maternal transfusion
- placental abruption
- haemolysis due to
  - Rhesus incompatibility
  - ABO incompatibility.

#### Treatment of anaemia

Haemolysis may continue for several weeks after birth even if it is not severe enough to require intervention in the first week of life. An attempt should therefore be made to check all infants with a positive Coombs' test for late anaemia when they are about 6 weeks old. Infants with a capillary haemoglobin level of less than 80 grams/litre or a haematocrit (PCV) of less than 25% should then receive a 'top-up' transfusion of 20 mL/kg of cross-matched or group O Rhesus-negative blood given over 2 hours. Red cell concentrate or packed cells are preferable. Daily folic acid (1 mg/day) for at least 1 week can help to reduce anaemia.

### The neonate with seizures, spasms or reduced conscious level

Seizures (also called fits or convulsions) have been reported to affect about 0.1% of term infants and 10% of those weighing less than 1500 grams at birth.

#### Presenting features

Seizures may be subtle (apnoea, staring, lip smacking/grimacing, deviation of the eyes, cycling movements of the limbs) or more obvious (tonic extensor posturing or clonic movements). Involvement of a limb or one side of the body does not necessarily imply a focal cause in the neonate. A bulging anterior fontanelle may suggest intracranial haemorrhage or infection. It is important to **always measure and note the head circumference**. Sometimes involuntary movements (e.g. extreme jitteriness) or benign myoclonic jerks can be difficult to distinguish from seizures. The presence of associated autonomic instability and/or lateral eye deviations may signal seizure activity, whereas the absence

TABLE 3.4.4 Differentiating between seizures and jitteriness

Well but jittery infant	Infant with clonic seizures
No abnormal eye movements	Abnormal eye movements
No apnoea	Apnoea
No colour changes	Pallor or cyanosis
No heart rate changes	Tachycardia
Easily triggered by handling and stopped by gentle passive flexion of the affected limb	Independent of handling
Rhythmical movements	Jerky with fast and slow components that are not equal

of these findings or elimination of these movements when the limbs are restrained indicate a non-seizure event.

#### Causes of seizures

These include the following:

- hypoxia
  - hypoglycaemia
  - meningitis
  - drug-related seizures
  - sepsis
  - polycythaemia
  - tetanus
  - hypocalcaemia
  - hyper- or hyponatraemia
  - metabolic abnormalities
  - **hypoxic ischaemic encephalopathy**: this is the most common cause of seizures in a term infant. Onset is usually within the first 24 hours, and it almost never starts after the third day
  - **intracranial haemorrhage, subarachnoid haemorrhage or cerebral infarctions**: these are also common causes of neonatal seizures. With subarachnoid haemorrhage, seizures may or may not be focal. However, unilateral tonic–clonic seizures are often observed with cerebral infarction. Although **intraventricular haemorrhage** occurs most frequently in low-birth-weight infants or at gestational ages under 32 weeks, very rarely it may manifest in term or near-term infants with neonatal seizures. Always give 1 mg IV vitamin K
  - **infection**: although meningitis is not the commonest cause of neonatal convulsion, it must always be excluded by lumbar puncture and antibiotics commenced urgently pending the results of culture
  - **metabolic causes** of seizures may include:
    - **hypoglycaemia**: always check blood glucose levels
    - **hypocalcaemia**: check plasma calcium and magnesium levels
    - **hyponatraemia and hypernatraemia**: seizures are uncommon unless the plasma sodium level is < 120 mmol/litre or > 160 mmol/litre. Seizures in infants with hypernatraemia may result from associated cavernous sinus thrombosis. A rapid fall or rise in serum sodium level, as may occur with too rapid therapeutic correction, may be more injurious than the absolute value of serum sodium level. A slow correction is desirable in such situations
  - **bilirubin encephalopathy** (see above section on jaundice)
  - rare **inborn errors of metabolism** (e.g. urea cycle defects, non-ketotic hyperglycaemia) require measurement of serum amino acids, urine fatty acids, serum lactate, serum pyruvate and blood ammonia levels. Measuring the anion gap can also be quite helpful. A high value may be suggestive of an inborn error of metabolism.
- Note: anion gap = (Na + K) – (Cl + HCO<sub>3</sub>). Normal anion gap = 5–17 mEq/litre in neonates**
- **maternal substance abuse**, particularly opiate withdrawal
  - **tetanus** remains a problem in many low-resource countries.

When managing neonatal seizures it is best to focus on the limited number of conditions where immediate treatment can have a major impact on long-term outcome. There are many situations where seizures are simply the outward sign of damage that cannot be reversed, even though it may be possible to stop continuing seizure activity from making matters worse.

**Focal seizures** can sometimes be the sign of what was otherwise a silent haemorrhagic infarction of part of the brain. While investigation would explain what was going on, it would not alter management.

If the infant is alert and well between episodes of seizure activity, appears normal on examination, and is feeding normally, sometimes it may be perfectly appropriate to do nothing.

### Investigations

These should include the following:

- lumbar puncture and blood culture
- full blood count, PCV, CRP
- blood glucose, calcium, urea and electrolytes, and blood ammonia (if available)
- arterial blood gas analysis to help further assess acid-base status
- cranial ultrasound (if available)
- intracranial imaging (head computed tomography if available)
- baseline and follow-up electroencephalograms (if available) may aid diagnosis and treatment
- save urine, plasma and CSF for metabolic studies (if available) if seizures are protracted.

### Treatment

Management of a neonate with seizures is as follows:

- Airway.
- Breathing.
- Circulatory access.
- Give glucose, IV or intra-osseous (2 mL/kg of 10% glucose).
- Give antibiotics, IV or IM, as there is a strong possibility of meningitis or sepsis.
- Stop the seizures with an anticonvulsant:
  - phenobarbitone, 20 mg/kg over 5 minutes IV or IM
  - paraldehyde, 0.2 mL/kg IM or 0.4 mL/kg rectally
  - diazepam 300 microgram/kg IV slowly or 500 microgram/kg rectally.
- Treat hypoglycaemia if present.
- Monitor the heart rate and respiratory rate, and oxygenation (ideally with pulse oximetry). Treat low SaO<sub>2</sub> or cyanosis with oxygen.
- Consider anticonvulsant therapy: the earlier the fits appear, the more frequent they are (more than two or three per hour) and the longer they last (more than 3 minutes), the more likely it is that anticonvulsants will be needed. Fits that interfere with respiration need to be treated and may require respiratory support.

### Emergency treatment of hypoglycaemia

Hypoglycaemia is a common cause of seizures in infants. Ideally, do a rapid bedside test for low blood glucose levels and act accordingly, but if this test is not available then a test dose of 2 mL/kg of 10% glucose should be given IV or, if venous access is not available, intra-osseously.

### Anticonvulsant treatment

**Phenobarbital** is the first-line drug for neonatal seizures. Give a 20 mg/kg IV loading dose slowly followed by 3–5 mg/kg once every 24 hours. Seizure control may be achieved more quickly if the first dose is given IV, but this loading dose must be given slowly, over at least 5 minutes, to minimise the risk of shock, hypotension or laryngospasm. Some texts recommend the use of a higher dose if the standard dose fails, but this can cause respiratory depression. **Always have a bag-valve-mask available to support ventilation.** With hypoxic encephalopathy usually only a loading dose is needed. Seizures have been reported to respond to this dose 40% of the time. An additional 10 mg/kg may be required if seizures persist or recur (70% response rate).

**Phenytoin** is the second-line drug for neonatal seizures. Initial seizure control with this drug requires the presence of a saline-filled IV line (because the drug crystallises out in dextrose solutions). The same problem also renders the IM route unavailable. Give a 20 mg/kg loading dose (diluted in 10–15 mL of normal saline) IV slowly over 10–20 minutes (monitor for hypotension and cardiac arrhythmia, making sure that the drug does not leak into the tissues), and then 2 mg/kg IV or by mouth once every 8 hours. Infants more than 2 to 3 weeks old may need a considerably larger maintenance dose. Oral absorption of phenytoin may be quite unpredictable, so this would need to be monitored. Phenytoin is dangerous in infants with hypoxic ischaemic encephalopathy who may also have ischaemic hypoxic heart injury.

**Paraldehyde** is the third-line drug for neonatal seizures. Give a single 0.4 mL/kg dose mixed with an equal volume of mineral oil by the rectal route. This route offers excellent bioavailability of the drug. The same dose can be repeated once if seizures persist. Give within 10 minutes after preparation when using a plastic syringe (because paraldehyde interacts with many plastics). Paraldehyde can also be given by the IM route. However, problems with muscle necrosis make this a less desirable route.

**Diazepam** is an alternative to phenobarbital as first line treatment for neonatal seizures. However, it is vital that hypoglycaemia has been excluded and treated before giving this drug. A working bag-valve-mask of suitable size must be ready next to the infant before this drug is given. It can be given IV at a dose of 300 microgram/kg over 5 minutes or rectally in a dose of 500 microgram/kg. The rectal dose can be repeated once after 10 minutes if the infant is still fitting.

**Clonazepam:** The loading dose is given as 100 micrograms/kg by slow IV infusion. It should not be administered for more than 3 days.

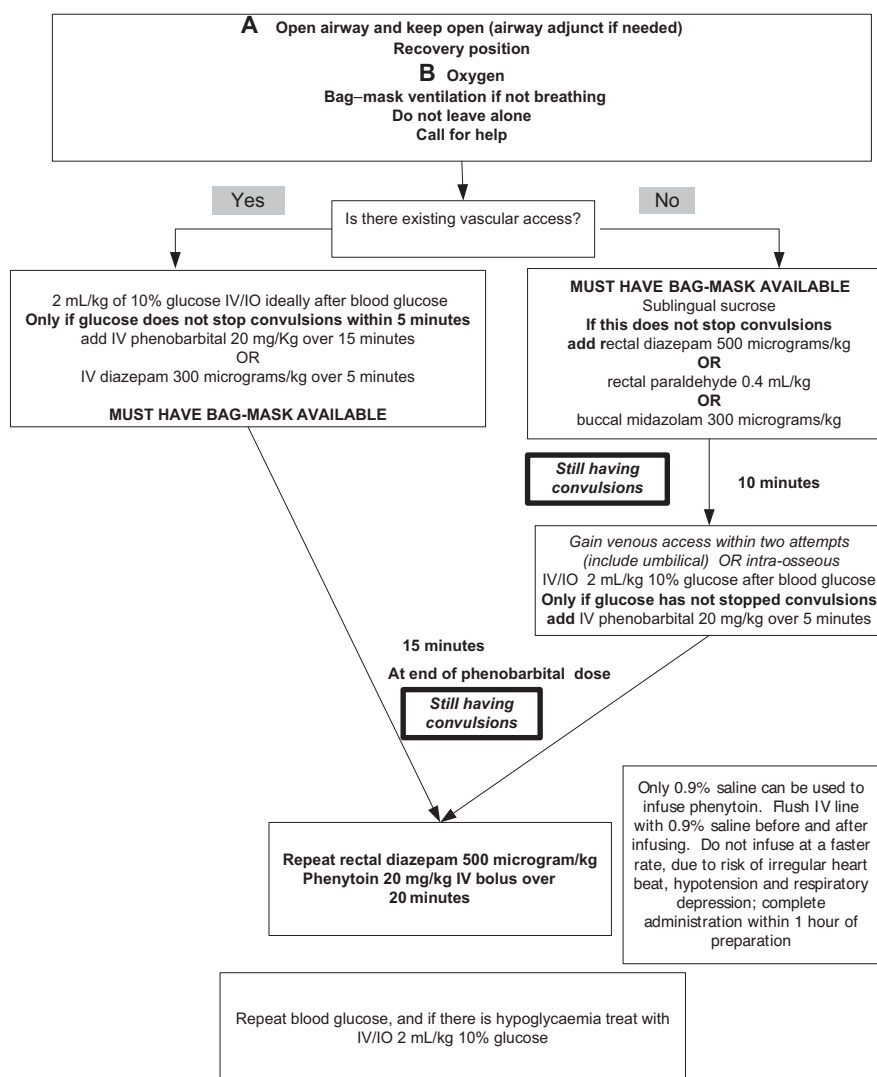

**Midazolam:** This has an immediate effect but a short duration of action. It can be given into the buccal cavity or IV. Like diazepam it can cause respiratory depression, so a bag and mask must be available when it is used, and the infant must be monitored closely.

**Anticonvulsants may precipitate a need for respiratory support. Therefore always have a bag-valve-mask available.**

Once seizures are controlled, maintenance therapy (which is rarely needed) with a single agent (usually phenobarbitone) is often possible. Discontinuation of treatment depends on the underlying aetiology, but aim to withdraw anticonvulsants as soon as possible.

It is essential to consider the four main treatable causes of fitting, namely **hypoglycaemia, hypocalcaemia,**

**FIGURE 3.4.4** Pathway of care for a neonate who is having convulsions.

meningitis and tetanus, as any delay in diagnosis could have serious consequences.

### Hypoglycaemia (glucose < 2.5 mmol/litre or < 45 mg/dL)

Hypoglycaemia is a common problem in the nursery; it can occur in infants who appear well, as well as in those who are sick. It is important to identify any infant at risk and implement preventative and curative measures as early as possible. **Untreated symptomatic hypoglycaemia can result in brain damage.**

Infants at risk of developing hypoglycaemia include the following:

- infant of diabetic mother
- preterm infant
- small-for-gestational-age or wasted infant
- large-for-gestational-age infant
- post-term infant
- sick infant with infections and respiratory failure
- infant who is not receiving adequate breast milk.

The definition of hypoglycaemia is controversial, and no studies have determined an absolute value at which organ

dysfunction will occur. However, it is known that a prolonged low level of symptomatic hypoglycaemia is associated with brain injury. At the time of writing, most neonatologists prefer to maintain blood glucose levels above 2.5 mmol/litre (45 mg/dL).

### Causes of neonatal hypoglycaemia

#### Increased utilisation of glucose (hyperinsulinism)

- Infants of diabetic mothers.
- Respiratory distress.
- Abrupt interruption of high glucose infusion.
- Polycythaemia.
- Hypothermia.

Rare causes of hyperinsulinism include:

- erythroblastosis fetalis
- islet-cell hyperplasia
- Beckwith–Wiedemann syndrome
- insulin-producing tumours
- maternal beta-agonist tocolytic therapy
- rarely malpositioned umbilical arterial catheter infusing a high concentration of glucose into coeliac and mesenteric arteries (T11–T12), stimulating insulin release.

**Decreased production/stores of carbohydrate**

- Prematurity.
- Small-for-gestational-age or wasted infant.
- Inadequate caloric intake.

**Mixed increased utilisation and/or decreased production from other causes**

- Perinatal stress (e.g. due to hypoxia, sepsis, shock, hypothermia).

**Rare causes**

- Defects in carbohydrate metabolism (galactosaemia, fructose intolerance, glycogen storage disease).
- Endocrine deficiency (adrenal insufficiency, hypothalamic insufficiency, glucagon deficiency).
- Defects in amino acid metabolism (maple syrup urine disease, propionic acidemia, methylmalonic acidemia, tyrosinaemia).

**Diagnosis of hypoglycaemia**

- There are few data on normal blood glucose levels in the first week of life, particularly for healthy breastfed term infants. **Moreover, there is little evidence that a transient low blood glucose concentration in term infants who show no physical signs is harmful. However, asymptomatic hypoglycaemia may rapidly progress to symptomatic hypoglycaemia.** Fits due to hypoglycaemia typically start in a previously well infant on or after the second day of life.
- Indications for measuring the blood glucose concentration of a term infant include lethargy, poor feeding, temperature instability, respiratory distress, new-onset apnoea/bradycardia, jitteriness, pronounced hypotonia, diminished consciousness and seizures. The association between such signs and low blood glucose levels is described as 'symptomatic hypoglycaemia'.
- Beware of blaming 'hypoglycaemia' alone for these signs. **Remember that an infant who seems drowsy may be infected, and low blood glucose concentration may merely be an associated finding.** It is important to try to establish the underlying cause of the problem.
  - Although laboratory estimates of blood glucose concentration are ideal for diagnosing and managing this condition, reagent strips can be helpful.
  - The blood glucose concentration in the first 6 hours of life is very often low (1.5–2.0 mmol/litre). There is no evidence that this is harmful for otherwise healthy term infants, who adapt by mobilising other fuels. Consequently, early testing (under 6 hours of age) is pointless, unless neurological signs are present or there are other conditions that necessitate testing.
  - In newborn infants the serum glucose concentration is about 0.5 mmol/litre lower than that of whole blood.

**When to test**

- **Symptomatic infants** (lethargy, poor feeding, temperature instability, respiratory distress, new-onset apnoea/bradycardia, jitteriness and seizures) should be tested immediately.
- **Infants at risk** should be tested within 1 hour after birth (as such infants rapidly become hypoglycaemic after

delivery) and then 3-hourly until blood glucose levels are stable at 2.5 mmol/litre (45 mg/dL) or higher. Continue to monitor until feeds are well established.

- In infants with **hypoglycaemia**, check the blood glucose concentration every 20–30 minutes from the beginning of treatment, then hourly until it is stable at 2.5 mmol/litre (45 mg/dL) or higher. Continue to monitor frequently (every 4–8 hours) during treatment, and while decreasing supplemental IV glucose infusions.

**Laboratory diagnosis**

- **Reagent strips** are useful and rapid, but in general are less reliable than laboratory plasma glucose measurements. Reagent strips may show a glucose level as much as 15% lower than plasma glucose levels. Whenever possible, it is preferable to use a calibrated glucometer.
- **Laboratory plasma glucose determinations** (if available) are useful for confirming hypoglycaemia detected by reagent strips, but blood samples must be processed promptly for accurate values, as glycolysis occurs in standing whole blood samples. **Do not wait for laboratory confirmation before initiating therapy.**

**Management of hypoglycaemia****Infants at risk of hypoglycaemia but appearing to be well**

- Initiate early feeding within 1 hour after birth with breast milk or formula (only if breast milk is not available) and repeat every 2–3 hours.
- Feeding with 5% glucose is not recommended in infants, because milk provides more energy.
- Infants of diabetic mothers are unlikely to develop hypoglycaemia on the second day of life if tests in the first 24 hours are satisfactory.

**Infants with symptomatic hypoglycaemia who are unable to feed or who failed correction of glucose levels with enteral feeding**

- Establish an IV line using sterile precautions, and take a sample for blood culture and other biochemical tests (if available).
  - Give an IV glucose bolus 200 mg/kg over 5 minutes (2 mL/kg of 10% glucose in water). If the infant almost immediately becomes more alert and active 'on the end of your needle' you have made the diagnosis, even before the laboratory report comes back.
  - In such situations it is then important to keep the blood glucose level stable by starting a sustained infusion of 10% dextrose at 5 mL/kg/hour (or 5–8 mg/kg/minute) for the next 2 to 4 days while gradually building up oral feeds.
- If further episodes of symptomatic hypoglycaemia occur, the bolus should be repeated and the infusion rate increased by 10–15%.
- An infant who seems drowsy may be infected, and a low blood glucose concentration may be an associated finding rather than the main cause of the problem. It is important to exclude infection and initiate antibiotics if indicated.
- When administering boluses, never use higher concentrations of glucose (> 10%) because of the risk of intra-ventricular haemorrhage and/or cerebral oedema.
- The concentration of glucose in the maintenance fluids

can be adjusted in accordance with the total daily fluid requirements.

- If using concentrations higher than 12.5%, a central venous line or umbilical venous catheter needs to be inserted because of the risk of tissue damage in the event of fluid extravasation.
- Most infants will correct hypoglycaemia with infusion of 5–8 mg/kg/minute; not infrequently, however, infants with severe intrauterine growth restriction or wasting and those with hyperinsulinism may require infusion rates of up to 12–15 mg/kg/minute.
- When normal blood glucose levels have been stable for 12–24 hours and the infant is tolerating enteral feeding, decrease the IV glucose infusion by 10–20% each time levels are higher than 2.5 mmol/litre (45 mg/dL).
- Always decrease the IV infusion gradually because of the risk of precipitating hypoglycaemia.
- If you are unable to gain IV access, a feed of breast milk should be started if the infant is conscious. Hypostop Gel, an oral glucose mixture containing 500 micrograms of glucose/mL, can be helpful (if available). Apply 1–2 mL to the oral mucosa.
- If hypoglycaemia persists beyond the first 48 hours of life and requires large infusions of glucose (greater than 8 mg/kg/minute), evaluation for endocrine or metabolic disorders should be considered.

### Meningitis

See p. 353.

### Tetanus

**Do not forget tetanus.** Neonatal tetanus has to be considered if a previously well and still conscious infant starts to develop increasingly frequent muscle spasms 3–14 days after birth. This becomes more relevant if there is any doubt about the way the umbilical cord was managed at birth, or if there is no proof that the mother was ever immunised with tetanus toxoid vaccine. Involuntary muscle contractions are typically triggered by quite light touch or sound, and the hands and jaw are often held firmly clenched.

- **Airway and breathing** are frequently compromised. Secure and maintain the airway, and ensure adequacy of ventilation. **Oxygen** may help if the spasms are causing cyanosis, but in severe cases survival may be dependent on the availability of **respiratory support**, sometimes with **tracheostomy** to protect the airway. Intubation may trigger very dangerous spasm of the airway and must be undertaken by a skilled professional.
- Insert an IV line for drug and antibiotic administration.
- Give high-dose **benzyl penicillin** 60 mg/kg IV one dose every 12 hours in the first week of life, every 8 hours in an infant aged 1–3 weeks, and every 6 hours in an infant over 3 weeks of age. Oral dosing (with **phenoxy-methylpenicillin**) can sometimes be used to complete a course of treatment.
- Give an 150 unit/kg dose of IM human tetanus immunoglobulin. **Other IM injections must be avoided altogether, as they will provoke spasms.**
- If the infant/child is in **acute spasm**, this should be terminated by giving **diazepam by bolus IV infusion over 15 minutes (dose 200 micrograms/kg) or rectally (400 micrograms/kg)**. Ensure that for IV infusion, diazepam is diluted to 100 micrograms/mL, and that extravasation (very irritant) does not occur. Slow and

incomplete absorption means that IM diazepam is not effective. **Always ensure that a bag and mask are immediately available when giving diazepam, in case apnoea occurs.**

- Also give an IV loading dose of 25–40 mg/kg of magnesium sulphate over 20–30 minutes.
- Subsequently give 10–20 mg/kg of magnesium sulphate IV 2- to 4-hourly to control spasms. If this is not available or does not control spasms, give IV diazepam 200 micrograms/kg every 4–6 hours.
- Stop diazepam if magnesium sulphate alone controls the spasms.
- Reduce the dose of diazepam if apnoeic episodes occur.
- **Always have a bag and mask available in case the patient stops breathing as a result of the diazepam plus magnesium.**
- When stable, a nasogastric tube, ideally passed by an anaesthetist, will allow fluids, food and drugs to be given with minimal disturbance. Feeds need to be given frequently (ideally hourly) and in small amounts due to reduced gut motility. **Regular breast milk feeds via a nasogastric tube are essential.**
- Excision of the umbilical stump is not indicated.
- The disease itself does not induce immunity, so after recovery tetanus vaccine must be given for future prevention.
- **Treat any obvious umbilical infection** with an additional broad-spectrum antibiotic.
- **Minimise handling, provide care in a quiet dark room and give frequent small tube feeds.**
- **Immunising the mother** (give two 0.5-mL doses 1 month apart) will prevent a similar tragedy in any future pregnancy.
- **Severe cases may need muscle paralysis and ventilation in a specialist unit (if available).**

### Treatment of neonatal tetanus

- **Airway and Breathing:** Oxygen as needed and tracheostomy may be required.
- Benzyl penicillin.
- Human tetanus immunoglobulin.
- Consider giving diazepam IV or by the rectal route to control spasms (with bag and mask available).
- Magnesium sulphate has been recently shown to help prevent spasms in tetanus.
- Minimise handling.
- Give frequent small tube feeds of breast milk.

### Other causes of neonatal seizures

Rule out any other cause, including biochemical causes other than hypoglycaemia.

**Remember that biochemical disturbance may not be the main underlying problem.** In many infants, the evidence of hypoglycaemia or any other biochemical disturbance is only a sign of another more serious underlying illness. Of these, by far the most important treatable condition is meningitis. Unless the infant is otherwise entirely well it is important not to miss this possibility.

- Other important diagnostic possibilities include hypocalcaemia, hyponatraemia and hypernatraemia. Often a history and clinical features will aid the recognition of these biochemical abnormalities, and a serum level will clinch the diagnosis. Any existing problem will be made worse if hypernatraemia is corrected too rapidly.

- Fits due to hypocalcaemia (a serum total calcium level of < 1.7 mmol/litre), with or without hypomagnesaemia, are generally benign and occur unexpectedly in an otherwise well but hyper-reflexic child more than 2 to 3 days old. As with hypoglycaemia, signs may settle 'on the end of the needle' if the infant is given 1–2 mL/kg of 10% calcium gluconate in equal dilution as a **slow** IV infusion. Such seizures usually respond extremely well to oral supplementation. It is appropriate to investigate the mother for an unrecognised endocrine abnormality (if facilities allow this). **Do not allow IV calcium to go outside the vein as it will cause severe tissue damage.**
- Toxic substances provided by a traditional healer create important causes of seizures and reduced conscious level in neonates in some countries.

### **Bilirubin encephalopathy**

Infants with brain damage due to jaundice are stiff and semi-conscious, but seldom have fits. Signs usually appear quite abruptly 3 to 6 days after birth, but by the time they appear it is too late to initiate treatment.

### **Inborn errors of metabolism**

Other more complex biochemical disturbances are usually associated with metabolic acidosis and progressively deepening coma in a child who was initially well for 1 to 2 days after birth. They are generally too complex to treat without substantial biochemical support, but it may be appropriate to take specimens for later diagnostic evaluation, because many of these conditions are familial and genetically determined. **Pyridoxine deficiency** is one of the few rare treatable conditions.

### **Hypoxic-ischaemic encephalopathy**

This is an abnormal neurological state of infants who have suffered significant lack of oxygen and/or circulation to vital organs before, during or immediately after birth. It is characterised by the following:

- signs of fetal distress in labour, cord blood pH < 7.0, and low Apgar score ( $\leq 3$  at 5 minutes) despite appropriate resuscitation measures
- neonatal neurological abnormalities soon after delivery
- evidence of multi-organ dysfunction such as oliguria (signifying acute tubular necrosis), increased transaminase levels (hepatic necrosis), necrotising enterocolitis or myocardial dysfunction.

### **Hypoxic-ischaemic encephalopathy-related problems in the days after birth**

- **Reduced consciousness and/or convulsions:** treat with phenobarbital and check glucose levels to rule out hypoglycaemia.
- **Apnoea:** this is common after severe perinatal asphyxia, and is sometimes associated with convulsions. Manage with oxygen administered by nasal cannulae and resuscitation with bag and mask.
- **Inability to suck:** feed with expressed breast milk via a nasogastric tube. Beware of delayed emptying of the stomach, which may lead to regurgitation of feeds.
- **Poor motor tone:** the infant may be floppy or have limb stiffening (spasticity).

Sarnat's clinical grading system (see Table 3.4.5) may be

used to help to guide treatment and give some indication of the prognosis.

### **Treatment**

- Treatment is generally supportive, with close attention to monitoring of good respiratory function, glucose levels and fluid balance. Avoid hyponatraemia, which may result from inappropriate antidiuretic hormone secretion and excessive IV hypotonic solutions. Acute renal failure is often present; if so, restrict fluids to measured urine output and gut losses plus 15 mL/kg/24 hours for full term and 24 mL/kg/24 hours for preterm infants (to reflect insensible losses), and avoid giving potassium supplements.
- Seizures are treated as described above. Note, however, that increasing doses of anticonvulsants may precipitate a need for mechanical ventilation and confound the clinical staging criteria below, which apply only to non-sedated infants.
- Keep the axillary temperature at 35.5–36.0°C. Avoid overheating.

Cooling infants for 72 hours under carefully controlled conditions has shown improved neurological outcomes. This should only be undertaken by experienced teams.

### **Prognosis**

The prognosis is good in stage 1, guarded in stage 2 and very poor in stage 3.

About 50% of stage 2 infants will recover without sequelae. Infants in stage 3 will either die or be left severely disabled. A decision must therefore be made with the family about the implementation or continuation of intensive care in such cases.

**TABLE 3.4.5 Sarnat's grading of hypoxemic-ischaemic encephalopathy**

	<b>Mild (stage 1)</b>	<b>Moderate (stage 2)</b>	<b>Severe (stage 3)</b>
Conscious level	Hyper-alert	Lethargic	Stuporose
Muscle tone	Normal	Hypotonic	Flaccid
Seizures	Rare	Common	Severe
Feeding	Sucks weakly	Needs tube feeds	Needs tube feeds or IV fluids
Respiration	Spontaneous	Spontaneous	Absent

### **Management**

Once bacterial meningitis has been excluded, intrapartum hypoxia or birth trauma will turn out to be the underlying problem in most infants presenting with fits in the first 2 to 3 days of life. Most of these infants already look stressed and unwell within a few hours of birth. The onset may be a little more sudden and abrupt in the preterm infant who suffers a sudden intra-ventricular haemorrhage. These infants usually become progressively more stuporose and unresponsive over time, and there is relatively little that can be done to improve the long-term outlook. An attempt should be made to minimise hypoxia, and anticonvulsant treatment is sometimes initiated in the hope that it will reduce the number of apnoeic episodes. Many of these infants are too ill to accept even tube feeds, and, where this is the case, it

may be appropriate to minimise the risk of hypoglycaemia by giving IV glucose. Unfortunately, an infusion of more than 3 mL/kg of 10% dextrose per hour may result in water retention if there is accompanying renal failure. The outlook is fairly bleak for infants who have not recovered and started to feed normally within 1 week of birth.

#### Other less common causes

**Drug-related seizures:** Accidental infiltration of the fetal scalp during the injection of lidocaine into the maternal perineum prior to episiotomy can cause fits simulating intrapartum hypoxia. With supportive treatment there is every prospect of complete recovery.

Some infants born to **drug-dependent mothers** show signs of drug withdrawal, starting 1 to 2 days after delivery. A small minority may have seizures. Minimal handling in a quiet dark room with small frequent feeds and a more gradual withdrawal from the drug to which they have been exposed is the only treatment usually necessary.

**Congenital brain abnormalities:** It is said that up to 10% of otherwise unexplained neonatal seizures are associated with the existence of some underlying cerebral problem (often cortical dysgenesis). Some of these infants will benefit from continuing anticonvulsant treatment.

### Other miscellaneous neonatal problems

#### Gastrointestinal problems

- **Oesophageal atresia** should always be considered in the infant with a history of polyhydramnios or excessive frothy salivation following delivery. Surgery is much more likely to be successful if it can be performed before aspiration pneumonia develops. Pass a large-bore catheter as far down the oesophagus as possible and aspirate frequently. If an X-ray shows that the tube has stopped at the level of the heart and has not entered the stomach, the diagnosis is made. Such an infant needs urgent referral for surgery, with steps taken to suck the blind upper oesophageal pouch clear of all accumulating secretions at least every 15 minutes before and during transfer. Site an IV line and ensure that the infant does not become hypoglycaemic.
- **Severe vomiting**, often associated with abdominal distension, in the first few days of life suggests the existence of a problem that requires referral for surgical review. This is particularly true if the vomit is green (bile stained), as this is suggestive of **duodenal atresia** or bowel obstruction requiring urgent surgical intervention. If severe vomiting develops in a infant who has passed changing stool, the diagnosis of **volvulus**, **pyloric stenosis** or **intussusception** must be considered. Duodenal atresia is more common in infants with Down's syndrome. A paediatric surgical opinion should be sought if available.

#### Necrotising enterocolitis (NEC)

This is a very serious condition with a mortality of approximately 20–40%. Preterm or small-for-dates infants are at increased risk of developing this condition. Prevalence is inversely related to birth weight and gestation. NEC is more common in ill infants. Although it is more common in infants who have received feeds, about 15–20% of affected infants may never have been fed. It is much less common in infants

fed exclusively on human milk. NEC may occur in epidemics due to cross-infection in the nursery.

#### Presenting features

The condition should be suspected in an infant who had started to accept oral feeds and then develops an ileus or becomes lethargic and starts passing a bloody stool. The problem is caused by the sudden focal invasion of bacteria into an area of ischaemic gut, and an abdominal X-ray will often show gas accumulating within the gut wall.

Common signs of NEC include the following:

- abdominal distension or tenderness
- intolerance of feeding
- bile-stained vomit or bile-stained fluid up the nasogastric tube
- blood in the stools.

Features of multisystem failure, such as coagulopathy, petechial haemorrhage, oliguria and haematuria, may be associated with NEC.

#### Investigations

A plain abdominal X-ray may show an abnormal gas pattern in the form of:

- **free intra-peritoneal air**, best seen with a left side down (lateral decubitus) X-ray, where free air may be easily seen overlying the dense hepatic tissue
- **intramural gas (pneumatosis intestinalis)** or **gas in the portal tracts of the liver**.

A complete blood count with differential cell count, blood culture and serum electrolytes should be obtained. Regular weighing, frequent blood pressure measurements, and continuous heart and respiratory rate monitoring are required.

#### Treatment

- Stop all enteral feeds for at least 5 days and provide IV fluids, typically 120 mL/kg/day of 10% glucose with added electrolytes. Adjust fluids as indicated based on weight change, urine output and serum electrolyte values.
- If available, place an orogastric tube on low-pressure continuous suction or leave the tube open with intermittent gastric aspiration (every 4 hours). The goal here is to keep the intestines decompressed. The volume of gastric fluid aspirated is usually relatively small, so replacement fluid is seldom required.
- Start parenteral broad-spectrum antibiotics (usually ampicillin and gentamicin). Because of the probable association of Gram-negative anaerobes, also give metronidazole, especially if there is pneumatosis, perforation or evidence of peritonitis. Broader-spectrum antibiotics may be considered in the presence of extensive disease or poor response, or based on culture results.
- Treat any accompanying shock with Ringer-lactate or Hartmann's solution or colloid, such as 4.5% albumin, 10 mL/kg over 15 minutes. Repeat if necessary.
- Measure the haemoglobin concentration daily and transfuse if it falls below 10 g/dL. If the infant is bleeding, give 1 mg vitamin K IV and fresh-frozen plasma 10 mL/kg (if available).
- The principal goal of therapy is to rest the bowel and treat any contributing or evolving bacterial infection with antibiotics. The duration of this therapy is usually

10–21 days, depending on the severity of the process. Serial abdominal X-ray studies (if available) are indicated early in this disease to monitor for pneumatosis intestinalis or perforation. Ideally, parenteral nutrition should be given at this time in place of simple 10% glucose and electrolytes. Enteral feeds (breast milk) are reintroduced slowly at the end of antibiotic therapy (initially 20–30 mL/kg/day), with careful monitoring for abdominal distension or other signs of obstruction.

In seriously ill infants or infants who do not improve after 48 hours a surgical opinion should be sought.

Even in hospitals with good surgical support, perforation of the bowel is not necessarily an indication for a laparotomy. The conventional surgical approach has been laparotomy with resection of the perforated and adjacent necrotic bowel. A stoma and mucus fistula may be created

with later anastomosis. An alternative surgical approach is to place a peritoneal drain, with laparotomy reserved for later complications, if they develop (e.g. bowel obstruction from adhesions or bowel wall strictures). Although there is some controversy about which approach is best, studies suggest that the overall mortality may be similar with either approach.

Immediate mortality is quite high, but many cases resolve without surgical intervention (although a stricture may occasionally develop about a month later in the affected area of gut), where it is usually possible to reintroduce feeds after about 5 days. An infant who is sucking and showing interest in feeding is usually ready for feeding. Intestinal perforation is generally the main indication for surgical intervention, but the prognosis really depends on whether there is generalised peritonitis and whether some part of the gut has become totally dead and gangrenous.

# Section 4

## Children in hospital

## 4.1

## The differential diagnosis of common or serious presenting symptoms and signs in children

## 4.1.A The child with diarrhoea

There are several groups of causes of diarrhoea. For the management of acute and chronic diarrhoea, see Sections 5.12.A and 5.12.B.

**Causes of diarrhoea****Infective**

- Acute (< 14 days).
- Persistent (> 14 days).

Viruses, bacteria and parasites are the agents of infection.

**Secondary diarrhoea**

- Malnutrition.
- HIV.
- Disaccharide intolerance.
- Malaria.

**Chronic (non-infectious)**

- Food intolerance:
  - Milk protein, soy protein
  - Coeliac disease (gluten sensitivity)
  - Multiple food intolerances.
- Inflammation:
  - Crohn's disease
  - Ulcerative colitis.
- Pancreatic disease:
  - Cystic fibrosis
  - Shwachman syndrome (cyclic neutropenia).

**Miscellaneous**

- Non-specific 'toddler's diarrhoea'.
- Irritable bowel syndrome.
- Excessive intake of squash/fruit drinks.

**History**

- Duration of symptoms.
- Nature of stool (e.g. fatty, floating, watery, with blood).
- Number per day.
- Dietary intake.
- Other accompanying symptoms.
- History of foreign travel.

- Possible food poisoning exposure.

**Examination**

- Chart growth/nutritional status.
- Document degree of dehydration.
- Look for fever, anaemia, lymphadenopathy, hepatosplenomegaly and finger clubbing.
- Look for signs of vitamin or mineral deficiency, oral ulcers and anal fissures.
- Look for candidiasis.

**Investigations**

TABLE 4.1.A.1 Investigations in the child with diarrhoea

Investigation	Looking for:
Stool Microscopy (warm stool for <i>Entamoeba histolytica</i> ), white blood cell count (WBC), red blood cell count (RBC), ova, parasites Culture	Infection
Stool pH (< 5.5) Clinitest tablets or Benedict's solution	Lactose intolerance
Stool Fat globules	Pancreatic disease
Hydrogen breath test	Lactose intolerance
Blood culture (high temperature, rigors)	Septicaemia (e.g. <i>Salmonella</i> )
Urea, creatinine, electrolytes (if oliguria)	Haemolytic uraemic syndrome Hyponatraemia/ hypernatraemia
Full blood count	Hidden bleeding
Albumin	Chronic diarrhoea
X-ray of abdomen, ultrasound scan	Ileus, bowel perforation
Urine microscopy	Haemolytic uraemic syndrome

## 4.1.B The child with jaundice

**Causes of jaundice**

- Neonatal jaundice (see Section 3.4).
- Excess haemolysis (pre-hepatic):
  - sickle-cell disease (see Section 5.11.B)
  - thalassaemia (see Section 5.11.C)
  - hereditary spherocytosis (see Section 5.11.C)

- malaria (see Section 6.3.A.d).
- Liver disease (see Sections 5.7.A and 5.7.B):
  - hepatocellular
  - obstruction to bile secretion
  - infective hepatitis
  - acute liver failure
  - chronic liver disease.

### History

- Family history of hereditary haemoglobinopathy or liver disorder.
- Blood transfusion.
- Anorexia.
- Abdominal pain.
- Pruritus.
- Colour, nature and contents of stools and urine.

### Examination

- Assess growth/nutritional state.
- Look for skin signs of chronic liver disease (e.g. spider naevi, clubbing, leuconychia, liver palms, scratches from pruritus).
- Assess liver and spleen (for enlargement and tenderness).
- Check for anaemia.

- Check for ascites.
- Look for frontal bossing or maxillary overgrowth (sickle-cell disease or thalassaemia).
- Observe colour of stool and urine.

### Investigations

TABLE 4.1.B.1 Investigations in the child with jaundice

Investigation	Looking for:
Full blood count and film	Anaemia
Reticulocytes	Haemolysis
Haemoglobin electrophoresis	Sickle-cell disease and thalassaemia
Urine	Bilirubin and urobilinogen
Liver function tests: Liver transaminases	Bilirubin conjugated (liver disease or biliary obstruction) or unconjugated (haemolysis) Hepatitis
Serology	Identification of viral causes
Coagulation	Liver failure
Auto-antibodies	Chronic active hepatitis

## 4.1.C The child with lymphadenopathy

### Common causes of generalised lymphadenopathy

- HIV infection.
- Infectious mononucleosis.
- Tuberculosis (TB).
- Leukaemia.
- Hodgkin's and non-Hodgkin's lymphoma.
- Cytomegalovirus (CMV), toxoplasmosis.
- African trypanosomiasis.

### Infective causes of local lymphadenopathy

- Local skin (especially scalp) infections.
- Tuberculosis (TB), see Section 6.1.N.
- Environmental mycobacteria.
- Cat scratch disease.

### History

- Known epidemiology of HIV and trypanosomiasis in the area.
- Contact with TB.
- Chronic ill health (e.g. malignancy, HIV, TB).
- Determine whether nodes are static or increasing in size.

### Examination

- Chart growth and nutritional status.
- Check for fever.
- Check for liver or spleen enlargement.
- Check for purpura or anaemia.
- Check for *Candida* infection.
- Conjunctivitis, red cracked lips and persistent high fever, if present, suggest possible Kawasaki's disease.

TABLE 4.1.C.1 Investigations in the child with lymphadenopathy

Investigations	Looking for:
Full blood count	Atypical lymphocytes, leukaemic picture
Thick blood film	Trypanosomiasis
Bone marrow	Malignancy
HIV tests	HIV
Paul-Bunnell test	Infectious mononucleosis (positive 60%)
Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)	Infection, TB
Mantoux test	TB, environmental mycobacteria
Serology	Epstein-Barr virus, CMV, toxoplasmosis
Chest X-ray	TB, malignancy
Lymph node biopsy	Diagnostic (lymphomas, etc.)

#### 4.1.D The child with abdominal pain

**Note that this group includes adolescent girls who may be pregnant.** – Peptic ulcer (upper abdominal pain, vomiting, blood in vomit/melaena stool).

#### Causes of acute and chronic abdominal pain

- Idiopathic:
  - Irritable bowel syndrome (intermittent stool variability).
  - Migraine (headaches with photophobia).
- Psychogenic.
- Gastrointestinal:
  - Appendicitis (central pain moving to right lower abdomen).
  - Gastroenteritis (contact history, watery and/or bloody diarrhoea).
  - Intussusception (redcurrant-jelly stool, spasms of pain, mass in left lower abdomen).
  - Oesophagitis (retrosternal pain).
  - Inflammatory bowel disease (loose bloody, mucousy stool, weight loss, systemically unwell).
  - Constipation (hard, painful infrequent stool).
  - Bowel obstruction (bile-stained vomiting, abdominal swelling).

**TABLE 4.1.D.1 Investigations in the child with abdominal pain**

Investigation	Looking for:	
Full blood count	Anaemia, eosinophilia, infection	
Erythrocyte sedimentation rate (ESR)/C-reactive protein (CRP)	Inflammation	
Urea, electrolytes	Renal disease	
Amylase	Pancreatitis	
Liver function tests	Liver dysfunction, hepatitis	
Urine stick test: blood, protein, glucose	Glomerulonephritis, nephritic syndrome, diabetes, urinary system calculi	
Urine microscopy for organisms, casts, culture	Infection, glomerulonephritis	
Stool, ova, cysts, parasites, white blood cell count (WBC) and red blood cell count (RBC)	Infestation, dysentery, inflammatory bowel disease	
Pregnancy test	See Section 2	
Ultrasound scan (abdomen and pelvis), X-ray (straight abdominal film)	Bowel obstruction, constipation, lead poisoning, ovarian cyst, pregnancy, calculi	
Barium studies and endoscopy	Peptic ulcer, inflammatory bowel disease	
Barium studies and endoscopy	Peptic ulcer, inflammatory bowel disease	
<i>Differentiating between organic and non-organic (psychological) abdominal pain</i>		
	<i>Organic</i>	<i>Non-organic</i>
Nature of pain	Day and night	Periodic, often peri-umbilical
History	Weight loss/reduced appetite Lack of energy Fever Change in bowel habit Urinary symptoms Intestinal symptoms Vomiting: <ul style="list-style-type: none"> <li>● bile stained</li> <li>● continuous</li> <li>● blood</li> </ul> Rectal bleeding	Migraine School and family problems Isolated vomiting, not bile stained
Examination	Appears ill Weight loss Distension Absent or accentuated bowel sounds Shock Abdominal mass: <ul style="list-style-type: none"> <li>● constipation</li> <li>● other</li> </ul>	Normal, thriving

- Food intolerance (e.g. milk protein, gluten) (dietary history).
- Meckel's diverticulum.
- Henoch–Schönlein purpura (purpuric rash and/or arthropathy).
- Sickle-cell disease (history, anaemia).
- Urinary tract:
  - Infection.
  - Calculi.
  - Hydronephrosis.
- Liver:
  - Hepatitis.
- Pancreas:
  - Inflammation (pancreatitis).
- Malignancy:
  - Lymphoma.
- Gynaecological:
  - Dysmenorrhoea.
  - Pelvic inflammatory disease.
  - Ovarian cyst.
- Pregnancy related (see Section 2).
- Respiratory:
  - Pneumonia/pleurisy.
- Trauma.
- Poisoning:
  - Lead.

### 4.1.E The child with anaemia

Anaemia, especially that due to iron deficiency, is very common in resource-limited communities. Anaemia can be caused by a combination of inadequate nutrition and recurrent infections, such as malaria. Intestinal parasites such as hookworm are important causes. Genetic disorders such as sickle-cell disease and thalassaemia should always be considered in relevant ethnic groups. Acute worsening of anaemia may present as heart failure in young children.

For children aged < 6 years, normal haemoglobin concentration is > 11.0g/dL (haematocrit is > 33%), see Section 5.11.A.

- Moderate anaemia: haemoglobin concentration is 6–9.3g/dL.
- Severe anaemia: haemoglobin concentration is ≤ 6g/dL, severe pallor (palmar/conjunctival), may have heart failure; gallop rhythm, enlarged liver and pulmonary oedema (fine basal crepitations in the lungs).

#### Causes of anaemia

##### Decreased production

- Prematurity: at 6–8 weeks postpartum.
- Hypochromic: iron deficiency (diet, blood loss, chronic inflammation).
- Normochromic: chronic infection or inflammation:
  - nutritional: malnutrition, scurvy
  - infiltration: leukaemia, malignancy
  - metabolic: renal and liver disease.
- Megaloblastic:
  - folic acid deficiency: infection, coeliac disease, anti-convulsants, haemolysis
  - vitamin B<sub>12</sub> deficiency: intestinal resections, Crohn's disease, vegan diet.
- Hypoplastic: sickle-cell crises, drugs (e.g. chloramphenicol), malignancy.

##### Increased haemolysis

- Haemoglobinopathies: sickle-cell disease, thalassaemia major.
- Non-immune: drugs, infection, hypersplenism, burns, haemolytic uraemic syndrome, disseminated intravascular coagulation, porphyria, snake venoms.
- Enzyme deficiency: drug-induced and spontaneous glucose-6-phosphate dehydrogenase (G6PD)

deficiency, glutathione synthetase deficiency, pyruvate kinase deficiency.

- Immune: Rhesus and ABO incompatibility, autoimmune (e.g. reticuloses), *Mycoplasma* infection, systemic lupus erythematosus, drugs.
- Membrane defects: spherocytosis, elliptocytosis, stomatocytosis, erythropoietic porphyria, abetalipoproteinaemia.

#### Blood loss

- Perinatal:
  - placental and cord accidents
  - foeto–maternal, twin-to-twin transfusions
  - birth injury (e.g. cephalhaematoma, sub-aponeurotic haemorrhage, severe bruising)
  - haemorrhagic disease of the newborn.
- Epistaxis.
- Trauma.
- Alimentary tract: haematemesis, rectal bleeding, hookworm.
- Blood clotting disorder (e.g. haemophilia, thrombocytopenia).
- Renal tract: haematuria.

#### History

- Symptoms of anaemia: lethargy, tiredness, shortness of breath on exertion, poor growth.
- Obvious blood loss: epistaxis, haematemesis, haematuria, blood in stools.
- Assess the diet (e.g. inadequate weaning diet).
- Steatorrhoea.
- Chronic infection, inflammation.
- Drugs: especially antibiotics, antimalarial drugs, anti-convulsants, analgesics, cytotoxic agents.

#### Examination

- Chart growth/nutritional state.
- Conjunctivae, nails and palms for pallor.
- Stomatitis.
- Jaundice.
- Bruising, lymphadenopathy or petechiae.
- Hepatosplenomegaly.
- Tachycardia, flow murmur, cardiac failure.

## Investigations

**TABLE 4.1.E.1** Investigations in the child with anaemia

Investigation	Looking for:
Full blood count	Haemoglobin concentration, white blood cell count, platelet count
Blood film	Red blood cell morphology, malaria, target cells, haemolysis
Haemoglobin electrophoresis	Sickle-cell disease, thalassaemia
Mean corpuscular volume (MCV), reticulocytes	Iron deficiency, haemolysis
Coombs' test	Haemolysis
Bone marrow	Leukaemia, malignant infiltration, aplasia
Bilirubin, liver function tests	Direct/indirect bilirubin
Urinalysis	Red blood cells, casts, bacteria, white blood cells, protein, culture
Serum ferritin	Iron stores
Barium meal/endoscopy	Inflammatory bowel disease
Platelets and clotting	Coagulation disorder
Stool microscopy, culture and occult blood	Hookworm (egg count), gastrointestinal blood loss

### 4.1.F The child who is vomiting

The history of the acute, recurrent or chronic nature of this symptom indicates the approach to the diagnosis.

#### Common causes (depending on age)

##### Infants

- Gastroenteritis.
- Gastro-oesophageal reflux (distinguish from possetting).
- Overfeeding.
- Bowel obstruction:
  - pyloric stenosis
  - intussusception
  - congenital bowel anomalies.
- Infection:
  - urinary tract in particular
  - meningitis
  - otitis media
  - pertussis.
- Poisoning:

##### Children

- Gastroenteritis.
- Appendicitis (with pain).
- Infection:
  - especially urinary tract
  - meningitis (including TB)
  - malaria.
- Bowel obstruction.
- Ingestion of drugs or poisons.
- Migraine.
- Pregnancy.
- Bulimia (but rarely does a child admit this).
- Raised intracranial pressure (RICP).
- Hypertension.
- Diabetic ketoacidosis.

##### History

- Accidental drug ingestion.
- Check whether it is vomiting, regurgitation or possetting (especially in an infant).
- Is it associated with coughing or a whoop?
- Is it projectile?
- Does it contain blood or bile?
- Is there any diarrhoea or constipation?
- Is there abdominal pain?
- Are there urinary or ear symptoms?
- Is there a family history of migraine?
- Are there difficulties in coordination during physical activity? Consider the possibility of a middle ear or brainstem problem.

##### Examination

- Does the child look ill?
- Is the child febrile? Is there neck stiffness, a full fontanelle and/or a rash?
- Measure the head circumference, especially in infants, and check fontanelles and sutures.
- Is the child dehydrated? Is there an odour?
- Assess growth and nutritional status.
- Examine vomit:
  - bile-stained vomit suggests bowel obstruction
  - blood (coffee grounds).
- Full examination (include blood pressure, fundoscopy and anorectal examination as indicated).
- Abdomen:
  - test feed for pyloric stenosis: swelling or visible peristalsis
  - tenderness or mass
  - check whether bowel sounds are present and, if so, what they are like.

## Investigations

**TABLE 4.1.F** Investigations in the child who is vomiting

Investigation	Looking for:
Urine microscopy	Urinary tract infection
Full blood count	Infection
Thick film	Malaria
Urea and electrolytes	Pre-renal or renal failure, pyloric stenosis
Blood culture	Infection
Lumbar puncture	Meningitis
Stool microscopy and culture	Ova, cysts, parasites, bacteria and viruses
Liver function tests	Hepatitis
Abdominal ultrasound	Masses, obstruction, free fluid
Straight abdominal X-ray/chest X-ray	Bowel obstruction, free air
Barium studies and/or endoscopy	Specific diagnosis
Pregnancy test	Pregnancy
Mantoux test	TB, meningitis
Brain imaging	Raised intracranial pressure

## 4.1.G The child with a rash

### Causes of a rash

#### Macular rash

- Viral infections such as measles, sometimes meningococcal infection.
- Juvenile rheumatoid arthritis.
- Erythema marginatum: rheumatic fever.

#### Papular (vesicles, pustules) or bullae (blisters of various sizes)

- Chickenpox.
- Herpes simplex.
- Impetigo.
- Scabies.

#### Purpuric, petechial, ecchymosis

- Meningococcal disease.
- Henoch–Schönlein purpura.

- Dengue fever.
- Thrombocytopenia.

#### Desquamation with or without mucosal involvement

- Scalded skin syndrome.
- Toxic epidermal necrolysis.
- Kawasaki disease.
- Post-scarlet fever.
- Post-toxic shock syndrome.
- Stevens–Johnson syndrome.
- Epidermolysis bullosa.

#### Erythema multiforme

- Allergic reaction to drug or infection.
- Stevens–Johnson syndrome if very severe (then with bullae and mucous membrane redness).

**TABLE 4.1.G.1** Investigations in the child with a rash

Investigation	Looking for:
Full blood count, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP)	Systemic bacterial infection (e.g. meningococcal disease) Kawasaki disease Thrombocytopenia
Blood culture	Bacterial infection
Skin swab	Bacterial infection
Skin scraping	Scabies
Throat swab and antistreptolysin O titre (ASOT)	Streptococcal infection
Urinalysis (red blood cell count, casts, protein)	Nephritis (e.g. Henoch–Schönlein purpura) or connective tissue disorders
Skin biopsy	Epidermolysis bullosa
Auto-antibodies	Connective tissue disorders

**Erythema nodosum**

Lesions begin as flat, firm, hot, red, painful lumps approximately 2.5 cm across. Within a few days they may become purplish, then over several weeks fade to a brownish, flat patch. Erythema nodosum is most common on the shins, but it may also occur on other areas of the body (buttocks, calves, ankles, thighs, and arms).

- Streptococcal disease.
- TB.
- Connective tissue disorders.
- Sarcoidosis.
- Drugs.

**4.1.H The child with failure to thrive**

**Approach to failure to thrive**

- Failure to thrive is due to inadequate delivery of nutrients to developing tissues.
- It is usually manifested by failure to gain weight as expected.
- In extreme circumstances, height (length) and head circumference may be affected. Plot the mid-parental height.
- The majority of cases are related to gastrointestinal disorders: poor intake/malabsorption.
- Observe feeding, mother's interaction, child's behaviour, vomiting, diarrhoea and weight gain before embarking on investigations.
- Investigations should take place when a likely system and/or disorder has been identified.
- Always remember the possibility of child abuse.
- See relevant sections on gastroenterology, chronic infections, organ failure, hyperimmune disorder.

**Failure to thrive: gastrointestinal disorders**

- Oropharynx: cleft palate.
- Oesophagus: incoordination of swallowing (e.g. cerebral palsy).
- Stomach:
  - Gastro-oesophageal reflux
  - Pyloric stenosis.
- Digestion:
  - Pancreas: cystic fibrosis
  - Liver: cirrhosis.
- Small gut disorders:
  - Milk protein intolerance
  - Coeliac disease
  - Carbohydrate malabsorption
  - Protein-losing enteropathy
  - Short gut syndrome
  - Crohn's disease.
- Large gut disorders:
  - Ulcerative colitis
  - Crohn's disease
  - Hirschsprung's disease.

**Causes of failure to thrive**

**TABLE 4.1.H.1 Mechanisms of failure to thrive**

Mechanism	Systems involved:
Inadequate intake	Anorexia Breastfeeding failure Feeding mismanagement Swallowing disorders
Loss	Vomiting Diarrhoea Malabsorption
Structural dysfunction of organs	Brain (cerebral palsy, learning difficulties) Respiratory Cardiac Urinary tract Gastrointestinal tract
Increased requirement for nutrients or metabolites	Infection Connective tissue disorders Immune disorders
Failure of end-organ response	Metabolic (e.g. amino acid disorders, organic acid disorders) Endocrine (e.g. thyroid disorder) Malignancy Chromosomal abnormalities
Emotional and/or psychological	Parental problem: <ul style="list-style-type: none"> <li>● Neglect</li> <li>● Abuse</li> <li>● Family dysfunction</li> </ul> Child problem: <ul style="list-style-type: none"> <li>● Feeding/behaviour disorders</li> <li>● Anorexia nervosa</li> <li>● Bulimia</li> </ul>

## 4.1.1 The child with fits, faints and apparent life-threatening events (ALTEs)

### Common causes of fits, faints and ALTEs

- Febrile convulsions.
- Epileptic seizures.
- Hypoglycaemia.
- Infantile apnoea/hypoxaemic events.
- Premature birth.
- Respiratory infection (e.g. bronchiolitis, pertussis).
- Sleep-related upper airway obstruction (see Section 5.1.D).
- Vaso-vagal episodes (simple faints).
- Cardiac arrhythmias.
- Cyanotic breath-holding.
- White breath-holding (reflex anoxic seizures).

### History

- Cyanosed:
  - Occurs with infant apnoea
  - Some febrile convulsions/epileptic seizures.
- Extreme pallor:
  - Vasovagal
  - Cardiac arrhythmia.
- Trauma/illness related (especially to head): white breath-holding.
- Emotional upset: cyanotic breath-holding.
- Snoring/inspiratory stridor during sleep, often with chest

recession and restlessness: sleep-related upper airway obstruction (see Section 5.1.D).

- Exercise related: cardiac arrhythmia (see Section 5.4.C).
- Drug abuse.
- Fabricated or induced illness (see Section 7.6).
- Convulsions (see Sections 5.16.D and 5.16.E).
- Preterm infant in first few weeks (see Section 3.4).
- Respiratory illness.
- Diabetes/starvation (see Section 5.8.A).

### Examination

- Growth and nutritional status.
- Signs of respiratory infection.
- Signs of anaemia (associated with cyanotic breath-holding and infant apnoea).
- Signs of fever.
- Neurological examination (to exclude or identify neurological abnormalities).
- History of breath-holding (see Section 5.16.I).
- Signs of cardiac disorder.
- Blood pressure lying and standing, for vasovagal episodes.
- Mouth and throat for enlarged tonsils or retrograde/small mandible for predisposition to sleep-related airway obstruction (the latter is also common in sickle-cell disease and Down's syndrome).

## Investigations

TABLE 4.1.1.1 Investigations in the child with fits, faints and ALTEs

Investigation	Looking for:
Full blood count	Anaemia, infection
Blood glucose concentration	Hypoglycaemia
Haemoglobin electrophoresis	Sickle-cell disease
ECG	Wolf–Parkinson–White syndrome and long QT syndrome Structural lesion of heart
Oxygen saturation during sleep	Low baseline SaO <sub>2</sub> predisposes to infant apnoea/hypoxaemic events Should be > 94% (at sea level) (see Section 9, Appendix) Especially common in preterm infants and infants aged < 6 months with respiratory infection
Video (if available) during sleep (parents can do this with a mobile phone)	Sleep-related upper airway obstruction
EEG and video during episode	Epileptic cause
Chest X-ray	Lung disease in infantile apnoea/hypoxaemic events

## 4.1.J The child with generalised oedema

The major differential diagnosis relates to the presence or absence of hypoalbuminaemia.

### Common pathophysiology

- Heart failure:
  - Jugular vein pressure increased, liver enlarged, triple rhythm, murmurs, basal lung crepitations.
  - Cardiovascular disorders.
  - Severe anaemia.
- Acute glomerulonephritis.
- Low serum albumin:
  - Nephrotic syndrome.
  - Liver disorders.
  - Protein-losing enteropathy (e.g. malabsorption, intestinal lymphangiectasia).
  - Malnutrition.
- Increased vascular permeability:
  - Anaphylaxis (history).
  - Shock.
- Over-hydration (particularly excessive IV solutions such as 5% dextrose).

### History

- Shortness of breath, chest pain (pericarditis).
- Blood in urine (nephritis).
- Facial swelling (nephrotic syndrome or acute glomerulonephritis, anaphylaxis).
- Nutritional history (malnutrition).
- Gastrointestinal symptoms (protein-losing enteropathy).
- Exposure to allergen or sting (anaphylaxis).
- Excess and/or inappropriate IV fluids.

### Examination

- Chart growth and nutritional status, and look for features of kwashiorkor and vitamin deficiencies.
- Cardiovascular system, including blood pressure.
- Rash with or without wheeze/stridor (anaphylaxis).
- Widespread purpuric rash/very ill patient (meningococcal septicaemia).
- Jaundice or other signs of liver disease.
- Anaemia and lymphadenopathy.
- Enlarged liver and/or spleen.
- Ascites (especially nephrotic syndrome). Ascites may be transudate (e.g. nephrotic syndrome) or inflammatory (e.g. TB, peritonitis). Abdominal malignancy may cause ascites and obstructive oedema of the lower limbs.

### Investigations

TABLE 4.1.J.1 Investigations in the child with generalised oedema

Investigation	Looking for:
Full blood count	Anaemia
Urinalysis: ● Dipstix: protein, blood Bilirubin Microscopy: red blood cell count, casts	Nephrotic syndrome, nephritis Liver disease Nephritis
Stool	Hookworm
Serum albumin	Low albumin levels
Imaging: abdominal ultrasound	Hepatosplenomegaly Malignancy Ascites (transudate/inflammation)
Echocardiogram	Cardiac disorders
Ascitic fluid Colour: clear, cloudy, bloody, chylous Cells: white blood cell count, malignant cells Protein: < 25 grams/litre transudate > 25 grams/litre exudate Ziehl–Neelsen stain Culture:	Inflammation (e.g. from TB) Infection, malignancy  TB TB/general

## 4.1.K The child with headaches

- Headaches are common in children.
- They should be taken seriously if they persist.
- Their prevalence increases with age.

### Acute headache

Common causes of acute headache include the following:

- Febrile illness.
- Meningitis/encephalitis.
- Acute sinusitis: pain and tenderness (elicited by gentle percussion) over the maxilla; there is usually a history of preceding upper respiratory tract infection and a postnasal discharge may be present.
- Head injury.
- Raised intracranial pressure.
- Intracranial haemorrhage (severe sudden headache, with rapid loss of consciousness).
- Migraine.

A careful history and physical examination will usually reveal the cause.

### Raised intracranial pressure (RICP)

- Headache may be sudden or gradual in onset, often occipital in location and becomes progressively more severe.
- Made worse by lying down (in contrast to migraine and tension headache, which are relieved by lying down), by coughing, stooping and straining, and may wake the child from sleep.
- Worse in the morning and often associated with nausea and vomiting.
- Other signs of raised intracranial pressure may be present, such as impaired consciousness, bilateral abducens sixth nerve palsies (false localising sign) and, when severe, bradycardia and hypertension.
- Papilloedema is a late sign.
- Localising neurological signs may be present, depending on the site of the lesion. Ataxia suggests a posterior fossa tumour; cranial nerve palsies suggest a brainstem lesion; visual field defect suggests a craniopharyngioma; unequal pupils suggest a supratentorial lesion such as subdural haematoma.
- In endemic areas, cerebral malaria and neurocysticercosis are important causes.

### Benign intracranial hypertension

- Raised intracranial hypertension without any space-occupying lesion or obstruction of the CSF.
- Can be caused by drugs (corticosteroids, especially during withdrawal, ampicillin, nalidixic acid) and sagittal sinus thrombosis.
- Most without cause, especially in young adolescent girls.

### Recurrent or chronic headaches

Two common causes are anxiety (tension) and migraine.

#### Tension headache

- This affects around 10% of schoolchildren.
- Typically the headache is symmetrical and described as hurting or aching over the cranial vault.
- The headache develops gradually and is not associated with other symptoms.
- It is induced by stress (e.g. due to school examinations, assignments, etc.) and can coexist with migraine in the same child.
- It may be caused by isometric contraction of the head and neck muscles in anxious children.

#### Migraine

See Section 5.16.J.

#### Conversion (hysterical) headache

- Headache can be a conversion symptom used by the child to gain attention.
- The initial headache may have been due to an organic cause (e.g. febrile illness), but its persistence and recurrence are due to psychological factors.

#### Management of headaches

See also Section 5.16.A relating to an acute onset of headache.

- A detailed history and a careful full examination should be undertaken in order to rule out serious underlying causes.
- Investigations are rarely needed.
- X-ray of the sinuses will confirm sinusitis and CSF examination will confirm meningitis/encephalitis.
- A CT scan of the brain is essential if raised intracranial pressure is suspected or if there are localising neurological signs.
- Treatment is directed at the underlying cause and at pain relief.
- Benign intracranial hypertension can be alleviated with corticosteroids (dexamethasone 0.6 mg/kg/day in two divided doses) and/or acetazolamide (8 mg/kg 8-hourly, increasing to a maximum of 32 mg/kg/day) and repeated lumbar puncture.
- For tension and conversion headaches, counselling and stress management are important.

#### Relief of pain

For most headaches, simple analgesics alone or combined with non-steroidal anti-inflammatory drugs (NSAIDs) will suffice (e.g. paracetamol with or without ibuprofen). Remember that frequent or recurrent use of analgesics can **cause** headaches.

## 4.1.1.L The child with respiratory distress

### Presenting features

- Tachypnoea.
- Increased effort of breathing: tracheal tug, inter/sub-costal recession.
- Poor feeding, sleep disturbance.
- Grunting.
- Unable to speak in sentences.
- Positioning: sitting up/forward, neck extension, splinting chest.
- Tachycardia.
- Altered mental state: agitation (hypoxaemia)/drowsiness (hypercapnia).
- Pallor/cyanosis (late sign).

### Causes

TABLE 4.1.1.L Causes of respiratory distress

Common cause	Findings on examination
Upper airway obstruction	Stridor, hoarse voice, drooling, sitting up, head held forward
Inhaled foreign body	Suggestive history, tracheal deviation, unilateral hyper-expansion on chest X-ray
Asthma	Hyper-expansion, wheeze, reduced air entry, reduced peak flow, hypoxaemic ( $\text{SaO}_2 < 94\%$ at sea level)
Bronchiolitis	Inspiratory crackles, wheeze, hypoxaemic ( $\text{SaO}_2 < 94\%$ at sea level)
Pneumonia	Fever, grunting, pleuritic or abdominal pain, signs of consolidation or effusion. Clubbing indicates chronic disease (e.g. bronchiectasis)
Tuberculosis	Contact history, lymphadenopathy, fever, weight loss
Pneumothorax	Unilateral hyper-resonance on percussion, tracheal deviation, apex displacement
Cystic fibrosis	Recurrent respiratory infections, failure to thrive, fat malabsorption, family history
Heart failure/pulmonary oedema	Sweaty, gallop rhythm, hepatomegaly, heart murmurs, basal lung crepitations, raised jugular venous pressure (JVP)
Sickle-cell disease/acute chest syndrome	Hypoxaemia ( $\text{SaO}_2 < 94\%$ at sea level), chest pain

### Investigations

TABLE 4.1.1.L.2 Investigations in the child with respiratory distress

Investigation	Looking for:
Oxygen saturation (pulse oximeter)	Hypoxaemia $< 94\%$ at sea level
Chest X-ray	Lung disorder
ECG, echocardiogram	Heart disorder
Mantoux	TB
Erythrocyte sedimentation rate (ESR), C-reactive protein (CRP)	Inflammation
Full blood count	Infection
Haemoglobin electrophoresis	Sickle-cell disease
Bronchoscopy	Foreign body
Sweat test or DNA analysis	Cystic fibrosis

### 4.1.M The child with pyrexia (fever) of unknown origin (PUO)

#### Definition

Pyrexia of unknown origin (PUO) is defined as a minimum temperature of at least 38.3°C for 1–3 weeks with at least 1 week of hospital investigation. It is very important to determine whether fever is continuous or recurrent by plotting it on a chart (see Section 9, Appendix).

#### Baseline investigations

- Full blood count and film.
- Erythrocyte sedimentation rate (ESR)/C-reactive protein (CRP).
- Blood cultures.
- Thick film and/or rapid diagnostic test (RDT) for malaria (endemic areas/recent foreign travel).
- Mantoux test.
- Epstein–Barr and other viral serology.
- Urine microscopy/culture.
- Chest X-ray.
- Lumbar puncture (if meningeal signs are present).

TABLE 4.1.M.1 Relatively common causes of pyrexia of unknown origin in children

	Cause	Specific investigation
Bacterial infection	Tuberculosis <i>Campylobacter</i> Typhoid Brucellosis Cat scratch disease Rheumatic fever	Chest X-ray, tuberculin skin test, lumbar puncture Stool culture Blood and stool culture; serology, but unreliable. Clinical signs Serology Lymph node biopsy Throat swab, anti-streptolysin O titre (ASOT)
Localised infection	Hidden abscess Bacterial endocarditis Osteomyelitis Pyelonephritis Cholangitis	Abdominal ultrasound scan Blood cultures, echocardiogram X-ray, bone scan Urine microscopy and culture Abdominal ultrasound scan
Spirochaete infection	<i>Borrelia</i> Syphilis Leptospirosis	Serology Serology Serology blood and urine culture
Viral infection	HIV Epstein–Barr virus	Serology Serology, Paul-Bunnell test, blood film; atypical lymphocytes
<i>Chlamydia</i> infection	<i>Psittacosis</i>	Serology
Rickettsial infection	Q fever	Serology
Fungal infection	Histoplasmosis	Serology and culture
Parasitic infection	Giardiasis Malaria Trypanosomiasis Toxoplasmosis Toxocarasis Leishmaniasis	Fresh stool microscopy Blood film, rapid diagnostic test Thick blood film Serology Serology, blood eosinophil count Serology, bone marrow
Connective tissue disorder	Juvenile idiopathic arthritis Systemic lupus erythematosus	Auto-antibodies Auto-antibodies
Neoplasia	Lymphoma Leukaemia Neuroblastoma Wilms' tumour	Node biopsy Blood film/bone marrow Urinary VMA Ultrasound or CT scan
Miscellaneous	Kawasaki disease Inflammatory bowel disease Fabricated illness	Erythrocyte sedimentation rate (ESR), platelets, clinical findings Barium studies/endoscopy Surveillance

## 4.2

## Caring for children and young people in hospital

## 4.2.A Nursing sick children

**BOX 4.2.A.1 Key points**

- Children are not 'small adults'.
- Good basic care is essential and may reduce the need for further intervention.
- Have a system for allocation of nurses to patients. Any system is better than no system.
- Keep the sickest children in the place where they can be seen most easily.
- Provide information for children and their families and involve them in decision making. This reduces anxiety, improves their compliance and will make your care more effective.
- Empower the parents to provide care. This is better for the child and will help you.

**Introduction**

The spectrum of professional nursing care is vast, and ranges from the challenges of meeting basic human needs, key assessment and monitoring roles, to complex case management. Irrespective of the particular arena of nursing, the priority is to ensure that healthcare retains a focus on humane actions that increase the quality and effectiveness of care.

Much can be achieved by a skilled 'child-friendly' approach that leads to minimal intervention and trauma and includes the family as caregivers and, where appropriate, the child in decision making.

Children are unique, both as individuals and as a group, with rights enshrined by the UN Convention on the Rights of the Child (UNCRC) 1989. They are not 'small adults' – they have physical, psychosocial and physiological needs and responses that are different from those of adults. Effective nursing requires knowledge of these differences (recording vital signs means little without an understanding of the normal range).

**Role and education of nurses**

The role and status of nurses, together with the education that they receive, varies widely, although there are steps to increase standardisation. Many countries provide no specific training in the nursing of sick children. Good care is often delivered despite many challenges, but optimum care can only be consistently achieved by education and professional accreditation that relates specifically to the holistic physiological, physical and psychosocial care of the child and their family.

The increasing demands of healthcare sometimes result in an overlap of roles undertaken by nursing and medical staff. In many situations, the nurse may be the most experienced or skilled healthcare professional present.

**The value of involving families in care**

Hospitalisation is often a frightening experience in an unfamiliar environment, where the family no longer have their usual control over everyday life. Nurses should aim to return much of that control back to the child and family, and work to ensure that they receive the best care possible, given the environment and resources at their disposal.

The potential benefit and contribution of the parents cannot be overestimated. If the child's family is available, they should be encouraged and supported to participate in the child's care. Parents provide valuable information about what is normal for their child and how this may have changed. Since they know their child best they are often the first to notice small changes in his or her condition that may later prove significant. However, this critical knowledge can only be utilised for the benefit of the child if the contribution of families is recognised and valued.

**Nurses as communicators and advocates**

Nurses are central to communication between the multi-disciplinary team and the family. They have a key role as an active advocate for the child, although this is often easier to say than to do. The hierarchical cultures in some healthcare systems can conspire against this, often to the detriment of the child. It is the responsibility of all healthcare professionals to promote an environment in which the views of all involved in the child's care, but especially the views of the child and their parents, are heard.

Inappropriate and unnecessary painful interventions and investigations, long hospitalisations without good reason and unnecessary separations from the family cannot be justified and are an abuse of children's rights under the UNCRC. Hospitals and other healthcare settings present numerous potential risks to children. It is the responsibility of every healthcare facility to be a place of safety, and of every healthcare worker to protect the best interests of children.

**Basic nursing care****Organising care**

In many places a small number of nurses have to look after many children. This makes it very difficult to provide good care, and this is a major (and sometimes overwhelming) challenge for nurses.

It is important to organise nursing care well and efficiently, particularly when resources and the number of nurses are low. Even when there are good resources, poor organisation will result in suboptimal and inequitable care.

A system of allocating certain numbers of patients to nurses, or grouping children by the acuteness of their needs, can help to make the best use of available resources

and ensure some continuity of care. However, any system of care is likely to be better than no system at all.

In busy settings it is also important to place the sicker children (particularly children without a parent present) in beds where they can be easily and most frequently seen – for example, near to the nurses' station.

### **The importance of basic care**

Although patients may sometimes require complex treatment, there are basic needs that will always have to be met. Unfortunately, these are sometimes viewed as being of secondary importance, but providing good basic care often reduces the need for further intervention, and can enhance other therapies (e.g. the beneficial effect of improved nutrition on wound healing), whereas poor basic care has the opposite effect (e.g. the adverse effects of stress on respiratory and cardiac function). Where therapeutic options are limited due to lack of availability, limited financial resources, etc., or perhaps where no further curative treatment is possible, the provision of good basic personal care is particularly relevant. It is invariably viewed as part of the nursing role, but in fact the underlying approach required is common to all healthcare professionals, and it should be understood that the provision of such care is rarely a simple task. It requires understanding, skill and patience, and is a subject that justifies a separate or expanded publication. Only the bare essentials are covered in this manual.

### **Information, participation and comfort**

Hospitalisation often represents a traumatic change in the life of a patient. Much that was previously familiar and predictable in their life has now been replaced by an unfamiliar environment and fears about an uncertain immediate (and maybe long-term) future over which they have little control. Our words and facial expressions convey a stream of messages, but we often have little understanding of how we are perceived. Effective communication plays a vital role in the care of patients, and has a dramatic impact on their experience of and response to treatment.

Both the patient and their family have a need to trust those who are caring for them, to be told what is wrong and also to know what is going to happen to them. This is a major factor in helping them to adjust to the situation, develop coping strategies and make decisions about their own care.

The 'information needs' of children are often neglected, sometimes because it is assumed that their understanding is limited. However, even young children have a need to be given information in a language that is understandable to them. In the absence of reliable information, a child's fantasy may well be far more distressing than the reality.

These issues are also very important in preparing the patient (and their family) for a procedure. They need to be told truthfully and sensitively what will happen, particularly if it might be painful. If the patient is not warned, their trust in those around them can be destroyed, future procedures will be feared, their anxiety will be increased and the nursing task will be made more difficult.

Communication is a two-way process. It involves both conveying the message effectively and having an understanding of the thoughts and feelings of the other person. Children and their families should be allowed and encouraged to participate in decisions that affect them. This requires a willingness and ability to engage with them and

actively listen to them, and to interpret non-verbal signs that often tell a different story to the words that are actually spoken. Patients need to express their worries and anxieties. Young children do not always have sufficient vocabulary to convey how they feel, so the use of play and other activities, such as drawing, is a useful way to enable them to express themselves and to give them control.

Factors that may appear trivial to an adult may be important to a child. There may be issues causing distress that can be easily resolved, and in cases where there is not a solution, the feeling of isolation that is often experienced by these children can be helped by having someone to share their anxieties with.

Where the situation is grave, families sometimes struggle to discuss distressing subjects with their child. Although these are difficult and emotional situations, even very young children are extremely sensitive to the distress and anxiety of their family. They often have a much greater level of awareness than is generally realised, and failing to acknowledge the reality of their position may intensify their feelings of isolation by denying them the opportunity to express how they feel or to ask questions.

This all takes time, which may well be in short supply (another reason for encouraging family involvement), so it is important to make the most effective use possible of the little time you may have with a patient. The way you approach, talk to and touch the patient can make a big difference to the way they feel. It helps to build trust and it influences their compliance. Touch is a powerful tool and can convey more than words in terms of comfort and reassurance. Having their personal needs attended to may unfortunately be one of the few times during the day that a patient has the opportunity for human touch, so it is important to be kind, gentle and thoughtful in your approach.

### **Personal hygiene and protection of privacy and dignity**

Personal care can contribute significantly to the way a sick or dying patient feels, and can prevent further problems such as sores at pressure areas. Attention to personal hygiene needs should always be given in a manner that protects the dignity of the patient. Even very small children often feel shy or uncomfortable when being attended to by an unfamiliar person, and this is particularly the case with older children and teenagers. It is another very good reason for encouraging the family to be involved in the patient's care, as well as helping to fulfil the natural wish of many parents to participate in this way.

When washing the patient, extra attention should be paid to skin folds, the neck, the back, the ears and the genitals, and the child should be encouraged to do as much as they are able. Patients who are malnourished, who have been sick for a long time or who have malignancies can have fragile skin that easily breaks down and requires special attention. An effective method that can be used by both professional and family carers is to gently change the patient's position at frequent intervals. This relieves the pressure on any given part of the body, and prevents reddening and breakdown of the skin. Pain relief should be given to prevent discomfort (see Section 1.15) and, when possible, pressure-relieving measures are also helpful.

Good mouth care is very important, and the patient should be encouraged to maintain this when in hospital. For children who have not brushed their teeth before, this

is a good opportunity to start, and help needs to be given to those who are unable to do this. In patients who are very sick or who are dying, mouth care can help to prevent many problems, including bad breath, bleeding, infection, ulceration and pain, that can significantly add to their suffering. For these patients the following measures can be helpful:

- using a soft toothbrush or mouth sponge to clean the patient's mouth regularly
- using wet mouth swabs if the patient's oral intake is low
- using lip balm for dry lips.

### Hydration and feeding

Children can quickly become dehydrated, particularly if they suffer from diarrhoea, vomiting and/or fever, or when they are too tired and lethargic to drink. Any caregiver should be able to recognise the observable signs of dehydration (for signs and symptoms, see below and Section 5.12.A).

**Severe dehydration:** two or more of the following signs are present:

- Lethargy/unconsciousness
- Sunken eyes
- Unable to drink or drinks poorly
- Skin pinch goes back very slowly (2 seconds or more).

**Some dehydration:** two or more of the following signs are present:

- Restlessness/irritability
- Sunken eyes
- Thirsty/drinks eagerly
- Skin pinch goes back slowly.

Other signs include the following:

- Reduced urine output/concentrated urine
- Increased pulse rate
- Increased respiratory rate
- Dry mouth
- Sunken fontanelle, where relevant.

A swift response to a patient who either is, or is likely to become, dehydrated can prevent a further deterioration and the need for IV fluids. Oral rehydration solution (ORS) powder to be mixed with boiled and cooled water (and also daily zinc supplementation) should be available in all hospitals, but in its absence the following will be suitable:

- To 1 litre of boiled water that has been allowed to cool add 6 level teaspoons of sugar and half a level teaspoon of salt (the solution should taste no saltier than tears).
- Dhal water, rice water, bean broth, fruit juices and thin porridge cereal are also effective.
- Breastfeeding mothers should be advised to breastfeed their child more often during episodes of diarrhoea.

Trying to persuade a patient, particularly a sick young child, to drink is not always easy:

- Encourage the patient to drink small amounts and often.
- Give them an age-appropriate explanation of why this is important.
- Involve the patient and decide together with them how much they will try to drink each hour.
- A child under 2 years of age needs to drink between a half and a quarter of a 250-mL cup for every watery stool.
- A child over 2 years of age needs to drink between a half and one full 250-mL cup for every watery stool.

For small children or those who are too tired to drink by themselves, the following measures can be helpful:

- Use a small cup, spoon or syringe.
- Encourage the child to play, or to participate by using the syringe him- or herself.
- Give small rewards for drinking.
- Give praise when fluid is taken.

Patients often lose their appetite when they are ill. In short acute episodes, the main priority is fluid intake and the replacement of salts. However, in longer periods of illness it is essential to ensure an adequate nutritional intake.

Anxiety caused by separation from their family can cause children to lose their appetite, and when they find themselves in an unfamiliar environment such as a hospital, a choice over whether or not to accept food or drink may represent the only control that the child still possesses.

Feeding difficulties often cause distress to families. The parents of a child who is dying may feel that a lack of nutrition will contribute to or hasten their child's death. These anxieties should be understood. It should also be explained to the parents that loss of appetite is sometimes part of the deterioration process, and the patient should be encouraged to eat what they want.

It is important to recognise and manage other factors that have an effect on oral intake, such as sore mouth, nausea, vomiting and constipation.

Try the following:

- Provide familiar food for the patient, and let them choose the food if possible.
- Encourage children to feed themselves if they are able to do so, and encourage the parents to help.
- Avoid performing invasive procedures immediately before or during a meal.
- Try giving small amounts of food often, rather than two or three large meals a day.
- Avoid giving the child highly spiced or strong-smelling foods unless such foods are the cultural norm for them.
- Give food at familiar times for the child, and try to make mealtimes fun.
- Praise the child when they eat, but do not criticise or punish them when they cannot.

Where possible, keep an accurate written record of all the patient's fluid and dietary intake, and also their output (urine, stool and vomit) (for an example of a chart, see Section 9, Appendix). Compare the total intake and total output over a given time period (usually 24 hours), and add an amount for insensible losses through perspiration and breathing (approximately 15 mL/kg/day, or more if the child has fever or is in a hot environment). Alongside clinical observations, this will give an indication of the patient's hydration level, and will also give warning of a patient who is becoming dehydrated. In reality, written records are often inaccurate and frequent weighing (e.g. once each day at the same time, wearing clothes of similar weight) can provide a valuable guide to fluid balance.

### Elimination

For the management of constipation and diarrhoea, see Sections 5.12.A and 5.12.C.

The elimination habits of children vary with the individual, but often change when they are sick or in hospital. There are many possible causes of this, including the disease

process, surgery, injury, and medication. Anticipating problems can do much to help. However, awareness of basic issues is always important.

- Maintain an adequate level of hydration.
- Obtain information about the child's normal elimination pattern.
- Children may be too frightened to go to the toilet in a strange place.
- Pain (e.g. from a urinary tract infection, anal fissure or post delivery in pregnant adolescent girls) may cause a patient to retain and deny the need to go to the toilet. Analgesia and simple measures such as sitting the patient in warm salty water can help to ease the pain and encourage urination or defecation.
- A patient who is passing bloodstained stools may be frightened and need reassurance.
- Praise and encouragement are important and effective.

## 4.2.B Nursing care for adolescents

### Introduction

Adolescents are not small adults. Between the ages of 10 and 19 years their needs are complex as they make the difficult transition from dependency to responsible and independent adulthood. They are feeling their way towards this independence but at the same time may not feel confident, even if they are reluctant to admit this. When they are ill enough to require hospital care, frequently because of pregnancy and delivery, these pressures are even more marked.

### Changes in adolescence that are relevant to hospital care

#### Sexual risk in adolescence

Adolescents, particularly girls, are vulnerable to sexual exploitation, especially if they are living in poverty. They may not know how to negotiate whether to have sex or not, or how to protect themselves from sexually transmitted infections (STIs) and pregnancy. They may have no caring adult to turn to. There are many stories of adolescent girls being coerced into unwanted sexual activity by those in positions of responsibility. They may be promised high school marks, or clothing, or money they need to help their families. They may fear reporting this, feeling that they will be shamed or not believed. They may be raped by men whom they know or to whom they are related, or by strangers, particularly in times of conflict and displacement. They may be endangered when rape is seen as bringing shame on the family. It may be difficult or impossible to prevent pregnancy, or they may not know how to do so. They may fail to report a pregnancy until it is too late for much of the antenatal care that is available. They may attempt to abort the fetus with extreme risk to their own life because they do not know what else to do. At the very least, these young women are vulnerable to STIs, including HIV and human papilloma virus (HPV) (the latter being a cause of cervical cancer). Such diseases (see Section 6.1.J) may be silent, or these young women may not know what to do or who to

tell about symptoms that they experience. There is a high risk that pelvic inflammatory disease will result in infertility.

#### Pregnancy and childbirth

For an adolescent girl, pregnancy itself brings additional threats. She may not yet have completed her own growth and physical development. Her pelvis may not be fully developed, and the risk of obstructed labour and its consequences, namely fetal damage or death, maternal death or fistulae, is greater than for older women. She needs good nutrition for her own growth but has to provide for the fetus, and then for lactation, at the same time. The potential for malnutrition is high unless she has access to all the nutrients she requires. For this reason it is important that her nutrition status is monitored during pregnancy. She should also be given advice, help and micronutrient supplementation.

Other health dangers await pregnant adolescent girls. They are at greater risk of developing anaemia and pregnancy-induced hypertension, including pre-eclampsia and eclampsia. Stillbirth and neonatal mortality rates are higher in this age group, and babies are often of low birth weight. These girls may also have undergone female genital cutting (FGC) (see Section 2.10), with the many and lifelong health problems this may cause, and even social exclusion because of resulting fistulae or death from obstructed labour. Overall, complications of pregnancy and childbirth are the leading cause of death among female adolescents according to the World Health Organization (WHO).

Despite the dangers, many girls achieve a successful pregnancy outcome and become competent mothers. They may have to do this without the support of the baby's father or even their parents, and will have their education disrupted or even ended. They will often have to bring up the child in poverty, perhaps also being excluded socially. Others are married at a very young age, not necessarily willingly. Any adolescent mother (and father) will need help with parenting and the development of life skills to prevent their circumstances from spiralling downward. Family planning advice will be very important to enable these young

women to avoid further pregnancies too soon, which would add to the downward spiral.

### **Mental health problems**

Mental health problems are not confined to adults. Apart from having psychiatric disorders such as schizophrenia, young people may be depressed and confused, bullied, abused emotionally and psychologically as well as physically, and have to take part in activities that cause great stress. They may be forced to become child soldiers, they may have to take responsibility for other children in their family and even care for adult relatives such as parents with AIDS, and they may experience personal loss. An unhappy home life may lead to self-harming, to life-threatening eating disorders and to attempted suicide, any of which may result in hospital admission.

### **Malnutrition**

It is not just in pregnancy that young people become malnourished. Malnutrition may occur because of poverty, or lack of access to healthy foods, or because of peer pressure and habit. This has substantial implications for their growth and development, their general health in the future, and their ability to recover from adolescent illness.

### **Implications for hospital care**

Hospital care for adolescents is particularly difficult. Providers need to be sensitive to the needs and fears of these young people, and avoid being judgemental. A bad experience or poor-quality services may lead to adolescents failing to return, and possibly spreading the word to their friends. For a girl to have to attend an antenatal clinic alongside older and obviously married women is hard. To have to sit in a family planning clinic alongside women from her own community, and to have to tell a nurse (who may be a relative or who may know her parents) that she is sexually active is even harder. Young men will find it equally difficult to attend for contraceptive advice, and for adolescents of both sexes, attending an STI clinic could be an ordeal that they do not wish to repeat. At the same time, the pressures on young people are often so great that bad experiences are not effective deterrents to risky behaviours.

### **Dignity, privacy and confidentiality**

Hospital care can be an experience of dignity and acceptance, or of rejection and embarrassment. Adolescents are unlikely to have special areas or wards except in the most well-resourced units. However, some kind of arrangement is needed to ensure that they are not nursed in the same space as very much older people, or with young children, and certainly not in mixed-sex areas. Facilities for privacy are needed, such as curtains around beds and interview spaces, and some arrangement should be made to ensure that interviews and conversations cannot be easily overheard.

Preservation of dignity, privacy and confidentiality is as important for adolescents as it is for adults. Going through puberty can make adolescents particularly self-conscious and even traumatised when examinations, such as those of their genitals, are performed insensitively or roughly. This may be especially difficult for young women (or men) who have experienced violence or sexual assault. Adolescent males may also feel great shame that an assault has

happened and that they have been unable to prevent it. Therefore every effort needs to be made by care providers, from healthcare professionals to cleaners and porters, to maintain the privacy, dignity and confidentiality of these young people.

Confidentiality can be a particular issue when patients are minors, under the age of consent for the country in which they live. Parents or guardians may need to be given information that young people would prefer was not shared. There is no clear answer about how much those responsible should be told if the adolescent indicates that information should be withheld. Carers will need to be guided by their ethical codes and make decisions according to the best interests of each individual young person, as well as to the prevailing laws.

Parents or guardians may have legal powers to decide what treatment adolescents should receive, such as giving consent for surgery, but every effort needs to be made to take the young person's wishes and views into account. In some countries, even a court of law will take a child's wishes into account as they near the age at which they have the right to make decisions.

### **Services for young people with a disability**

Care providers need to be particularly vigilant in providing services for young people living with disabilities, especially mental or learning disabilities. These people are vulnerable to abuse, to finding services inaccessible or inappropriate, and to misunderstanding of their needs. When they are away from their normal environment, as when in hospital, they may become withdrawn, confused and possibly uncooperative. Ensuring that young people with a disability feel secure and well treated is the responsibility of all grades of staff.

### **Emergency services**

Emergency services for young people should not be neglected. Young women may need gynaecological assistance, for example, for the consequences of female genital cutting or sexual assault. They may need access to post-exposure prophylaxis for HIV, or to emergency contraception where this is acceptable, or to post-abortion care. Mental health problems may be acute and arise as emergencies, especially following major emotional stresses, when illnesses such as schizophrenia first arise, or when young people self-abuse or attempt suicide.

### **Building relationships**

Trust is of primary importance for young people. Services that take into account the need to build trusting relationships are likely to be more acceptable, and therefore more effective and better used. Continuity is important, so that adolescents do not see a new face every time they attend for healthcare or counselling, but instead have the opportunity to develop a relationship of trust. This is a significant management issue, but it is important in terms of service uptake, effective use of human and other resources, and overall effectiveness of treatment programmes.

### **Advocacy**

Healthcare providers have a strong advocacy role for adolescents, particularly in the context of working together, as for example in professional associations. This may involve campaigning for better services, talking to colleagues about

their behaviours, or providing professional development opportunities. It may involve listening to young people, working with them, or campaigning against harmful local practices such as female genital cutting, early and/or forced marriage, ritual sexual initiation by older men, and erroneous and damaging beliefs (e.g. that having sex with young girls will cure HIV).

### Hospital care summarised

The WHO suggests that services need to be accessible, acceptable, equitable, appropriate and effective. This means that young people need:

- appropriate, acceptable, accessible and gender-sensitive hospital and community services
- carers who have approachable, accepting and non-judgemental attitudes
- confidentiality, preservation of dignity and privacy
- accurate and honest information
- choice and some control over what happens to them
- avoidance of inappropriate hospital inpatient facilities where possible
- targeted health promotion
- targeted services, for example:
  - for young people with long-term physical disability or illness
  - for young people with learning and developmental disability
  - for family planning
  - for STIs and HIV
  - for pregnant adolescents, including post-abortion care, emergency contraception (if permitted), antenatal, labour and postnatal services, and nutrition services

- for young mothers, whether supported or not, and young fathers
- for displaced adolescents (e.g. refugees, internally displaced persons, the homeless)
- emergency health and counselling services for support in crisis
- advocates who understand their needs and can support them both as a group and individually (e.g. with families).

Finally, nurses, midwives and doctors may be the only people whom adolescents feel able to talk to, especially as others, such as parents, teachers and religious leaders, may be seen as authority figures. This vital role goes way beyond simply providing medical, surgical or obstetric care.

## 4.2.C The child with a disability in hospital

### BOX 4.2.C.1 Minimum standards

#### *Prevention of avoidable disability*

- Good antenatal care, including folic acid, iodination of salt, iron, antimalarial drugs and anti-tetanus immunisation.
- Good care during delivery, including access to obstetric surgery and blood transfusion.
- Effective neonatal resuscitation and care of the newborn.
- Injury prevention.
- Effective immunisation programme.
- Good management of acute illness and injury.

#### *Management of existing disability*

- Access to diagnostics.
- Multidisciplinary care.
- Aids for disabled children.
- Promoting equality of opportunity for children with a disability.

illness or injury are at risk of becoming disabled due to their condition and/or their management.

### Disabled children: definitions

- Disorder is a medically definable condition or disease.
- Impairment is the loss or abnormality of physiological, anatomical or psychological structure or function.
- Disability is any restriction, due to an impairment, in the child's ability to perform an activity in the normal way for a child of that age.
- Handicap is the impact of the impairment or disability on the person's pursuits or achievement of goals that are desired by him or her or expected of him or her by society
- Special needs refers to children who have needs greater than the normal needs of children of their age.

In 2001, the WHO introduced a new system of classification, The International Classification of Functioning, Disability and Health (commonly known as ICF) ([www.who.int/classifications/en/](http://www.who.int/classifications/en/)) which uses two lists, a list of body functions and structure, and a list of domains of activity and participation. Since an individual's functioning and disability occur in a context, the ICF also includes a list of environmental

### Introduction

Around 10% of children in most developing countries are disabled in some way. All children who are hospitalised for

factors. The ICF replaces the previous classification based on 'impairment', 'disability' and 'handicap', and shifts the emphasis to functioning. The ICF puts the notions of 'health' and 'disability' in a new light. It acknowledges that every human being, through illness or injury, may develop a disability. It 'mainstreams' the experience of disability and recognises it as a universal human experience. Furthermore, the ICF takes into account the social aspects of disability, and does not see disability only as a 'medical' or 'biological' dysfunction, but includes contextual factors, such as environmental factors. The ICF encourages assessment of the impact of the environment on the person's functioning. For example, hospital staff should be vigilant about preventing the development of contractures in a comatose child because they are concerned to ensure the best functioning of the child when he or she recovers.

### Children's rights

Article 23 of the UN Convention on the Rights of the Child ([www.ohchr.org/en/professionalinterest/pages/crc.aspx](http://www.ohchr.org/en/professionalinterest/pages/crc.aspx)) defines the right of disabled children to special care, education and training designed to help them to achieve the greatest possible self-reliance and to lead a full and active life in society. It also encourages states to develop free and accessible services where possible, and to share information with other countries regarding the latest findings of research into the management of disabling conditions.

The main care of children takes place in the community. Children with special needs and chronic illness and their parents are entitled to receive the same standard of care as any other family when their child is in need of acute care for any other condition described in this book. The attitude of healthcare professionals should reflect this important principle. Many cultures in resource-limited countries have a greater degree of acceptance of disabled people than is found in more well-resourced countries. However, some cultures regard disability as a punishment or as a cause of shame. Accepting, encouraging and supportive behaviour of healthcare providers towards children with disabilities will go some way towards dispelling these attitudes.

### Planning of services

Ministries of health and hospitals should consider establishing a register of disabled children, but only after careful consideration of the aims of registration, the likely benefits and costs, and the resources available.

#### The aims of a service for disabled children

These are as follows:

- to provide health services which ensure that children reach their maximum potential, optimising their independence and ability to lead a high-quality life
- to ensure that disabilities are promptly identified and treated where possible
- to promote active involvement of disabled children and their families in all aspects of healthcare, working in partnership with healthcare professionals
- to promote access to the healthcare facility for families with disabled children
- to provide comprehensive, integrated and coordinated services both in the healthcare facility and in the community, utilising outreach and community-based services, including community-based healthcare workers

- to enable health services to work with other key agencies, such as social services and education and training services.

### The prevention of impairment and disability in children

This is the main issue in resource-limited countries, where facilities to support such children are very limited. Of most importance are the quality of antenatal care, the quality of neonatal resuscitation (see Section 3.2), the prevention of cerebral oedema due to inappropriate fluid management (see Section 5.12.A), the prevention of hypoxic-ischaemic cerebral injury (see Section 3.2), provision of adequate nutrition, the avoidance of accidents and protection from abuse (see Section 7.6). Adequate immunisation to combat poliomyelitis, measles, malaria, TB and meningitis, which are major causes of disability, is also mandatory.

#### Antenatal, peripartum, infant and child care

- Doctors and nurses working in hospital maternity services should work closely with local leaders, women's groups, and the Ministry of Health to improve pregnancy outcomes. This will involve promotion of early attendance at antenatal clinics. Detection and treatment of diseases such as syphilis and malaria, which can cause intrauterine growth retardation (IUGR) and prematurity, management of HIV and prevention of mother-to-child transmission, and the detection and management of intestinal worms and nutritional deficiencies are all essential.
- Every attempt should be made to provide good nutrition for women who may become pregnant. Folic acid supplements at the time of conception are vital for preventing spina bifida and other congenital abnormalities.
- Iodination of salt is inexpensive and should be universal.
- Iron-deficiency anaemia during pregnancy is associated with low-birth-weight babies and should be screened for and prevented. Malaria in pregnant women is another cause of low birth weight and prematurity, and should be prevented or, if contracted, be treated vigorously (see Section 2.8.D). Ministers of Health should be persuaded of the value of providing malaria prophylaxis or intermittent preventive treatment (IPT) for all pregnant women in endemic areas.
- Immunisation against tetanus (see Section 1.17) is essential.
- Obstetric care within hospitals should aim to prevent impairments due to complications of labour and delivery. Crucial to this is the availability of oxygen, obstetric surgery and anaesthesia, and a blood transfusion service.
- Effective neonatal resuscitation should be available 24 hours a day in every maternity unit and for all home deliveries. Staff must be trained and should have the basic equipment (see Section 3.2) necessary to prevent those causes of birth asphyxia which arise after the delivery of the baby.
- Simple interventions such as not bathing immediately after birth, prevention of hypothermia, and 'kangaroo care' for low-birth-weight babies should be taught to village health workers and traditional birth attendants in regions where they play an important role in home deliveries.
- Recognition of danger signs and the setting up of

community-based referral systems to deal with emergencies should be implemented at village level.

- Breastfeeding must be encouraged (see Section 3.3), and special support must be given to help mothers provide breast milk for babies with developmental impairments that make sucking or attachment difficult.
- Adequate training and facilities for the correct management of dehydration in gastroenteritis (see Section 5.12.A), hypoxic-ischaemic injury (e.g. in injuries) (see Section 7.3.C) and severe anaemia from malaria (see Section 6.3.A.d) all reduce the frequency of preventable brain damage.
- Paediatricians in hospitals should advocate for programmes of injury prevention and the prevention of injuries to children resulting from conflict, displacement or other social factors.

### Management of disabled children: identification and primary diagnosis

**All babies should be systematically examined at birth and, if possible, at 6 weeks of age to detect preventable disabilities such as dislocated hips and congenital cataracts. In regions where most babies continue to be born at home, community health workers (CHWs) should be trained to detect these problems or to encourage mothers to attend for postnatal checks at a clinic where these can be undertaken.**

**Postnatal services should be established in all healthcare facilities that provide antenatal care and delivery services.**

**Protocols for postnatal care should be developed based on WHO guidelines.**

Signs or symptoms of an emerging disability should be actively sought. Findings which suggest that the child may be disabled should be communicated to the parents in a culturally sensitive manner in accordance with locally developed guidelines. This communication must include information about the local availability of services and social support.

### Comprehensive interdisciplinary assessment

- This should always include the child's strengths as well as their weaknesses, and an assessment of their home circumstances and educational needs.
- It should result in decisions about management, including any immediate surgical or medical treatments available to alleviate the condition.
- It should include an assessment of sensory, motor, behavioural and intellectual capabilities as outlined below.

### Convening a team to plan long-term management

- The team will include those people whose skills and training are relevant to the needs of the child. The team is often led by a named paediatrician.
- Representatives from outside agencies such as education and social services must be included if they are available.
- A care manager or key worker should be appointed, who will act as a liaison between professionals and the parents to ensure that the child fully benefits from the available resources.

### Development of local guidelines for clinicians

- Hospital staff should aim for an early diagnosis and identification of treatable causes of disability.
- Resources to support the child and their family should be sought.
- In the absence of social support, hospitals must develop sensitive policies to inform parents of the diagnosis and expected prognosis in a way that is compatible with the best outcome for the child.
- Such policies should be decided by each hospital, and all personnel should be informed of the policy.
- Culturally sensitive disclosure of information about the diagnosis and expected prognosis should be given by a senior clinician who has experience in this area and is aware of local attitudes and beliefs regarding disability and the services available to the child and their family.
- Services should be developed as resources allow.
- Policies with regard to the intensity of resuscitative treatment given to children with various impairments should be developed by doctors, other healthcare professionals, representatives of the local community, including disabled people, and politicians. These policies must take into account ethnic and cultural issues and local support available for the care of severely disabled children. Such policies must be reviewed frequently. A hospital ethics committee can be valuable in this respect (see Section 1.20).
- Development of services for and the rights of disabled people should be promoted wherever possible. Front-line staff should feel confident that they know and can work within the framework of the policy.

### Diagnosis

All newborn babies should be examined before leaving hospital by a member of staff (usually a nurse or midwife, or a paediatrician if one is available), who has been trained to perform a competent neonatal examination. Any possible impairment must be reviewed by an experienced paediatrician.

### The neonatal examination

- **General:** Signs of dysmorphism should be looked for. The baby should be examined for tone and observed to have normal limb movements. Disordered tone, feeding difficulties, irritability and seizures should be noted.
- **Hips:** The hips should be checked for dislocation, remembering the three major risk factors, namely family history, female gender and breech presentation. Dislocated or dislocatable hips should be referred to an orthopaedic specialist.
- **Jaundice:** Any jaundice in the first 24 hours should be taken seriously and monitored appropriately. Causes of jaundice, such as blood group incompatibilities, glucose-6-phosphate dehydrogenase deficiency and sepsis, should be diagnosed and treated. Severe jaundice can lead to deafness and cerebral damage (see Section 3.4).
- **Cardiovascular system:** This should be examined looking in particular for cyanosis and equality of pulse volumes, and listening to heart sounds. If abnormalities are detected, the baby should be referred to a paediatrician (see Section 5.4.A).

- **Hearing:** Behaviour should be observed, although hearing defects are difficult to detect in the neonatal period without special equipment.
- **Vision:** The child's eyes should be examined for infection, which must be treated with suitable medication. The absence of cataracts should be ascertained by the presence of a good red reflex in each eye (see Section 5.15).

## Comprehensive assessment of disabled children

Most children in resource-limited countries are born at home, and therefore children with disabilities are more likely to present at the hospital in later life.

### History

A complete paediatric history, including antenatal, perinatal, postnatal and family history, should always be taken. Many countries have found that the 'Ten Questions' are helpful for establishing the prevalence and distribution of various disabilities:

- 1 Compared with other children, did he/she have any serious delay in sitting, standing or walking?
- 2 Compared with other children, does he/she have difficulty seeing, either in the daytime or at night?
- 3 Does he/she appear to have difficulty hearing?
- 4 When you tell him/her to do something, does he/she seem to understand what you are saying?
- 5 Does he/she have difficulty in walking or moving his/her arms, or does he/she have any weakness and/or stiffness in the arms or legs?
- 6 Does he/she sometimes have fits, become rigid or lose consciousness?
- 7 Does he/she learn things like other children of his/her age?
- 8 Does he/she speak at all? Can he/she make himself/herself understood in words. Can he/she say any recognisable words?
- 9 For 2-year-olds: 'Can he/she name at least one object (for example, an animal, a toy, a cup, a spoon)?' and 'Compared with other children of his/her age, does he/she appear in any way to have difficulties in learning?'
- 10 For 3- to 9-year-olds: 'Is his/her speech in any way different from normal (not clear enough to be understood by people other than his/her immediate family)?'

### Examination

A full clinical examination of all physical, sensory and psychological systems should be undertaken.

### Additional issues

- Determine how the child and their family have adapted their lives in response to the child's difficulties.
- Determine the extent to which the available treatment, training and management will improve the situation.
- Evaluate the emotional adjustment of the child and their family to the disability.
- Investigate the educational facilities available to the child and how they may be adapted to his/her needs.
- Determine the child's and family's strengths, abilities and positive personality traits which can be encouraged to help them to cope with the disability.

## Protocols for particular conditions

These should be developed to ensure that the child is thoroughly investigated initially and reviewed at regular intervals to ensure that they can reach their maximum potential.

For example, a protocol for a child with Down's syndrome could include the following:

- full medical examination
- chromosome studies (if facilities are available)
- ECG and chest X-ray with echocardiography (if available)
- development of a care plan with the parents/carers as partners
- audiological assessment
- visual assessment
- assessment by a speech therapist (if available) to promote communication skills
- assessment by an occupational therapist (if available) to determine any aids or equipment which may be of help
- thyroid function test at appropriate intervals.

## Sensory impairments

Liaison between health services and local education facilities is particularly important for the support and understanding of children with sensory impairments.

### Visual impairment

#### Evaluation (see Section 5.15)

Most newborn babies can focus on and follow the mother's face and large brightly coloured objects. Impaired vision can therefore be detected soon after birth. It is normally the mother who will suspect this because the baby is not looking at her when she is breastfeeding. There may be roving eye movements.

- Use appropriate objects to confirm visual impairment – for example, human face for neonates, toys for older infants, and pictures (whose dimensions correspond to Snellen letters) for older children.
- Determine whether visual impairment is an isolated problem or associated with other developmental defects (e.g. cerebral palsy) by undertaking a detailed history and physical examination.
- Check for the red reflex as follows. Shine a light on the pupil from arm's length. Normally it will appear red because of light reflected from the retina. If it appears white, consider the possibility of dense cataract, severe retinopathy of prematurity, or retinoblastoma. If the red reflex is normal, check the pupillary response to light. If the latter is normal, a local cause (i.e. optic nerve or retinal degeneration) is unlikely, and impaired vision is then most probably due to occipital lobe damage.
- Check the retina and optic nerve by fundoscopy to exclude optic atrophy and retinal degeneration. If in doubt, refer the child to an ophthalmologist.

### Causes of visual impairment

Common causes of blindness in children include optic atrophy, congenital cataracts and retinal degeneration, and in resource-limited countries they include vitamin A deficiency, measles, onchocerciasis and meningitis.

Trachoma remains a major cause of blindness in many developing countries. Early detection and treatment can prevent blindness. Prevention activities should include hygiene. Mass drug administration in affected areas can be considered.

Close liaison between paediatricians and

ophthalmologists is required to develop policies to detect and treat visual defects as early as possible.

### Management of impaired vision

- **Treatable causes:**
  - **Cataract:** Children with congenital cataract should be referred to an ophthalmologist as soon as possible for early treatment. If no treatment is available, the parents should be shown ways of stimulating residual vision by playing with bright lights and presenting visual stimuli to the child as much as possible.
  - **Xerophthalmia:** Treat with vitamin A (see Section 5.10.A).
  - **Eye infections** (see Section 5.15).

Community healthcare workers should have training sessions on eye care emphasising simple hygiene measures and sources of food rich in vitamin A to be found in local diets.

- **Non-treatable causes:**
  - Perform a visual assessment and provide suitable visual aids.
  - Surgical correction of squints should be undertaken (when possible).
  - Mobility training should be provided for blind children and their carers.

The family will need support and advice about appropriate schooling, changes to the home, and mobility training.

### Hearing impairment

Hearing loss is a hidden defect and may easily be missed if healthcare workers are not vigilant. Because hearing defects often lead to lack of development of speech and language, the child is sometimes assumed to have learning difficulties and may be further isolated from their family and society because of this. All children who present with failure to develop language should have a good-quality hearing assessment.

Hearing is essential for language development, so early detection of hearing impairment is essential. A newborn responds to sudden noise with the startle response. A normal baby will listen to the mother's voice. Formal hearing assessments in the newborn are possible using the acoustic cradle. The distraction test is used at 4 to 8 months of age, and audiometry is used in older children.

There are two types of hearing loss:

- **Conductive hearing loss:** The commonest cause is recurrent/chronic infective otitis media (see Section 5.1.C).
- **Sensorineural hearing loss:** The commonest causes are meningitis, cerebral malaria, genetic defects, drugs (e.g. excessive doses of aminoglycosides) and intrauterine infections. A hearing aid is required, and the child may need to learn a sign language.

Children with the following are at risk of hearing impairment:

- family history of sensorineural hearing loss
- dysmorphic features
- abnormalities of the pinnae
- severe birth asphyxia
- severe neonatal jaundice
- other neurological abnormalities
- postnatal infections (e.g. meningitis, measles)

- treatment with ototoxic drugs (e.g. gentamicin, streptomycin).

It is most important to identify and treat causes of conductive deafness, such as chronic otitis media (see Section 5.1.C).

- Treatable causes of sensorineural hearing loss are very rare.
- Hospitals in association with community health services and education authorities should seek to develop services for early identification and prompt treatment of children with irreparable hearing problems. These should include simple audiological assessment and the provision of hearing aids.

### Neurological problems

#### General advice

- Parents and carers should be given information and training so that they can modify daily activities to promote the development of the child and enhance functioning (e.g. information on prevention of contractures). Lifting, carrying, seating, playing and bathing will all need to be discussed and demonstrated.
- Physiotherapy should be commenced as early as possible to prevent the development of contractures in hypertonic children.
- Good positioning and movement are helped by appropriate aids and appliances (see Section 4.2.D).
- Local people are often resourceful in developing appropriate equipment for their own children out of locally available materials (see *Disabled Village Children* referenced on p. 405). Advice from occupational therapists and physiotherapists is very useful (if available).
- Communication aids may also be required, and the advice of speech and language therapists is very useful.
- Children with motor difficulties often have feeding difficulties, and may not have the same access to food sources as children without impairments. Hospital staff, community health workers and family members should receive training on safe feeding techniques in order to improve the nutritional state of these children.
- Feeding may require the placement and management of a nasogastric tube, and parents or carers should be shown how to undertake this.
- A care plan should be developed and a key worker appointed to monitor long-term plans to support the parents and keep them informed and involved in the long-term planning of services for their child.
- Aids to enable the child to have mobility, an effective means of communication and access to education should be developed in the community.
- All hospitals should seek to develop specialist therapy services to help such children.

#### Neural tube defects

(See also section on paraparesis and incontinence below.)

- Where possible, neural tube defects should be prevented by adequate maternal nutrition, including folic acid and vitamins at the time of conception.
- Children born with neural tube defects should be treated urgently to prevent worsening of their condition (see Section 5.16.K).
- Parental wishes in terms of surgical treatment are very important.
- Later complications involve the urinary tract and bowel

function. Poor blood flow to the lower limbs associated with a lack of sensation and mobility may result in pressure sores.

- Many children with spina bifida require alternative means of mobility.
- Spina bifida occulta may result in clumsiness and continence problems. Some of the associated problems may be improved by surgical intervention.

**Delayed development (see Tables 4.2.C.1 and 4.2.C.2)**

Delayed development presupposes knowledge of normal development. Development proceeds in an orderly fashion, but there is considerable variation in the age at which milestones are achieved.

**TABLE 4.2.C.1 Normal milestones in development**

Age	Milestone
Birth	Focuses with eyes and responds to sound
4–6 weeks	Social smile
6–7 months	Sits without support, transfers objects from one hand to the other
9–10 months	Pulls to stand, pincer grasp, waves bye-bye
12 months	Stands, walks with one hand held, two or three words, stranger anxiety
15 months	Walks, drinks from cup
18 months	Says ten words, feeds with spoon
2 years	Runs, draws straight line, says two-word sentences
3 years	Draws circle, draws cross, says three-word sentences, dresses in simple clothes without assistance
4 years	Stands on one leg, fluent speech <b>Note:</b> in societies where access to pens and paper is very limited, even adults find drawing a line or a circle difficult as such an action is outside their experience

**Developmental assessment**

The purpose of developmental assessment is threefold:

- 1 to confirm normal or delayed development
- 2 to identify possible causes of delayed development
- 3 to plan a strategy for intervention.

To achieve these aims, a detailed history and physical examination are essential. Particular emphasis is placed on perinatal and developmental history. As well as looking for signs and symptoms of severe malnutrition or micronutrient deficiencies, allowance must be made for prematurity. Evidence of microcephaly, dysmorphic features and signs of neglect must be looked for, and a detailed neurological examination, including primitive reflexes, undertaken. The following questions must be addressed:

- Does the child have global delay (i.e. delay in all areas of development)?
- Is the delay confined to one area of development? If it is confined to the motor area, this suggests a possible neuromuscular disorder. Delayed speech development with normal motor and social skills could suggest a hearing disorder.
- Has the child lost previously acquired skills, and if so,

**TABLE 4.2.C.2 Warning signs in development**

Age	Sign
10 weeks	Not smiling
3 months	Not responding to noises or voice, not focusing on face, not vocalising, not lifting up head when lying on stomach
6 months	Not interested in people, noises or toys, does not laugh or smile, has squint, hand preference, primitive reflexes still present
9–12 months	Not sitting, not saying 'baba' or 'mama', not imitating speech sounds, no pincer grasp
18 months	Not walking, no words, no eye contact, not naming familiar objects, not interested in animals, cars or other objects Passive – not moving about exploring, excessive periods of rocking and head banging
3 years	Unaware of surroundings, not imitating adult activities, little or no speech, long periods of repetitive behaviour, unable to follow simple commands
4 years	Unintelligible speech
At any age	Parental concern, regression of acquired skills

has the loss been progressive? This suggests a neurodegenerative disorder.

**Delayed walking (not walking by 18 months)**

- Family history of late walking and otherwise normal: give reassurance.
- Global delay (especially in language and social skills): the child probably has mental impairment.
- Child failing to thrive, and showing signs of malnutrition and poor nurture: this suggests neglect.
- Cerebral palsy with upper motor neuron signs (spasticity, clonus, brisk reflexes) or dystonia, ataxia and involuntary movements.
- Neuromuscular disorders (see Sections 5.16.F, 5.16.G and 5.16.H) with flaccid weakness, wasting or fasciculation of muscle, absent or diminished reflexes.
- Congenital dislocation of the hips or rickets can cause delayed walking.

**Delayed language development**

For meaningful speech to develop, the infant must be able to hear, and have intact language pathways and normal oropharyngeal structures. The child must also receive verbal communication.

The following approach to evaluating a child with language delay is useful:

- Is there a hearing defect?
- What is the problem in language delay? Is it in understanding or in expressing thoughts, or both?
- Is the delay confined to language or is it part of global delay (consider severe learning difficulty)?
- Is there any dysfunction or defect of the mouth and pharynx (obvious on physical examination)?

If the child cannot communicate and has normal intelligence, they will try to compensate by using gestures and/or signs. They are also likely to be frustrated and angry. The

child whose language delay is part of a general learning difficulty is likely to be more passive and less frustrated.

Does the child have a problem with social interaction? Consider autism, signs of which include loss of social interaction, little or no non-verbal communication, no eye contact, and repetitive ritualistic behaviour.

### **Cerebral palsy (see Table 4.2.C.3)**

Cerebral palsy refers to the disturbance of movement and/or posture that results from a non-progressive lesion of the developing brain. The commonest causes are hypoxic-ischaemic insult to the brain occurring prenatally or perinatally, or occasionally postnatally (e.g. meningitis, head injury). There are several different types of cerebral palsy, including the following:

- spastic diplegia (common with prematurity)
- spastic quadriplegia and spastic hemiplegia
- dyskinetic type (abnormal non-purposeful writhing movements induced by voluntary activity).
- ataxic type (involves mainly the cerebellum and is rare).

### **Diagnosis**

The child normally presents with delayed development and is found to have abnormalities of tone, delay in motor development, abnormal posture or movements, and persistence of primitive reflexes. The diagnosis is made on clinical grounds and investigations are not required.

### **Evaluation**

Assess the functional status of the child with regard to the motor system (this is best performed by a physiotherapist), and identify associated problems.

### **Management**

The child with cerebral palsy has multiple problems and invariably will require care from a multidisciplinary team. The doctor and the physiotherapist play a prominent role. Physiotherapy advice enables the parents to move and handle the child in their daily activities to improve mobility and aim to prevent contractures. Parents need support in ensuring both that the educational needs of the child are met and that the child is integrated as fully as possible into society.

### **Deterioration in children with cerebral palsy**

Children with cerebral palsy usually remain stable. If a child shows apparent deterioration consider the following possible causes:

- pain from dislocation of the hips
- dyspepsia from gastro-oesophageal reflux
- non-convulsive status epilepticus
- deterioration in mobility during growth spurt
- wrong diagnosis – the child may have a progressive neurodegenerative disease.

### **Paraparesis and incontinence**

Paraparesis (paralysis of both legs) is usually due to a spinal cord problem. This may be congenital, as in spina bifida, or acquired (e.g. following trauma, infection or malignancy). Some causes are treatable if diagnosed early (e.g. TB of the spine). Burkitt's lymphoma with paraparesis is a sign of advanced disease and is often associated with a poor prognosis. Both thorough clinical assessment to establish the level of the lesion, and reassessment to look for

**TABLE 4.2.C.3 Problems in children with cerebral palsy**

Problem	Action
Visual and hearing impairment	Refer to appropriate specialist
Epilepsy	Anti-epileptic drugs
Contractures	Physiotherapy and (rarely) surgery
Dislocation of hips	Surgery to relieve pain
Feeding difficulties, failure to thrive	Monitor intake Correct positioning for feeding Increase energy content of food Consider gastro-oesophageal reflux
Recurrent aspiration	Close attention to feeding position, pacing of feeds, and positioning
Respiratory infections	Antibiotics
Gastro-oesophageal reflux	Feed thickener (starch), H <sub>2</sub> -receptor antagonist (e.g. ranitidine) or proton-pump inhibitor (e.g. omeprazole) Exclude oesophageal stricture and/or aspiration
Constipation	Diet and stool softeners
Learning difficulties	Additional help with education

changes, are essential. Any suspected space-occupying lesion needs surgical advice.

Many children with paraparesis **will** suffer preventable complications **unless** carers and staff are aware of the risks of the following:

- **Poor nutrition:** many children with paraparesis find it difficult to eat and drink. They need good food to enable them to withstand infection, keep their muscles from wasting, prevent constipation and maintain good skin.
- **Contractures:** all joints need to be moved through their full range of movement to prevent contractures developing. If the child has presented late and contractures are already established, a programme of gradual passive stretching may help to improve the range of movement.
- **Pressure sores:** these are prevented by ensuring that the child is moved regularly. The child can often learn to do this by using their arms and upper body strength to pull on a suspended strap or ring to move their own position. The child can use a mirror to inspect their own skin to look for sore patches. Established pressure sores take a long time to heal. They must therefore be kept clean and free from pressure.

Rehabilitation should start immediately, but will depend on whether the child's spine is stable. A creative approach to mobility, using locally available materials (see *Disabled Village Children* by David Werner), is more likely to succeed than waiting for sophisticated rehabilitation equipment to be purchased.

Incontinence is usually associated with paraparesis, and can be both socially and medically disastrous. Some children have neuropathic bladders which are usually full, empty incompletely and may lead to reflux nephropathy, hydronephrosis and renal damage. These children need intermittent clean catheterisation to prevent back pressure and infection. Clean catheterisation may be required up to every 3 or 4 hours. This technique can be easily learned by

a carer or by the older child. Other children have bladders that are not full and which empty themselves frequently. These children are at less medical risk of kidney problems, but it is much more difficult to enable them to be socially dry without complex surgery to enhance the size of the bladder.

Most children with bowel continence problems associated with paraparesis will be constipated due to their relative immobility. A healthy diet and plenty of fluids will prevent constipation. Bowel evacuation in young children is often managed by abdominal massage. Older children can learn to use a Shandling catheter, which is a plastic tube that is passed up the rectum for a washout of the bowel contents with saline.

### **Learning difficulties and developmental delay**

- Children who do not meet their expected developmental milestones should be assessed for possible causes.
- Some children have specific learning difficulties and may be assumed to have general learning difficulties unless they are carefully assessed. **Full psychological assessment is helpful (if available).**
- Treatable causes (e.g. hypothyroidism, abuse/neglect, malnutrition, anaemia, etc.) should be ascertained. Problems such as autism and attention deficit disorder, with or without hyperactivity, should be documented.
- In planning services for these children, social and educational involvement is essential.

### **Severe learning difficulties**

Severe learning difficulties (formerly referred to as mental retardation) are suspected when there is global developmental delay especially in language, social and fine motor skills. Gross motor milestones may be normal. Causes include fetal alcohol syndrome, hypoxic-ischaemic injury to the brain, Down's syndrome, fragile X syndrome and neurocutaneous syndromes, among others. **Treatable causes should be excluded** (e.g. hypothyroidism, phenylketonuria).

The parents will need considerable support in coming to terms with the diagnosis and its implications. They should be encouraged to stimulate the child's cognitive, language and motor development. Provide advice on appropriate play activities, suitable toys and reading material. Some children will be able to attend mainstream schooling but will need additional help; others will be better supported in special schools (if available). Their progress must be continuously monitored and associated problems dealt with. They deserve the same care as normal children.

### **Autism and communication disorders**

- Autism usually presents in the second or third year of life.
- It is primarily a communication disorder associated with an absence of or disordered speech and language development.
- It is often associated with obsessional behaviours or interests.
- It may or may not be associated with mental retardation.
- It is often associated with learning difficulties because of inability to understand social situations.

The following should arouse the suspicion of autism: no babbling by the age of 1 year, no pointing by the age of 1 year, no single-word utterances by 16 months, no

spontaneous two-word utterances by 24 months, and any regression in social skills and language.

### **Developmental coordination disorder**

About 5% of children have difficulties with coordination which may affect their ability to perform motor tasks such as writing or sport. It is important to exclude a serious neurological cause and identify that the child cannot do these activities well, so that teachers and others do not conclude that the child is 'lazy'.

### **Attention deficit disorder**

This is a major problem associated with the following:

- difficulty with concentration
- impulsivity
- difficulty in predicting the outcome of actions, so the child does not learn from their mistakes
- a strong association with hyperkinesia/hyperactivity
- poor listening skills.

Attention deficit disorder improves with maturity.

Treatment is difficult. The most important points are to recognise the disorder, explain it to the parents and provide them with family and/or other support to cope with it. **Stimulants, such as methylphenidate, used by an experienced health worker, may be very helpful.**

### **Behaviour disorders**

- Exclude attention deficit disorder and other developmental impairments.
- Try to exclude abuse, although a behaviour disorder may coexist with abuse (see Section 5.9).

### **Psychiatric disorders (see Section 5.9)**

- These are rare in young children.
- Severe malnutrition, deprivation and abuse can lead to depression and the signs of frozen awareness/watchfulness (see Section 7.6 on child abuse).

Surgically treated disabilities such as hare lip and cleft palate are addressed in the section on surgical problems (see Section 5.19).

### **Transition to adulthood for children with disabilities: a human rights perspective**

The transition from childhood to adulthood takes time, and the process of adolescence is experienced and managed in very different ways in different cultures. This transition is much more challenging for disabled children whose abilities to achieve independence may be constrained by their condition. Disabled children are at higher risk of abuse and exploitation, and are likely to be more vulnerable as they pass through adolescence into adulthood. It is best to view this transition from a **human rights perspective**. Thus the disabled child has rights as stated within the UN Declaration of the Rights of the Child, and the same perspective informs any consideration of the transition to adulthood.

### **Conditions, cultures and economies**

Different cultures and economies make it relatively easy or difficult for young people with different types of conditions to integrate and find a role. For example, a young person with a severe physical disability, such as spastic quadriplegia, but of normal intelligence may find it relatively easy to find

a fulfilling role as an adult in a technologically advanced urban environment where there are relatively few physical barriers for wheelchair access. However, a young person with learning difficulties and good mobility may find it difficult to find a fulfilling role in such a society. By contrast, a less technologically advanced society can be much more accepting of the young person with learning difficulties, for whom there are many welcome roles in the rural economy, and the intellectually competent but physically impaired young person may find it much more difficult to find fulfilment in such an environment.

There may be very different cultural expectations of young men and young women, and deep-seated prejudices and cultural taboos that cause further disablement and devaluing of young disabled people unless the human rights perspective is paramount.

### **Child-friendly and child-safe environments**

- All buildings that are used as healthcare facilities and playgrounds for children should be surveyed with the needs of their disabled users in mind.
- When new buildings are planned, it should be remembered that wheelchairs need wider doors and that where steps are needed ramps should also be provided.
- If the building has several floors, lifts should (when possible) be in place. If this is not possible, clinics serving disabled people should be located on the ground floor.
- Areas used by visually impaired people should be well lit, with steps and drops highlighted. Written notices should be as large and clear as possible.
- Special facilities may need to be provided for deaf and blind children to access information.

### **The challenges of transition Independence**

Good practice includes involving children in decision making about their own lives well before they enter adolescence. Learning from failures as well as successes is part of normal development. Many children in resource-limited communities are expected to work on the land or in industry, to look after livestock or to take responsibility for the care of their younger siblings at an age when they are not developmentally equipped to do so. Many children who have been involved in civil war and other armed conflict have been deprived of an ordinary childhood and may have had 'independence' forced upon them at an early age (see Section 1.23). Disabled children may have similar experiences or worse (e.g. being used as beggars), which deprive them of their human right to a childhood. If 'independence' means the insecurity of street children progressing to prostitution or a life of petty crime, this is not the sort of independence that young people need.

At the other extreme, disabled children worldwide are often overprotected by their families, who may feel ashamed, or there may be cultural taboos and beliefs about the origins of particular conditions. The parents may wish to do everything for their disabled child, but this can result in the child not learning from experience. The end result may be that the disabled young person does not get the opportunities for education and training that would enhance their self-esteem and ability to at least make some contribution to society, rather than be seen merely as an object of pity and charity.

Enabling the disabled child to become an integrated member of adult society is a challenge that requires the following:

- imagination, resources and flexibility on the part of the health, education and social services
- active engagement with the young person, their family and their community
- a real commitment to working with the strengths of the young person and minimising their weaknesses by reducing the barriers to their participation in society
- anticipating difficulties in advance and balancing the risk of failure against the benefits of increasing independence.

### **Information**

Disabled young people often do not have access to information about their own condition, necessary health education to prevent secondary problems developing, training and employment opportunities, self-help groups and their rights.

### **Sexuality**

The challenge of emerging sexuality is often more difficult for the disabled young person. Young people commonly have inaccurate information about the basic facts of sexual development, and disabled young people often miss out on the opportunity to learn these facts in a straightforward way. Many young people may be unaware of any genetic implications of their own condition, although it is more common to assume that there are genetic risks to their offspring when this is **not** the case.

Families, and indeed some healthcare professionals, may make inaccurate assumptions about the ability of disabled young people to have normal sexual experiences. These young people may have their own inaccurate beliefs which may cause much unnecessary suffering unless they have the opportunity to understand the facts about their own bodies. Even when there are some physical problems that will affect sexual experience (e.g. lack of genital sensation for some young people with paraplegia), this does not preclude an active and fulfilling sexual relationship.

### **Services for the transition to adulthood**

Healthcare facilities that provide services for children with disabilities should develop expertise in enabling children to make the transition to adulthood. This expertise is likely to be achieved by developing shared knowledge among a group of relevant professionals working in partnership with young people. The service should be able to offer the following:

- information that is relevant and up to date
- individual counselling
- opportunities to meet other young people with similar difficulties
- careers advice
- a service to loan out equipment to increase independence
- close links with education facilities and any social and housing services.

### **Further reading**

- Werner D (1987) *Disabled Village Children: a guide for community health workers, rehabilitation workers and families*. Palo Alto, CA: Hesperian Foundation.

## 4.2.D Care of children and young people with a spinal cord injury

### BOX 4.2.D.1 Minimum standards

- Cervical collars.
- Dexamethasone.
- Physiotherapy.
- Jewett brace.
- Urinary catheters (in-out and Foley).
- Glyceryl trinitrate.
- Laxatives.
- Suppositories.
- Parent training.

### Introduction

The acute and immediate management of children and adolescents with a traumatically injured spine in the context of major injury is described in Sections 7.3.A and 7.3.G. Much of the important advice given in this section is adapted from the following excellent book, which is essential reading for all healthcare workers in resource-limited settings:

- Werner D (1987) *Disabled Village Children: a guide for community health workers, rehabilitation workers and families*. Palo Alto, CA: Hesperian Foundation.

### Mechanisms

- The following conditions predispose to spinal injuries: achondroplasia, Klippel–Feil syndrome, Down's syndrome and juvenile rheumatoid arthritis.
- Injuries can occur during birth and from abuse.
- Most of the injuries occur in road traffic accidents, sports, falls from trees or donkeys, bullet wounds and diving accidents.
- Non-traumatic causes include transverse myelitis (e.g. epidural abscess, tuberculosis of the spine, neuroblastoma, astrocytoma, eosinophilic granulomata, lipoma, teratoma and aneurysmal bone cysts).

### Diagnosis

- In the conscious patient, localised tenderness in the spine, and impairment or loss of sensation, voluntary motor power and reflexes can help to determine the level of vertebral involvement.
- In the semiconscious or unconscious patient, hypotension associated with bradycardia, dilated peripheral veins in the lower limbs, paradoxical respiration, lack of spontaneous movement of limbs, lack of response to painful stimuli applied by pressure over bony prominences at various levels, and urinary retention are all signs suggestive of a spinal cord injury.
- Around 10–20% of injuries are in more than one site. Therefore an X-ray of the whole spine is necessary.
- Other associated injuries are common, and loss of sensation may delay their diagnosis.

### Level of the injury

The magnitude of the area of the body that is affected will depend on the level of the injury. The higher the injury is, the greater the area of the body that is affected.

In paraplegia:

- there is loss of controlled movement and feeling in the legs

- the hips and part of the trunk may be affected (the higher the injury, the greater the area of the body that is affected)
- there may be partial or complete loss of urinary and bowel control
- there may be spasticity (muscle spasms) or hypotonia in the legs.

### Complete and incomplete injuries

When the spinal cord is damaged so completely that no nerve messages get through, the injury is said to be 'complete'. Feeling and controlled movement below the level of the injury are completely and permanently lost. If the injury is 'incomplete', some feeling and movement may remain. Alternatively, feeling and controlled movement may return (partly or entirely) little by little over a period of several months. In incomplete injuries, one side may have less feeling and movement than the other.

X-rays often do not show how complete a spinal cord injury is. Sometimes the backbone (spinal column) may be badly broken, yet the spinal cord damage may be minor. And sometimes (especially in children) the X-ray may show no damage to the backbone, yet the spinal cord injury may be severe or complete. Often only time will tell how complete the injury is.

### Neurological deterioration

This may be caused by:

- further mechanical damage and/or further non-mechanical damage to neural tissue during treatment
- hypoxia, hypotension and sepsis that develop due to poor management of the multisystem malfunction.

### Acute management of spinal cord injuries: overall approach

For acute ABC management in the context of major traumatic injury, see Sections 7.3.A and 7.3.G.

- Aim to prevent complications related to multisystem dysfunction by good ABC resuscitation.
- Aim to contain the 'biomechanical instability' of the spinal column by preventing movement at the site of the fracture.
- Dexamethasone should not be given routinely to children with spinal injuries, as there is no evidence that steroids improve the neurological outcome, and the risk of complications is high.
- Dexamethasone should only be considered if there are signs of neurological deterioration following acute spinal injuries. The recommended dose is 500 micrograms/kg immediately, followed by 50 micrograms/kg every 6 hours for 48 hours.
- 'Rehabilitation' should begin in parallel with the medical treatment as soon as possible.
- Arrange early counselling and psychological support for the child, their parents and family members.
- Start physiotherapeutic procedures to prevent contractures of paralysed muscles, chest infections and pressure sores.
- Train all systems of the body to function as safely and with as near normal convenience as possible.

- Aim for psychosocial and physical reintegration of the child in the community without significant loss of education.
- Ensure a teaching programme for the child and/or their parents aimed at minimising the development of complications (medical, physical and psychological) in the medium and long term.
- Offer lifelong regular hospital assessment and treatment if necessary to maintain health and rehabilitation.

### Acute spinal injury

- Keep the spine in a neutral position (with pillow arrangements). For cervical spine injury, immobilise with a cervical collar or sandbags at the side of the head for about 6 weeks, followed by bracing for 6 to 8 weeks. In children under 6 years of age, the sagittal diameter of the skull exceeds that of the chest, forcing the neck into flexion. A cut-out should be made in the board or the mattress to recess the occiput.
- Children with an unstable fracture of the spine but with intact neurology can be adequately braced in a Minerva cast for cervical spine injuries and a body cast for thoracolumbar injuries. Alternatively, or later, surgery can be undertaken, but only in a specialist centre (if available).
- Minerva and body casts should not be applied to children with sensory loss, because of the risk of pressure sores.
- A hard cervical collar for the quadriplegic patient and a Jewett brace for the paraplegic child are likely to provide adequate support until healing occurs.

### Temperature control

The patient may not be able to control their body temperature, becoming pyrexial in a hot environment or hypothermic in a cold environment.

### Cardiovascular and peripheral vascular system problems

- Spinal shock (autonomic areflexia) may cause bradycardia with hypotension.
- Care is needed with IV hydration, as circulatory overload and pulmonary oedema can easily occur.
- Hypoxia, hypothermia and tracheal suction can aggravate the bradycardia.
- Postural hypotension is most profound during the state of spinal areflexia. Early mobilisation can result in a significant drop in blood pressure which may affect spinal cord blood flow and adversely affect neurological recovery.
- Following the return of autonomic reflex activity, patients with cord lesions above T6 can develop autonomic dysreflexia (sudden onset of pounding headaches, flushing, blotchiness of the skin above the level of the injury, conjunctival congestion associated with sweating, and high blood pressure). The commonest causes are urinary retention and constipation. Treat this condition by placing the patient in the upright position (usually sitting) and if they are over 12 years of age the administration of sublingual glyceryl trinitrate (300 micrograms). If urinary retention is the cause, catheterisation following the liberal instillation of urethral lubricant with local anaesthetic will rapidly reduce the blood pressure and relieve the symptoms.

### Respiratory system

- Children with injuries above C4 are unlikely to be able to breathe spontaneously.
- Children with lesions below C4 (most children with activity in the biceps) are able to breathe independently using their diaphragm, provided that no major chest injury is present.
- Encourage deep-breathing exercises and postural drainage, assist coughing and monitor oxygen saturation if possible.

### Gastrointestinal system

- In the acute phase after a spinal cord injury, all patients are at risk of developing paralytic ileus. The resulting abdominal distension can embarrass the diaphragm and further impede diaphragmatic breathing. Avoid oral intake in the first 48–72 hours following injury and until bowel sounds are audible.
- The risk of gastrointestinal bleeding from stress ulcers is high. Therefore administer H<sub>2</sub>-blockers such as ranitidine, 2–4 mg/kg twice daily up to a maximum of 150 mg twice daily, or antacids, for the first 3 to 4 weeks following injury.
- A regular bowel regime consisting of suppositories at fixed and regular intervals not exceeding 24 hours should be instituted initially by a nurse or parent, and later by the child (see below for details).

### Hypercalcaemia

- This occurs in 10–20% of children, especially in quadriplegia and complete spinal cord injuries. The onset is insidious in the first few weeks following injury. Nausea, anorexia and vomiting can mimic an acute abdomen. Polydipsia, polyuria, dehydration, lethargy and occasionally psychosis can occur.
- Adequate hydration and furosemide are the first-line treatment.

### Management of nutrition

#### What food should be given?

If the child is malnourished, give them 200 kcal/kg/day (see Section 5.10.A and 5.10.B). The daily number of kilocalories should be divided by the number of meals given during the day, usually four meals per day.

F100 can be used to correct malnutrition (see Section 5.10.B).

#### Commercial F100

This special milk is prepared in a sachet. All that the family has to do is open the packet and dilute the contents in 2 litres of water.

#### Home-made F100

When commercial milk is not available, F100 can be prepared from the recipe shown in Table 4.2.D.1.

The basic diet is composed of F100 meals. However, when the patient is gaining weight quickly other foods can be introduced. For example, the usual food eaten in the area can be used, but this should be enriched with the addition of oil and vitamin and mineral mix, and sometimes dried skimmed milk.

**Example of calculation:**

A child who weighs 20 kg should receive  
 $200 \text{ kcal} \times 20 = 4000 \text{ kcal per day}$ .

They will receive 4 meals per day, therefore 1000 kcal per meal.

**Doses of supplemental nutritional aids**

These are as follows (see Section 5.10.A and 5.10.B):

- **Zinc:** 2 mg/kg/day, or for children over 5 years of age, 40 mg once a day (of the elemental formula).
- **Vitamin C:** 45 mg/day.
- **Iron:** one ferrous sulphate tablet of 200 mg once weekly for children over 5 years of age.

**TABLE 4.2.D.1 Recipe for preparing 1 litre of high-energy food**

Food item	Quantity
Dried skimmed milk (DSM) or oiled full cream milk	80 grams (900 mL)
Vegetable oil	60 grams (20 mL)
Sugar	50 grams
Water (boiled)	Add water to make 1 litre of preparation
CMV (minerals and vitamin mix)*	20 mL (should be added after the water)

\*The CMV should be added when the preparation of milk is ready. Whisk to prevent the oil from separating. This keeps for 12 hours.

## Subsequent nursing and medical management and education of the child and their family

### Early questions that a child with spinal cord injury and their family may ask

#### Will my child always remain paralysed?

This will depend on how much the spinal cord has been damaged. If paralysis below the level of the injury is not complete (e.g. if the child has some feeling and control of movement in their feet) there is a better chance of some improvement.

Usually the greatest improvement occurs in the first months. The more time that goes by without improvement, the less likely it is that any major improvement in feeling or movement will occur.

**After 1 year, the paralysis that remains is almost certainly permanent. As gently as you can, help both the child and their parents to accept this fact.** It is important that they learn to live with the paralysis as best they can, rather than waiting for it to get better or going from clinic to clinic in search of a cure.

Immediately after a spinal cord injury, the paralysed parts are in 'spinal shock', and are hypotonic. Within a few days or weeks the legs may begin to stiffen, especially when the hips or back are straightened. Also, when it is moved or touched, a leg may begin to 'jump' (a rapid series of jerks, or 'clonus').

This stiffening and jerking is an automatic reflex called

'spasticity'. It is not controlled by the child's mind, and often happens where spinal cord damage is complete. It is **not** a sign that the child has begun to feel where they are touched or is recovering control of movement. Some children with spinal cord injury develop spasticity, while others do not.

If the spinal cord injury is above the level of the top edge of the hipbone (above the second lumbar vertebra), spasticity is likely. If the injury is below this level, paralysis is usually floppy (no muscle spasms).

Severe spasticity often makes moving and control more difficult. However, the child may learn to use both the reflex jerks and spastic stiffness to help them to do things. For example:

- When the child wants to lift their foot, they hit the thigh, triggering the jerks that lift the leg.
- In lower back injuries, the spasticity or stiffness of the legs may actually help the child to stand for short periods.

#### Will my child be able to walk?

This will mainly depend on how high or low in the back the injury is.

If the child's injury is in the lower back and if their arms are strong and they are not overweight, there is a chance that they may learn to walk with crutches and braces. However, they will probably still need a wheelchair to go long distances.

It is best not to place too much emphasis on learning to walk. Many children who do learn to walk find it so slow and tiring that they prefer to use a wheelchair.

It probably makes sense to give most paraplegic children a chance to try walking. However, do not make the child feel guilty if they prefer a wheelchair. Let the child decide which is the easiest way for them to move about.

**For independent living, other skills are more important than walking**, and the family and child should place greater emphasis on these skills, such as dressing, bathing, getting in and out of bed, and toileting. Self-care in toileting is especially important, and is made more difficult because of the child's lack of bladder and bowel control.

#### What are the prospects for my child's future?

The likelihood of a child with **paraplegia** leading a reasonably normal life are good, provided that:

- Three major medical risks are avoided:
  - skin problems (pressure sores)
  - recurrent urinary tract infections
  - contractures (shortening of muscles, causing deformities); these are not life-threatening, but they can make moving about and doing things much more difficult.
- The child is helped to become more self-reliant:
  - home training and encouragement to master basic self-help skills such as moving about, dressing and toileting
  - education: learning of skills that make keeping a household, helping other people, and earning a living more achievable.

It is more difficult for children with **quadriplegia** to lead a normal life because they are more dependent on physical assistance.

In well-resourced countries, many children with paraplegia manage to lead full rich lives, earn their own living, get married, and play an important role in the community.

With effort and organisation, the same potential for leading a normal life can exist in all countries.

### **Can anything be done about loss of bladder and bowel control?**

Yes it certainly can. Although normal control rarely returns completely, the child can often learn to be independent in their toilet, and to stay clean and dry (except for occasional accidents). Often they will need to learn to use a urinary catheter, and learn to bring down a bowel movement with a finger or suppository (see below).

### **What about sexual relationships and having children?**

Many people with spinal cord injuries marry or have fulfilling sexual relationships. Women with spinal cord injuries can become pregnant and have babies.

### **Helping the child and their family to adjust to and accept the injury**

Perhaps the biggest problem is that one day the child is physically active and able, and the next they are suddenly paralysed and (at first) unable to do much for themselves. They have lost all feeling and control in part of their body, which feels like a 'dead weight'. This is very hard for both the child and their family to accept. Both have enormous and partially justified fear and uncertainty about the future. The child may become deeply depressed, or angry and uncooperative. They may refuse even to sit in a wheelchair because this means accepting that they are unable to walk.

There are no easy ways to address the child's fear and depression, but here are some suggestions that families have found helpful.

Recognise that **the child's fear, depression and anger are natural responses**, and that with love, understanding and encouragement they will gradually overcome them.

Be honest with the child about their disability. Do not tell them 'We will find a cure for you' or 'Soon you will get well and be able to walk again.' Very probably this is untrue, and misleading the child in this way only makes it more difficult for them to accept their disability and begin to shape a new life. Also, as the promised 'cure' fails to materialise, the child will become more uncertain, distrustful and afraid. In the end, it will be much easier if you gently tell them the truth.

Provide opportunities to **keep the child's mind active by playing, working, exploring, and learning through stories, games, and studies**. But at the same time **respect and be supportive of the child when they feel sad and frightened**. Let the child cry, comfort them when they do so, but do not tell them not to cry. Crying helps to relieve fear and tension.

Start the child with **exercises, activities and relearning to use their hands and body** as soon as possible. Start with what the child can do, and build on that.

Try to arrange for the child to **watch, talk with and get to know other people with spinal cord injury**.

Invite the child's friends to come and visit, play with him or her, and let the child know that they are eager for the day he or she will be back in school.

**Encourage the child to do as much for him- or herself as possible**, even if it takes a little longer.

As far as possible **avoid the use of 'tranquillisers'** or other inappropriate medication. The child needs an alert mind and the ability to move actively all day.

To prevent or reduce the harmful effects of the

complications of spinal cord injury, **special precautions need to be taken early and continued throughout life**.

### **Early care**

**Early care following spinal cord injury is best provided in hospital**. Family members should stay with the child to make sure that he or she is kept clean and turned regularly, so that bed sores and pneumonia are avoided. Busy hospital staff with little experience of treating spinal cord injuries sometimes allow severe bed sores to develop, which may be life-threatening for the child.

**The damage that has already been done to the spinal cord cannot be corrected with surgery or medicine.**

### **Preventing pressure sores (bed sores)**

When sensation has been lost, pressure sores can easily form on the skin over bony areas, especially on the hips and bottom. The time of greatest risk of sores developing is in the first weeks after the injury. This is because the child must stay very still, and has not yet learned to move or turn over their body. Prevention of pressure sores is extremely important, and needs understanding and continuous care, both by the child and by those caring for them.

### **Early prevention of pressure sores**

- Lie the child on a soft mattress or a thick firm foam rubber pad.
- Place pillows and pads to keep the pressure off bony areas.
- Change their position (turn over from front to back and side to side) every 2 to 3 hours. To avoid pressure sores, lying on the abdomen is the best position.
- Keep the skin and bedclothes clean and dry.
- Give the child healthy food rich in vitamins, iron and protein.
- Move and exercise the child a lot to promote healthy flow of the blood.
- Check their skin daily for the earliest signs of pressure sores, and keep all pressure off areas where sores might be developing until the skin is healthy again.

### **Avoiding contractures**

In the first weeks following a spinal cord injury, when the child is in a lying position, joint contractures (muscle shortening) can easily develop, especially in the feet and elbows. Pillows and pads should be placed to keep the feet supported, the elbows straight, and the hands in a good position. Gentle range-of-motion exercises of the feet, hands and arms should begin as early as possible, taking care not to move the back until the injury has healed.

### **Movement and exercise**

Do range-of-motion exercises for about 10 minutes for each leg. In the first weeks, do the exercises twice a day; later on, once a day may be enough. If any signs of contracture develop, spend more time and effort on those parts of the body. From the start, exercises should be both **passive** (someone else moving the child's body parts) and, whenever possible, **active** (the child moving them).

Range-of-motion exercises should begin with great care the day after the spine is injured. The exercises will help to improve the flow of blood (which reduces the likelihood of bed sores), prevent contractures, and build the strength

of the muscles that still work. Range-of-motion exercises should be **continued throughout life**, when possible as a part of day-to-day activity.

### Cautions

- Until any breaks or tears in the spine have healed (this takes 6 weeks or more), exercise must be very gentle and limited, with smooth motions and no jerking.
  - Especially at first, take great care that exercises do not move the position of the back and neck (depending on the site of injury). Start with the feet, ankles, hands, wrists and elbows.
  - If exercises trigger severe muscle spasms or jerking, do not do them until the break in the spine has healed.
- Do not use force in trying to get the full range of motion, as joints can easily be damaged.
- Try to keep the full range of motion of all parts of the body, but **work most with those joints that are likely to develop contractures**, especially:
  - paralysed parts that tend to hang in one position, such as the feet
  - joints that are kept straight or bent by spasticity or by muscle imbalance.

### Maintaining a healthy position

The position that the body is in during the day and night is also important to prevent contractures.

**Contractures that cause 'tiptoeing' of the feet can develop easily, especially when there is spasticity. Keep the feet in a supported position flexed at 90 degrees to the lower leg, not in the extended position, for as much of the time as possible when lying down and when sitting.**

Teach the child to check that their feet are in a good position. Even for the child who may never walk, maintaining the feet in a flexed position makes moving from chair to bed, toilet or bath easier.

Another common problem for children with spasticity is that the knees pull together and in time contractures prevent the legs from separating. To prevent this, when the child lies on their side, they should learn to place a pillow between the legs, and to keep it there most of the time.

A common problem with wheelchair users is that they slump forward. In time this can deform the spine. In a wheelchair with a straight-up back a person with spinal cord injury slumps like this in order to balance. A chair can be designed (or adapted) so that it tilts back. This provides balance for a better position.

A special cushion also helps to prevent the child's bottom from sliding forward (and also helps to prevent pressure sores). If possible, use a cushion made of 'micropore' foam rubber (foam containing very tiny air bubbles). Rubber-coated coconut fibre also works well.

### Early physical development

The goal is for the child to become as independent as possible in doing what they want and need to do. However, even before the skills of daily living are relearned, the child needs to **learn to protect the body where functions that used to be automatic have been lost**. The protective functions that may be lost or changed include the following:

- adjustment of the blood pressure to changes in body position

- sensation (including pain) that protects the body from injuries (e.g. bed sores)
- the sense of body position and ability to keep balance
- muscle strength and coordination.

**A sudden fall in blood pressure in the brain when the person rises from lying to sitting, or from sitting to standing**, can cause dizziness or fainting. This is a common problem in spinal cord injury because the blood pressure adjustment mechanism is partly lost. The body can be helped to gradually readapt, but precautions are needed. (These same precautions are the same for anyone who has been kept lying down for a long time.) Before beginning to sit, raise the head of the bed – a little more and a little longer each day. If the child starts to feel dizzy or faint when sitting, tilt their back and lift their feet. Lifting exercises help the body to relearn to adjust blood pressure, and also prevent bed sores and strengthen the arms.

The loss of sensation **in parts of the body can lead to pressure sores and other injuries**, such as burns and cuts. This is because the body no longer feels pain, so does not warn the child to change position or move away from danger.

It is important that the child learns to protect him- or herself by changing positions often and avoiding injuries. This includes the following:

- learning to roll over
- turning at least every 4 hours when lying or sleeping
- lifting from a sitting position every 15 minutes
- washing daily
- examining the whole body every day for signs of injuries or sores
- learning to protect him- or herself from burns and other injuries.

Keeping clean is very important for people with reduced sensation, especially if they lack bladder and bowel control. Take care to bathe them daily. Wash and dry the genitals, the bottom, and between the legs as soon as possible each time they get wet or dirty.

If redness, rash or sores develop, wash more often and keep the sore area dry. Keep the legs spread open and exposed to the air. When they must be covered, use soft absorbent cotton cloth.

For treatment of specific fungal, yeast and bacterial infections of the skin, see Section 5.18.

**Loss of the sense of body position** affects a person's sense of balance, as does **loss of muscle control**. The child needs to develop new ways to sense the position of their body and keep their balance.

Start with the child sitting on a bench, if possible, in front of a mirror, and help them to progress through the following stages:

- 1 Place both hands on the bench.
- 2 Place both hands on the knees.
- 3 Lift one arm sideways, forward and back.

After doing this in front of a mirror, ask the child to do it without the mirror.

- As the child begins to develop better balance, start doing different movements with first one and then both arms, such as lifting weights or playing ball.

- Some children may experience so much difficulty with balance that they have to start in a wheelchair or a chair with a high back and arm supports.

**Redeveloping muscle** strength and coordination. All muscles that still work need to be as strong as possible to make up for those that are paralysed. Even imagining movements helps to re-educate the brain about body posture. The most important muscles are those around the shoulders, arms and stomach.

### Self-care

With the help and encouragement of family, friends and rehabilitation workers, the child can learn to become as independent as possible in meeting their basic needs, including moving about, eating, bathing, dressing, toileting, and in time other skills for daily living.

Progress toward self-care, especially at first, may be slow and frustrating. The child will need a great deal of understanding and encouragement. To make activities easier both for the child and for their helper, it is important that **they avoid becoming overweight**.

Useful methods and techniques have been devised for helping to relearn basic skills. Much depends on determination, imagination and common sense. Start with movements like rolling over and sitting up in bed.

### Keeping active

Many of the 'complications' of spinal cord injury occur because the person spends a lot of time either lying down or sitting. To stay healthy, the body needs to keep active. Lack of movement and activity causes poor flow of the blood. This can lead to pressure sores, swollen feet, painful or dangerous blood clots (thrombosis), especially in the legs, increasing weakness of bones (osteoporosis) with the risk of fracture, bladder or kidney stones, increased risk of urinary tract infections, and general physical weakness and poor health.

It is important for both body and mind that people with a spinal cord injury keep physically active. Children should be allowed to do as much for themselves as they can, including pushing their own wheelchair, bathing, transferring, washing their clothes, helping to clean the house, and helping with work.

Active participation in games and sports can also be encouraged. Swimming, basketball and archery can be done well using only the upper body.

To keep the leg bones growing well and to prevent them from becoming weak and breaking easily, even children who may always have to use a wheelchair should if possible stand for a short time every day. This can be done by strapping the child to a 'standing board', or by making some kind of standing frame. Standing also helps to prevent constipation.

### Management of bowel movements

When a person's spinal cord is damaged, they almost always lose control over when they will open their bowels. This makes it difficult to stay clean, which can be inconvenient and embarrassing. Although they can never regain complete control over the muscles that hold in or push out the stool, **they can learn to help the stool come out, with assistance, at certain times of day**. This kind of 'bowel programme' can greatly increase the person's

self-confidence and freedom to take part in school, work and social activities.

People with spinal cord damage often have problems with constipation. Some constipation can be an advantage when a person lacks bowel control. However, sometimes it can lead to serious problems, such as impaction or dysreflexia. It is therefore important to prevent serious constipation by adopting the following measures:

- Drink plenty of water.
- Eat foods that are high in fibre (e.g. bran, wholegrain cereals, fruits, vegetables, cassava, beans, nuts).
- Stick to a scheduled bowel programme.
- Keep active.

### Planning a bowel opening programme

Any bowel programme will work better if the child:

- does the programme every day (or every other day) and at the same time, even if they have had an accidental bowel movement shortly before, or have diarrhoea
- does the programme at the same time of day as they normally had bowel movements before their injury
- performs the task after a meal; often the bowels move best after a meal or a hot drink
- if possible, performs the task on a toilet or pot; the bowels work better in a sitting position than when lying down
- is patient; the bowels sometimes takes days or even weeks to change their pattern.

### Types of bowel programme in spinal injury

Different people require different types of bowel programme, depending on whether their bowels are 'automatic', 'flaccid' or 'pull back'.

- **Automatic bowel** usually occurs in people who have muscle spasms in their legs, and an 'automatic bladder'. The muscle or 'sphincter' in the anus remains shut until there is a stimulation of the bowel to make it open, so that the stool can come out. An automatic bowel will 'move' in response to a suppository or stimulation by a finger.
- **Flaccid bowel** usually occurs in children with low spinal cord damage who have limp (not spastic) legs and bladder. The sphincter muscle in the anus is also limp, so the person tends to 'ooze' or 'dribble' faeces. A limp bowel does not respond to finger stimulation.
- **A bowel that pulls back** is neither automatic nor limp. When you insert a finger in the anus, the stool moves back up instead of coming out.

### Management of an automatic bowel

- 1 Start with a suppository (Dulcolax or glycerine) prior to digital evacuation of the bowel. Glycerine suppository sizes are as follows: for an infant, 1 gram; for a child aged < 12 years, 2 grams; for a child aged > 12 years, 4 grams. With a finger covered with a glove or plastic bag, and then vegetable oil or Vaseline, push the suppository about 2 cm (1 inch) up the anus. Do not push it into the stool, but push it against the wall of the bowel. It is possible to try this same activity without a suppository; often finger stimulation alone is enough to stimulate a bowel action.
- 2 Wait for 5–10 minutes. Then help the child to sit on a toilet or pot. If they cannot sit, have them lie on their left side (on top of toilet paper or newspaper).
- 3 Put an oiled finger into the anus for a distance of about

- 2 cm. Gently move the finger in circles for about 1 minute, until the anus relaxes and the stool pushes out.
- 4 Repeat the finger action three or four times, or until no more stool is felt.
  - 5 Clean the bottom and anus well and wash your hands.

### Management of a flaccid bowel

Since the bowel does not push, the stool must be taken out with a finger. This is best done after each meal, or at least once a day.

- If possible, the child should be sitting on a toilet or pot, or lying on their left side.
- With a gloved and oiled finger, remove as much stool as you can.
- Since a limp bowel tends to ooze stool, the child should be given foods that make the stool firm or slightly constipated (**do not give the child stool-loosening foods**).

### Management of a bowel that 'pulls back'

For this kind of bowel, the bowel programmes described above do not usually work. Finger stimulation makes the bowel act in the opposite direction and pull the stool back in. The child will have 'accidents' during the day. Often it is more effective to first put some anaesthetic jelly (e.g. lidocaine) up the anus. If you cannot obtain the jelly, you can mix some liquid injectable lidocaine with Vaseline or any other jelly. Wait for several minutes, and then proceed to the automatic bowel management.

### Other important issues

- Children can almost always learn to do their own 'bowel programme'.
- Do not use enemas or strong laxatives regularly. They stretch the bowel, injure its muscles, and make following a regular programme more difficult. A mild laxative (senna or Dulcolax; see Section 5.12.C) may be taken occasionally when needed. However, drinking more liquid and eating food high in fibre is usually sufficient.
- If there is bright red blood in the stool, a blood vessel was probably torn during the management described above. Be more gentle! If there is dark old blood and the stools are black and tar-like, and the child is generally unwell, the parents should seek hospital advice urgently.
- A small amount of liquid stool (diarrhoea) may be a sign of 'impaction', which is a ball of hard stool stuck in the bowel. Only liquid stool can leak around it. Do not give medicine that is used to stop diarrhoea, as this could make the impaction worse. Try to remove the stool with a finger, or use stronger laxatives on a temporary basis (see Section 5.12.C).

A bowel management programme may at first seem difficult and messy, and is initially very embarrassing for the child. However, it soon becomes an easy habit. It is very important both for the child's health and for their social well-being. Do it regularly at the same hour of the day, and do not miss a day.

Constipation is almost always a potential problem, and can cause haemorrhoids, anal fissures and mucosal tears. For management of an acute episode, see Section 5.12.C. If constipation is regularly a problem, consider giving regular senna tablets (7.5 mg sennoside): aged 6–12 years, 1–2 tablets once daily; for 12–18 years, 2–4 tablets once daily or liquid (7.5 mg sennoside in 5 mL); for children under

6 years of age, 2.5–5 mL once daily; and for children over 6 years of age, 5–10 mL or 1–2 tablets once daily.

### Locomotor system

- There is a high risk of contractures of muscles, limitation of the range of movement in the joints of the paralysed limbs, excess spasticity and fractures of long bones which are preventable.
- Passive movements and good positioning in bed and early splinting (if necessary) should prevent contractures.

### Urinary system

- Urinary retention occurs during the stage of spinal areflexia, and is usually permanent in children with lower motor neuron lesions.
- Reflex micturition gradually develops in children with upper motor neuron lesions, usually from the sixth week onwards.
- Extra fluid intake should be encouraged.
- Up to the age of 2 to 3 years, 4-hourly gentle suprapubic pressure will empty the bladder.
- Children above the age of 3 years are best managed with intermittent catheterisation until effective reflex micturition occurs and the residual urine is consistently below 60 mL.
- Children with lower motor neuron lesions are likely to require intermittent catheterisation for the rest of their life. Initially this should be done by an attendant or parent. However, with teaching and training, a child with good hand function can learn to do clean intermittent self-catheterisation. Intermittent catheterisation is the safest method of bladder drainage.
- The use of indwelling urethral catheters is not recommended after the first 48–72 hours, but may sometimes be appropriate (see below).
- Antibiotics should be reserved for urinary tract infections with systemic manifestations.

Most children with spinal cord injury do not have normal bladder control. This can be inconvenient, embarrassing, and causes social and emotional difficulties. In addition, the loss of control can cause skin problems and **dangerous urinary tract infections**. For these reasons, it is important to learn ways to stay clean, dry and healthy. Most of the methods are not difficult, so children should be able to do this themselves, and this in turn will help them to feel more self-reliant.

The main goals of urine system management are as follows:

- 1 to prevent urinary infection
- 2 to promote self-care in staying as dry as possible.

Prevention of urinary tract infections is extremely important. **Infections of the urinary system (bladder and kidneys) are very common in spinal cord injury, and are one of the main causes of early death.** Therefore any method that is used for self-care or staying dry must also help to prevent urinary tract infections. Make every effort to prevent infection from entering the bladder. **Keeping clean is essential.** It is also important to empty the bladder regularly and **as completely as possible**. If some urine remains in the bladder, bacteria will grow in it and cause infection.

The ideal method of urinary control empties the bladder completely and in a clean, regular, easy and self-reliant way.

### Types of bladder problems

**Automatic bladder:** A child with paralysis whose legs have 'reflex spasms' (uncontrolled stiffening or jerking) may have reflex spasms in their bladder. As the bladder fills with urine, the walls of the bladder stretch and cause a reflex spasm. As the bladder squeezes, the muscles that hold back the urine relax, letting the urine flow out. This is called an 'automatic bladder' because it empties automatically when it gets full.

**Flaccid bladder:** When a child's paralysed legs are limp (due to lower motor neuron damage) and do not have spasms, usually the bladder is also limp or flaccid. No matter how much urine fills the bladder, it will not squeeze to empty. The bladder stretches until it cannot hold any more urine. The urine then begins to drip out and overflow incontinence develops. The bladder does not completely empty, and because some urine remains in the bladder, there is an increased likelihood of infection.

The most simple methods of bladder management work well with an automatic bladder but do not work with a limp bladder. Therefore **it is important to try to establish which type of bladder the child has.**

For the first few days or weeks after the spinal cord injury occurred, the bladder is almost always flaccid. Urine either drips out or does not come out at all. Then, as the 'spinal shock' wears off, people with higher back injuries (above the second lumbar vertebra) usually develop an automatic bladder. In people with lower back injuries the bladder usually remains flaccid.

During the first weeks after the spinal cord injury, usually a Foley catheter is kept in the bladder all the time. However, after about 2 weeks it is a good idea to test how the bladder works by removing the catheter and trying one of the methods described below. If the child is often wet, try another method for that type of bladder.

### Methods for managing the automatic bladder

**Triggering programme:** This method usually causes the bladder-emptying reflex to work when the person is ready to pass urine. It can be done using a urinal, toilet, potty or jar. **This is the first method to try**, because nothing is put into the bladder. It is easy, so a child can do it unaided.

- 1 Tap the lower belly (over the bladder) firmly with your hand for about 1 minute. Stop and wait for the urine to flow.
- 2 Tap again. Repeat several times until no more urine flows.

If possible, once a week after triggering, use an in-out catheter to see how much urine is left. If there is less than a cupful (150 mL), continue the triggering programme. If there is more than a cupful on several occasions, the bladder is not emptying well enough, and another method should be tried (see below).

**Periodic use of a catheter:** This method allows the bladder to be emptied completely before it becomes too full. Sometimes it can be used to prepare the body for triggering. Put a clean or sterile standard catheter into the bladder every 4–6 hours to empty the urine, and then remove the catheter. If the child drinks more liquid than usual, put in the catheter more frequently to keep the bladder from stretching too much.

To reduce the risk of urinary tract infections, **regular frequent use of the catheter is more important than using a sterile catheter.** It is a mistake to stop using the

catheter only because you have not had an opportunity to boil it (e.g. when travelling, or at school). Just wash out the catheter with clean drinkable water after use, and keep it in a clean jar or towel. **Do not go too long without catheterising, and do not stop catheterising altogether.** It is important not to leave a large amount of urine in the bladder.

### How to insert a catheter

Healthcare workers and parents can easily be taught to put in a catheter. With a little practice, children with paraplegia can also learn to do this. A mirror can help girls to see the perineal area.

- The best catheter size is usually #8 or #10 for a small child, and #14 or #16 for a large child.
- Vigilance about cleanliness (i.e. boiling the catheter and wearing gloves) is important when using a fixed (Foley) catheter. However, for periodic use of a regular (in and straight out) catheter, a clean rather than sterile technique is more practicable (and therefore may be safer). Wash the catheter well with clean water after each use, and keep it in a clean container. Wash your hands well before using it.

The procedure for insertion of a catheter is as follows:

- 1 If possible, boil the catheter for 15 minutes, or at least wash it well and keep it clean.
- 2 Bathe the child well (at least daily). Wash well under the foreskin or between the vaginal lips and the surrounding areas.
- 3 Wash your hands with soap. After washing, touch only things that are sterile or very clean.
- 4 Put very clean cloths or towels under and around the area.
- 5 Put on sterile gloves, or rub your hands well with alcohol or surgical soap.
- 6 Cover the catheter with a lubricant (slippery cream) such as KY Jelly that dissolves in water (do not use oil or Vaseline).
- 7 Pull back the foreskin or open the vaginal lips.
- 8 Holding the foreskin back or the vaginal lips open, gently put the catheter into the urethra. Twist it as necessary, **but do not force it.** Hold the penis straight at this angle.
- 9 Push the catheter in until urine starts to flow out, then push it in 3cm further.
- 10 If using a regular catheter, each time the child passes urine they should tighten their stomach muscles or gently massage the lower abdomen to empty all urine. Then take out the catheter, wash it well, boil it, and store it in a clean jar or towel.

**To avoid introducing infections when using a catheter, it is important to be very clean and to use only a catheter that is sterile, boiled or very clean.**

**Using a fixed (Foley) catheter:** With this method, the catheter is left in all the time to drain the urine from the bladder continuously. A Foley catheter is often used immediately after injury, and in some cases for many months or years. The catheter connects to a collection bag that can be attached to the leg and worn under the clothes. The catheter should be changed using a sterile technique once weekly or more frequently if there is a urinary tract infection (see below).

In many areas this is the easiest method because other

supplies are difficult to obtain. However, a Foley catheter can cause many problems, including the following:

- bacteria entering the bladder, causing a **high risk of infection**
- **continuous bladder irritation**, which can cause bladder stones to form.

If you have tried other methods unsuccessfully or no other equipment is available, a Foley catheter may be the only option. To prevent complications from occurring **it is very important that the Foley catheter is used carefully:**

- Always wash your hands thoroughly before touching the catheter.
- Clean the skin around the catheter with soap and water at least twice a day, and after each bowel movement.
- Do not disconnect the collection bag except to empty and wash it. Wash out the collection bag with soap or diluted bleach and water once a day.
- If the catheter must be clamped, use a sterile plug, **never a glass ampoule (small bottle)**, as this may break and cause injury.
- **Keep the collection bag below the level of the bladder** to keep the urine from flowing back into the bladder via gravity.
- Tape the catheter to the leg when the child is in a wheelchair.
- Check regularly to make sure that the urine is emptying and that the catheter is not blocked. Make sure that there are no sharp bends or folds in the tubing.
- When turning, lifting or moving the child, remember to move the bag, too. Do not let it pull at the catheter or stay under the child.
- If the catheter becomes blocked, take it out, squirt boiled water through it, and put it back. Alternatively, use a new catheter. Use a sterile or very clean syringe.

**Condom catheter for male children:** This is a practical method for male children and adolescents who cannot control their urine flow. It can be used in combination with triggering, to avoid accidental wetting.

A condom catheter is a thin rubber bag that fits over the penis. It has a tube that connects to a collection bag. Condom catheters are available in different sizes. If they are too costly or not available, a regular condom can be attached to the collection tube with a rubber band or tape. Alternatively, a thin, very clean plastic bag or the finger of a rubber glove (or a 'finger cot') can be used.

To hold the condom on the penis, stretchy adhesive tape can be used.

**Important precautions for condom catheter use** include the following:

- Ensure that it is not too tight, otherwise it could stop the blood flow and seriously harm the penis. Avoid the use of non-stretch tape.
- If the penis has erections, try to put on the condom when it is erect.
- Remove the condom once a day and wash the penis well.
- If possible, remove the condom at night, and use a bottle or urinal to catch the urine.
- Check the condom and penis often, to ensure that everything is all right.
- If the penis becomes injured, swollen or looks sore, remove the condom until it is healthy again.

### Methods for the limp bladder

If the person's bladder is flaccid, it never empties by reflex. The bladder will constantly contain some urine unless an effective emptying method is used.

**Girls** can use a Foley catheter. This is often the simplest method, but it can lead to urinary tract infections. Alternatively, try an 'intermittent' (in-and-out) programme, using a regular catheter every 4–6 hours. If there is leaking in between catheter times, use diapers, rags or a thick sanitary pad to catch the urine. Change them often and wash the skin often to protect the skin and prevent sores.

**Boys** can use an intermittent catheter every 4–6 hours.

### Other suggestions for the flaccid bladder

- **The push method:** Strain to push the urine out by tightening the abdominal muscles. This method is recommended by many professionals, but it can cause problems. If the muscles do not relax to let the urine flow out, pushing on the bladder can force urine back into the kidneys, causing kidney infection and damage. Therefore **the push method should only be used if the urine flows out easily with gentle pressure, or if no other method is possible.**
- However, it is best to also use a regular catheter at least three times a day. This is because the bladder may not have emptied completely, which makes infection more likely.

### Management of urinary tract infections (see Section 5.6.A)

Children with spinal cord injury have a high risk of urinary tract infections, for the reasons discussed above. Long-term or untreated infections and kidney problems are a common cause of early death. Preventive measures are essential, but even when precautions are taken, some urinary tract infections are still likely to occur. Therefore it is very important to recognise the signs and provide effective treatment.

### Clinical signs

When a person who has normal sensation has a urinary tract infection, pain is felt when they pass urine or when they pass urine more frequently, including at night. The person with spinal cord damage may not feel this pain or be able to have frequency or nocturia, and therefore has to use other signs to know when they have an infection. The child may learn to recognise certain unpleasant feelings, or may only know that they do not feel as well as usual. Parents and healthcare workers should learn to listen to the child and be aware of changes in behaviour or other signs that might mean that an infection is probably present.

Possible signs of a urinary tract infection include the following:

- cloudy urine, possibly with mucus, pus or blood specks
- dark or red urine
- strong-smelling or bad-smelling urine
- increased bladder spasms (cramps)
- increased wetting or changes in bladder function
- pain in the back or loins
- body aches
- general discomfort
- increased muscle spasms
- fever

- dysreflexia (headache, 'goose-bumps' when sweating, high blood pressure).

### Treatment

At the first signs of infection, the child should drink even more water than usual. Antibiotics may also be necessary. However, avoid frequent use of antibiotics because they may become less effective as bacterial resistance develops.

If the child has had urinary infections before, they can start with the last medicine that was effective (for details of antibiotic treatment, see Section 5.6.A).

If a medicine seems to help, continue taking it for at least 1 week, or for 4 days after the last clinical signs have disappeared. Do not change from one medicine to another unless the medicine is not working or causes serious side effects.

### Prevention of urinary tract infections in patients with spinal injury

- Drink plenty of liquid (for normal daily fluid intake that should always be maintained, see Section 9, Appendix), with higher intake if there is a high ambient temperature. An intake of at least 2 litres (eight 250-mL glasses) a day is required for a teenager.
- Eat apples, grapes or cranberries, or drink juice made from these fruits, or take vitamin C tablets to make the urine more acidic. It is more difficult for bacteria to grow in acidic urine. (Note: the fruit and juice of oranges, lemons and other citrus fruits do not have this effect, and in fact make the urine **less** acid.)
- Keep hands, catheter and collection bags very clean before, during and after the child's bladder programme.
- Encourage the child not to lie in bed all day, but to remain active.
- Do not clamp the Foley catheter or plug it with anything unless absolutely necessary, in which case always use a sterile plug.
- Adhere strictly to the bladder programme, and do not allow urine to remain in the bladder.
- Ensure that the catheter does not become bent or twisted so that the flow of urine is blocked.
- If you are using an in-out catheter, put it in regularly, at least every 4 to 6 hours. For prevention of infections, frequency of catheter use is even more important than cleanliness. It is safer to put in the catheter without boiling it, than not to put it in. If infections are common, catheterise more often.

### Sexuality and fertility

- Discuss the situation with sensitivity as soon as the child reaches early adolescence.
- Advice about contraception is necessary for girls, as fertility is not affected, regardless of the level and severity of the spinal cord injury.
- Boys with upper motor neuron lesions will have reflexogenic but not psychogenic erections. Male fertility is significantly affected. However, male adolescents should be reassured that the results of assisted fertility (if available) are good.

### Psychosocial integration, education, vocational training and employment
